In civil life, the physician whose advice is sought regarding means of prevention of venereal infection gives an opinion ranging somewhere between two viewpoints. The first is that of the man who maintains that extramarital intercourse, wholly aside from moral conditions, is unnecessary and that sexual continence for the unmarried is entirely compatible with health, and should be advised. While no one will deny the moral and medical correctness of such a statement, one wonders how many of these physicians seriously expect their advice will be followed.

The other viewpoint is that of medical men who realize that the sexual instinct ranks perhaps next to that of self-preservation, and that attempts to prevent or regulate extramarital intercourse and prostitution have failed for centuries. They therefore become very pessimistic about expecting their patients to follow advice to observe sexual continence, and very frankly discuss with them means to prevent future infections. Most physicians feel, I think, that it is not within their province to discuss with the patient the moral element in the question.

When we come to consider the same question in military life, however, we find a new factor enters into the problem. A man's moral or sexual habits in private life concern no one but himself, except when he causes injury to others. The soldier, on the other hand, owes his maximum physical efficiency to the service, and any deliberate interference with that efficiency, such as may follow the disability incident to a venereal infection, is rightly held as rank an offense only slightly below a self-inflicted wound or mutilation in gravity. Although in one sense no soldier ever voluntarily becomes infected with venereal disease, still it is none the less true that at each sexual exposure he voluntarily places himself in an environment where an infection becomes possible, and as a result of which his efficiency may be impaired or lost to the service.

The Government accordingly takes the position that one way of securing physical efficiency is by advising sexual continence, and that the acquiring of a venereal infection which diminishes a man's power of service constitutes an offense for which punishment is provided. At the same time it recognizes the frailty of human nature enough to go halfway to meet the soldier who exposes himself, and offers him in a system of prophylaxis, a means of prevention of infection which if properly administered and taken in time may check the development of the disease in the vast majority of cases. Soldiers who develop infection following prophylaxis treatments are still liable to punishment, as it is considered *prima facie* evidence that the treatment was not taken in time. This is, of course, the only consistent attitude for the Government to take, as during the course of the infection it is partially or wholly deprived of the soldier's services, and it naturally can not guarantee the results of prophylaxis.

This position of the Government is outlined in detail in General Order No. 6, of July 2, 1917; General Order No. 34, of September 9, 1917; a further confidential circular to the soldiers of the United States Army, issued November 15, 1917, containing extracts from the two previous orders, and in General Order No. 77, of December 18, 1917, giving supplementary information as to the further details of carrying out the campaign against venereal disease by commanding officers and medical officers in the various units from the ports of debarkation up to the front line. Each officer should obtain copies of these orders and familiarize himself very carefully with their provisions, as many of you will later be held responsible for their proper administration.

General provisions to prevent venereal infection include:

- a. The biweekly medical inspection of all troops.
- b. Frequent lectures to troops on venereal subjects by medical officers.
- c. Provision of properly equipped prophylaxis stations at which shall be posted general orders regarding venereal disease.
- d. Inquiry as to exposure of all persons returning to camp from pass by the guard.
- e. Enforced prophylaxis for intoxicated soldiers.
- f. Interrogation of infected soldiers as to the source of infection, and withdrawal of the woman from her trade until noninfectious. The latter to be done in cooperation with the civil authorities.

g. The placing "off limits" at ports of debarkation of all houses of prostitution. At other points where troops are stationed, a certain latitude is allowed commanding officers as to measures to be adopted in this regard.

h. Landing restrictions placed on troops or members of crew, with venereal infection, of vessels or transports arriving at ports of debarkation.

i. Restrictions on the sale of alcohol to troops.

j. Provision of amusements and recreation for soldiers whenever possible.

Similar measures are adopted in the French Army, and include:

- a. Bimonthly sanitary inspection of all troops.
- b. Monthly lectures to troops on venereal diseases and their prophylaxis.
- c. A medical examination at the time of going on leave and on return from leave of each soldier.

d. Suspension of leave for all soldiers with venereal diseases.

e. Obligatory statement by the soldier of the circumstances of infection, with indication of the woman.

f. Regulation of recognized and clandestine prostitutes. The latter are under the supervision of military rather than civil authorities and measures are taken wholly without regard to private considerations.

In the English Army much the same means are used, and the subject is constantly kept before the minds of the troops by the reading of British Army regulations concerning venereal disease to all soldiers by the orderly officer at stated intervals.

Details of prophylaxis.—Certain suggestions may well be given soldiers by their medical officers in their talks to them on venereal subjects as to immediate measures to take directly after exposure, before reaching the prophylactic station.

1. Urinate at once if possible.
2. Wash penis thoroughly with soap and water; dry on clean towel.

3. Get to prophylactic station as soon as possible; certainly under three hours following exposure.

Though the actual administration of the prophylactic treatment is not done by the medical officer, he is responsible for its being given properly, and he should supervise the technique carefully until he is sure that it is being efficiently carried out by those to whom it is intrusted.

The actual technique varies somewhat, but in general principles consists of two procedures.

1. An injection of some silver salt into the urethra, which is retained for five to seven minutes before being allowed to escape.

Usually a 2 per cent protargol solution is used, made up with 15 parts of glycerine to 85 parts of water.

2. The thorough smearing of the penis with calomel ointment, preceded by careful washing with warm water and soap, and thoroughly drying; the penis is then covered with a paper napkin or toilet paper to prevent soiling the underwear.

The calomel ointment is usually made in $33\frac{1}{3}$ per cent of equal parts of lanoline, vaseline, and calomel powder.

The first measure is, of course, to prevent urethral infection with gonorrhea, the latter to guard against syphilis and chaneroid.

The urethral injection of 2 per cent protargol causes in itself a certain amount of irritation which may in some cases be mistaken for gonorrhea. It disappears in a day or two, however.

Results: One naturally asks what results experience has shown that we may expect from this method of prophylaxis.

In the first place, there are certain types of infection which we may very definitely say it will not prevent; these includes all extragenital infections, usually syphilitic, whether acquired innocently or not. Among these are chaneres of the lip or tonsil, from kissing or degenerate practices; chaneres of the face or neck from barber-shop infections; chaneres of the knuckle or other parts of the hand following bruising the hand against the teeth of a syphilitic in a fight, or surgeons' infection of the fingers during an operation or post-mortem examination. There are also the rare cases of gonorrheal ophthalmia and proctitis. Luckily these infections seldom occur, though in a series of years of private practice one may see quite a number. Apparently no one has yet thought it worth while to institute a system of oral prophylaxis to be used in connection with genital measures. There is this definite possibility of infection to be borne in mind against the occurrence of which we are taking no prophylactic measures.

On the other hand, it has been equally clearly shown that the timely and proper administration of the genital prophylactic treatment is an almost perfect prevention of genital venereal infection. As a definite proof of this I have available two sets of statistics gathered in the United States Army base hospitals in France covering the period from June 1 to December 1, 1917. In one case over 1,000 exposures were followed by not a single case of either gonorrhea or syphilis. That, indeed, is a record of which to be proud, and one which, so far as I know, has never been equaled. The other instance was that of my own unit stationed at British General Hospital No. 9, at Rouen, where in the same period of time something over 600 exposures were followed by 7 cases of gonorrhea. In none of the 7 cases, however, were we satisfied that prophylaxis was taken within three hours after exposure. One case of syphilis developed, but no prophylaxis treatment was taken. This unit was in a city of 150,000 civilian population, to which was added the constant presence of 40,000 to 60,000 British troops in training. The number of prostitutes is large, and probably a large percentage of them have been infected during the three and one-half years of the war. Though the figures in the second instance are not as good as in the first, I regard the environment of our unit as having offered a more severe test of the value of prophylaxis than in the other instance when one considers the number of troops. These statistics, which doubtless could be supported by many others were they available, are in themselves convincing evidence of the efficiency of the prophylactic system, and should instill into every medical officer who has work of this sort under his charge a feeling of confidence in it and a firm resolve to protect his troops by its careful and thorough administration.

The semimonthly inspection.—It should be borne in mind that this inspection is for the purpose not only of detecting venereal diseases but also for noting, (a) lack of cleanliness of body or clothing, (b) presence of pediculosis, scabies, lice, or infectious disease, (c) bad condition of feet and footwear.

This inspection may be carried out promptly if the men are instructed as to what is desired and the medical officer has proper assistance. When possible the man should be examined in a warm room. If this can be secured, all clothing except the trousers, drawers, and shoes should be removed and arranged for inspection. The shoes should be unlaced so that they may be taken off quickly. Each man reaches the inspecting officer with his shoes in his hands, and puts them on again as soon as they and the feet are inspected. The medical officer should sit with his back to a good light. The line of men should not be delayed for unusual cases; these should be held for later and more thorough examination. Where marks of scratching or insect bites appear, careful search should be made for pediculosis and scabies, examining also the seams of the underclothing under the arms and between the thighs. In inspection of the penis, do not neglect the region of the frenum, and palpate the inguinal glands for possible syphilitic enlargement.

Responsibility of company commanders and squad leaders.—The attention of surgeons is invited to the fact that company commanders are required to pay strict attention to the cleanliness of their men, and the police of their tents and barracks, and that paragraph 288, Army Regulations, states that chiefs of squads will be held responsible for the cleanliness of their men. In cases observed by surgeons where bodily cleanliness is being neglected, as indicated by the presence of itch or vermin, the name of the company commander or squad leader concerned should be reported to the commanding officer for proper disciplinary action with reference to the terms of the Army Regulations mentioned above.

LECTURE NO. 2

Incidence of venereal diseases among troops.—British Army: In 1912, out of an army of 107,000, the average daily number incapacitated on account of venereal disease was 593, representing a loss of over 216,000 working days a year. In 1913 the rate of incidence was 5.3 per cent per annum. In 1916 it had fallen to 2.1 per cent, due to the fact that these cases are better cared for in war than in peace. At present the British Army has so increased in size that they estimate that they lose the equivalent of 7,200,000 working days per year on account of venereal diseases.

French Army: It has been noticed that the amount of venereal infection diminishes in direct ratio the nearer the troops are to the trenches. At points of debarkation and at bases are concentrated the greatest number of prostitutes, and consequently the greater opportunities for infection. On the line of communication and behind the fighting zone, infections are more apt to occur from unorganized and clandestine sources of prostitution, shop girls, waitresses, etc. In the fighting zone, for 10 to 15 miles behind the lines almost no infections develop.

United States camps: It has been noticed that there is a low percentage of venereal infections in camps where games, amusements, and the like facilities were provided, and where temptations in near-by towns was removed as far as possible. In one camp of this sort there were less than one-half of 1 per cent of applicants for prophylaxis, while in another camp where conditions were favorable to a low standard of conduct the applications were nearly 20 per cent, about forty times as great as in the other instance.

General scheme for treating venereal infections in the United States Army.—In the British Army the men are sent down to stationary hospitals for the treatment of venereal diseases. This separates them usually some distance from their units; complicates transportation, since they travel only on certain trains under restrictions and tends to keep them out of the service longer than if they remained with their organization. In an endeavor to prevent this waste of efficiency it will be the policy of our Army—

1. To treat all uncomplicated cases of venereal disease in the infirmaries located in the immediate vicinity of the troops. (General Orders No. 34, par. 4.)
2. To treat complicated cases at camp hospitals, base hospitals, or urological hospitals, or such other hospitals as may later be designated.

The reasons for this plan are self-evident. It is hoped that it will prevent unnecessary transportation of these cases; prevent troops from getting the idea that they may escape duty at the front by acquiring venereal infection, and stops the transportation of infection to the civil population by these cases en route to the rear, as has happened in the British and French Armies. Further, under this scheme, treatment may be begun as soon as possible after the diagnosis is made, and syphilitic cases may be followed as soon as possible and as long as necessary.

Syphilis.—A method of treating syphilis has been adopted for the Army which, in simplicity of technique, the small amount of apparatus required, and time consumed in its application as well as in the efficiency of its results, seems to meet war conditions best of any methods now in use.

Diagnosis: With early diagnosis and vigorous treatment properly carried out it is now clearly established that syphilis can be cured, but both requirements are necessary for its accomplishment. In the primary lesion, smears from the sore should be taken, dried, stained, and examined at the laboratory as later described. In the later stages of syphilis, where the diagnosis is doubtful, the blood should be taken according to directions issued by the laboratories, and sent to them for a Wassermann test. If this is reported negative a provocative intravenous injection of 0.45 gm. novarsenobenzol should be given, and the blood taken again in from 12 to 24 hours afterwards for a second Wassermann test.

Drugs used (with demonstration):

- a. Novarsenobenzol in increasing doses from 0.15 to 0.90 gm.
- b. Cyanide of mercury 1 per cent solution in 1 cc. ampoules (dose 1 cc.).
- c. Intramuscular injections of mercury (usually gray oil, 40 per cent).
- d. Protiodide of mercury ($\frac{1}{2}$ gr. to $\frac{1}{3}$ gr.) by mouth.
- e. Ampoules of sterile water for dissolving the arsenobenzol.
- f. Syringes (Luer type), 3 cc. for novarsenobenzol.
- g. Syringes (Luer type), 1 c. c. for cyanide of mercury.
- h. Syringes (Barthelmy type) for gray oil (also in syringe ampoules).

Suggested standard treatment for primary syphilis. (A typewritten outline was given to each officer.)

Suggested standard treatment for secondary tertiary and latent syphilis: These cases require more thorough and prolonged treatment than primary cases.

a. (1) 6–10 injections novarsenobenzol, accompanied by (2) mercury (cyanide, intravenously; or gray oil, intravenously; or protiodide, $\frac{1}{2}$ gr. to $\frac{1}{3}$ gr. t. i. d.) by mouth.

b. Continue mercury for six weeks after the course of novarsenobenzol.

c. Repeat course of novarsenobenzol with mercury, continuing mercury for six weeks after second course as before. Stop mercury for one month and do a Wassermann test. If negative, discontinue the novarsenobenzol, but keep up the mercury for two months longer. Then after one month without treatment of any kind, take specimen of blood for Wassermann test after a provocative injection of novarsenobenzol. If negative, discontinue all treatment, but do Wassermann test every two months.

d. If either of the above Wassermann tests proves positive, give courses of 5 to 7 injections of novarsenobenzol every two or three months, with mercury continuously.

Precautions before treatment is begun with novarsenobenzol and mercury:

1. Examine urine for nephritis.
2. Examine eyes for syphilitic involvement.
3. Examine for symptoms of syphilis of central nervous system.
4. Examine for nonsyphilitic cachexia.
5. Examine heart.

6. Before injections (a) thorough catharsis, (b) no solid food at meal before injection, (c) urge drinking of water to dilute urine and take strain off kidneys in excreting novarsenobenzol.

Required for novarsenobenzol injection:

1. Luer syringe, 3 c. c.
2. Needle—should be short, with short point.
3. Tourniquet or bandage.

4. Forceps.
5. Alcohol, 95 per cent.
6. Sterile cotton.
7. Sterile gauze or towel.

Sterilization of instruments: Both syringes and needles should be boiled in clean water to avoid sediment. Syringes should be taken apart and not thrown directly into boiling water. Allow syringe to cool after boiling, before using.

Preparation of patient: The patient sits facing physician, the arm with sleeve rolled above elbow, extended across a table toward the operator. The skin over a suitable vein is cleared with alcohol, and the tourniquet applied tight enough to obstruct venous return, but not to stop arterial inflow. The patient is told to open and close his fist slowly to make the vein distend.

Preparation of solution: File and break neck of novarsenobenzol ampoule and place in a container (a cordial glass may be used), or have it held by an assistant. Break off one tip of the distilled water ampoule and place the contents of the broken ampoule into the novarsenobenzol. Shake until solution is complete. Draw the novarsenobenzol solution into the syringe through the needle, taking care not to blunt the point of the needle.

Injection: With the left thumb pull down the skin over the vein so as to steady it, and introduce the needle at an angle of 22° with the skin either directly into the vein or, if the vein is not prominent, introduce the needle, first, through the skin at the side of the vein and later by turning it toward the vein into the vein.

As soon as the needle is in the vein a small amount of blood will flow back into the syringe. When this occurs, advance the needle point slightly, release the tourniquet and inject slowly. Do not attempt to inject until you are sure the needle is in the vein. Press sterile gauze or cotton over the point of insertion of the needle as it is withdrawn, and hold the arm up for a few moments, which will prevent bleeding.

Dose and contraindications: Follow the schedule in ordinary cases, unless contraindications arise, beginning with 0.30 gm.

With syphilitic nephritis, cardiovascular lesions of the central nervous system, nervous patients, women, and small men, one should begin with 0.15 or 0.20 gm.

Contraindications to the use of novarsenobenzol are uræmia, cardiac decompensation and nonsyphilitic cachexia.

Reactions following novarsenobenzol: These are less frequent and severe than those following the larger dilutions of the drug. They are of three kinds:

1. (a) Slight elevations of temperature, lasting 6 to 24 hours; (b) nausea and vomiting; (c) diarrhea; (d) skin eruptions, with earial or scarlatini form; (e) headache; (f) conjunctivitis.

These are rarely lasting or serious, but should be carefully watched for and a second dose not given until they have entirely disappeared, and then not larger than the preceding one.

2. Immediate reactions: (a) Flushing of face, congestion of conjunctiva, fullness in throat with cough, ringing in the ears, puffiness of the face. All these are usually transient. (b) Pain across lumbar region, gradually growing worse. This may be transient or result in complete prostration, loss of consciousness, feeble pulse. This is rarely seen and rarely serious if treated immediately. Patient should be kept in lying position. Both these sets of reactions are cured by an injection of 1 c. c. of a 1 per cent solution of adrenalin chloride. This may also be used as a preventive by injection before the administration of the novarsenobenzol.

3. A more serious complication is an acute encephalitis, which may appear after the second injection, especially in cases where the first injection has been poorly borne. At times its appearance is delayed until weeks after a course of treatment. Accompanying paralysis of cranial nerves is usually transitory, but may be lasting. The French guard against assuming responsibility for any accidents which may follow the administration of novarsenobenzol by having each soldier before treatment sign the following statement.

"I respectfully request the physician in chief to admit me in order to follow a treatment with "606" and I assume all responsibility myself."

One fatality has followed the use of novarsenobenzol in one of the divisions here in France. While recognizing the value and efficiency of the drug in the treatment of syphilis, and the fact that it is borne by the great majority of patients without unpleasant results, we must always watch very carefully for signs of its poor toleration, and proceed in these cases with the greatest caution.

Injections of cyanide of mercury: A course of novarsenobenzol is well preceded by 5 to 10 injections of cyanide of mercury. The usual dose is 1 c. c., but it is well to begin with a somewhat smaller one. In cases where the novarsenobenzol is poorly borne it is wise also to reduce the dose of mercury. When its administration is followed by intestinal colic, diarrhea, and salivation it must be stopped until all symptoms have disappeared. Some form of opium is the best thing to control the colic and diarrhea.

Instructions to patients taking syphilitic treatment: (1) Bad teeth should be treated as soon as the patient is well under the influence of mercury. The dentist should be notified that the patient has syphilis. Brush teeth twice a day. (2) Wear warm clothing—avoid exposure. (3) Keep bowels well open while taking mercury. (4) Avoid alcohol, tobacco, very acid fruits.

After injections of novarsenobenzol: (1) Patients should lie down 3 to 4 hours. (2) No solid food for 3 hours; resume regular diet after 6 hours. (3) Soldiers should not be expected to report for duty during the remainder of the day on which an injection is taken.

Inspection of patients: *a.* Inspect patients the day before and the day after taking novarsenobenzol (1) for signs of reaction following injections; (2) for skin eruptions; (3) for conjunctivitis; (4) for albumen in urine, presence, increase, decrease.

b. Inspect regularly mouths of all patients taking mercury (1) for condition and care of the teeth; (2) stomatitis, swollen gums, sore or loose teeth.

Gonorrhea.—The last few years have brought little that is new to the treatment of gonorrhea—unless it has been the conviction that much more is gained by blood medicines and gentle methods than by more vigorous but misguided efforts which simply increase the irritation.

It is also difficult to inspire the average medical officer with any wild enthusiasm for the systematic following through of the treatment of a case of gonorrhea. This usual lack of interest results in half-hearted methods and low percentage of actual cures.

The proper treatment of chronic gonorrhea can not be hoped for under war conditions outside of hospitals; and as the majority of cases reach a chronic stage, the results will be poor. It will possibly be found necessary to send the unusually resistant cases to camp hospitals, together with the complicated cases, where they may find specially trained men to care for them. It is somewhat unreasonable to expect a medical officer to massage a prostate under shell fire.

If these facts are true, they simply present another strong argument for efficient prophylaxis, and medical officers in whose units this is thoroughly carried out will save themselves much later trouble.

Venereal sores.—It is often very difficult to distinguish between a soft chancre and the primary sore of syphilis. Very often a mixed infection occurs, the sore at first will present the characteristics of a chancre, and the syphilitic appearances develop later. Hence all sores should be examined for the organisms of syphilis and should not be treated as soft sores until at least three separate examinations have failed to show any evidence of syphilis.

When a venereal sore develops, careful smears should be made, dried, and sent to the laboratory with the required data. A proper smear is obtained by cleaning the sore carefully, drying it, and smearing from its base a drop of serum without the presence of too much blood. A large admixture of blood interferes with the examination of the smear and renders less probable the discovery of any syphilitic organisms.

No mercurial preparation should be used on a sore until the diagnosis is settled, as the mercury makes the detection of the syphilitic organisms very difficult. Meanwhile use on the sore the treatment advised for soft chancres.

Treatment of chancres (specific).—Local treatment consists in mercurial preparations, either calomel powder or ointments of calomel or mercury. This in connection with the constitutional treatment should cause their rapid healing.

Treatment of chancroids.—Sores which have free secretion may be treated with powders, of which thymol-iodide and iodoform are the best. In chronic dry sores, the use of powder might form a crust, damming back secretions and tending to dissemination of infection and inguinal adenitis.

Ointments of the above powders, or nonmercurial drugs, should be used. A useful form of treatment is the application of tincture of iodine to the sore. After first applying crystals or 4 per cent solution of novocaine for a few minutes, follow by an ointment dressing.

Patients should not be circumcised before sores have completely healed. The infection may be spread to the circumcision wound, or an undiagnosed syphilitic sore might be removed.

If phimosis is present, and something must be done to relieve it, a dorsal incision is sufficient.

Cases suitable to be sent to a camp hospital.—1. Syphilis: (a) All eye lesions; (b) definite involvements of the central nervous system; (c) severe nephritis.

2. Gonorrhea: (a) Severe epididymitis; (b) prostatic abscess; (c) persistent complete retention of urine; (d) suppurative inguinal adenitis; (e) endocarditis; (f) rheumatism; (g) continued fever; (h) gonorrheal ophthalmia.

3. Chaneroid: (a) Suppurating inguinal glands; (b) sores, acute or chronic, which are enlarging and not responding to treatment.

Wounds and injuries of the genitourinary tract as seen at British casualty clearing stations.—The outstanding impression which one gets from a four months' experience with wounds and injuries of the genitourinary tract at British casualty clearing stations is that the unavoidable conditions of battle, of transportation, and of military hospital management radically modify the whole treatment of this type of case and make impossible the use of what might be termed the textbook methods which would be employed under the more ideal conditions attending similar injuries in civil life. These modifications will be better understood by a short consideration of the nature of these wounds and injuries and the progress of such cases from the battle field to the casualty clearing station.

Origin: Wounds of the genitourinary tract under the present conditions of warfare are caused by bullets (rifle, machine-gun, shrapnel balls), shell fragments, bomb fragments, bayonet thrusts (rare).

Injuries most frequently seen are due to contusions following patients being found in dugouts or elsewhere or by being blown against solid structures in shell explosions. These injuries are frequently complicated by large hematomata or abscesses.

Routine progress of cases from the battle field to the casualty clearing station.—At present, in the British lines, wounded pass through the following stations in the order mentioned: (1) Regimental aid post, (2) advanced dressing station, (3) main dressing station (field ambulance), (4) casualty clearing station, (5) base hospital (or stationary hospital), (6) England.

It will be readily appreciated that under the pressure of battle conditions no attempt at finer diagnosis of the exact location of lesions is possible before the patient reaches No. 4 in the list. Hence it happens that not only all wounds of the anterior and parietal abdominal walls are classed as "penetrating abdomen" cases, but also wounds of the back, wounds of the lower chest wall where the course of the missile is evidently downward, wounds of the buttock, upper thigh, perineum, and groin, where the course of the missile is evidently upward, are also included in the same category. It is important to realize this grouping because it has a very definite influence on the disposition of the case.

Following, then, the progress of such a case, he is picked up by regimental stretcher bearers as soon as battle conditions permit, is carried to the regimental aid post, then by another set of stretcher bearers to the advanced dressing station. If the probably abdominal nature of his wound is recognized, he wastes no time in either of these first two stations, as a special effort is made to send through this class of case with the utmost speed.

The advanced dressing station, which is controlled from the main dressing station of the field ambulance, usually marks the beginning of motor transport. The patient has come thus far by hand transportation on a stretcher. Here, unfortunately, begins a portion of his journey of which the patient with this type of injury most bitterly complains. The motors have to traverse roads broken by shell holes, and with movement at night, without headlights, severe shaking of the wounded is impossible to avoid.

At the main dressing station the patient is halted only long enough to be given a field medical card on which certain particulars are set down. The antitetanic serum is given, possibly morphia, and in some instances a drink of water or thin hot soup.

From the main dressing station of the field ambulance, and now provided with his field medical card, the patient takes another smoother motor journey to the casualty clearing station. This means that cases marked "perforated abdomen" have passed through four stations, a distance of from 8 to 12 miles, occupying at least two to three hours, and generally much longer, before they finally reach the place where a very definite effort will be made to diagnose exactly and treat their condition.

The British have recently made attempts to locate hospitals near the line for the special treatment of abdominal cases in order that they might reach the operating table with as little delay as possible. Some abdominal operating has also been done at main dressing stations of field ambulances. The location of the special abdominal hospital was difficult, as it is not always possible to forecast the situation of the next "push," and the field ambulance proved to be too mobile and poorly equipped a unit to handle such cases successfully. Hence the greater part of the abdominal surgery is at present done at the casualty clearing station.

The casualty clearing station.—At the casualty clearing station the patient goes at once to the dressing room, where his wounds are examined by the surgeon on duty, who also inspects the patient's field medical card, containing a record of the opinions of the other surgeons through whose hands the case has passed, together with their treatment thus far. If the case is marked "penetrating abdomen," and the casualty clearing station surgeon agrees, the patient automatically, and without further delay, is sent to the resuscitation ward, where he is seen at once by the surgeon specialist, as the British call their head surgeons.

The resuscitation ward in the British casualty clearing station is a development of the last year or so. And many of its features and procedures have been suggested by American surgeons. It represents a definite attempt to sort out from the others the more severely wounded and to concentrate them in a ward where especial efforts may be made by stimulation, blood transfusion, and heat to combat shock and hemorrhage. This treatment is carried out by medical officers, nurses, and orderlies who do nothing else.

The resuscitation ward is the surgical city of forlorn hopes. Here the patient must prove his right to take the time and attention of a surgical team. Surgical efficiency dictates that those patients must first be worked on who seem most likely to prove paying investments by subsequent recovery.

Our cases with wounds of the genitourinary tract accordingly have now reached the resuscitation ward of a casualty clearing station. Thus far no attempt at exact diagnosis has been made, but they are here as "penetrating abdomens," with sometimes a query. In the resuscitation ward the head surgeon makes frequent rounds, noting improvement in general condition due to the resuscitation procedures; studying the patient's general condition as to fitness for operation more than the local lesion, though that too is of course considered. He speculates as to the probable course of the missile, and the injuries it would cause. In cases of through and through wounds quite exact estimates may be made.

Diagnosis: It must be realized that wounds of the urinary tract are very rarely simple uncomplicated wounds of a single organ, but occur in connection with perforations and lacerations of other adjacent structures. In certain instances perfectly definite evidence is present of injury to the urinary tract by the occurrence of hematuria or the presence or odor of urine in the wound.

In the extreme pressure of work at casualty clearing stations where these cases are operated, it has been the writer's experience, first, that they go to operation as "penetrating abdomens," with the urinary picture generally subordinated to the probable injury to other abdominal contents; and, second, that whether they are operated at all or not depends upon two factors—the length of time which has elapsed since being wounded, and their reaction to stimulation during their stay in the resuscitation ward.

Catheterization has been advised in cases of suspected perforation of the bladder or deep urethra as a routine diagnostic measure. Theoretically, this is correct, but actually, is unwise under the conditions which obtain in casualty clearing stations. Patients are moved as little as possible when in shock. They lie on the muddy stretchers on which they came; their

clothes are carefully cut off and dry blankets and heaters put over them. It is almost impossible to avoid the danger of infection in these cases. If the patient rallies enough to be fit for operation, very often, under the relaxation of anesthesia, urine is voided, and the presence or absence of blood in the urine can then be determined. Catheterization on the operating table may be done if necessary, but should always be avoided if the required information can be secured during the operation or in any other way.

Operative indications: Remembering that most of the injuries to the urinary tract are still being grouped under "penetrating abdomens" and that but few will get to the operating table with a definite diagnosis, the indications for operation will be those of the class in which they are placed.

In many casualty clearing stations, experience has taught the head surgeons arbitrarily to classify these cases as "fit" or "unfit" for operation according as to whether they reach the station within 30 hours after being wounded or subsequent to that period of time.

All cases of less than 30 hours' duration, after being "warmed up," are put on the operating table as soon as their general condition will permit. The cases of longer duration are considered *ipso facto* unfit, and are held in the resuscitation ward for observation and stimulation to prove their right to operative consideration. This is the first great general indication which, though arbitrary, has been proven by experience to be sound.

The second general consideration involves the question of surgical efficiency, and incidentally conserving man power to win the war.

With the greatest available surgical skill, the general mortality in cases of penetrating wounds of the abdomen is at least 50 per cent. Furthermore, the time consumed in these cases, involving multiple suture or extensive resection, is great. And a surgical team doing nothing but abdominal cases will perhaps perform one-third or one-half as many operations as the team taking general cases, in which the mortality will not run over 10 to 20 per cent. Accordingly it becomes a grave question whether it is good policy to employ the time of surgeons on a class of cases which takes twice the time and has twice the mortality at the expense of less severely wounded, who, if promptly operated, would show a much greater percentage of recoveries, and many of whom would return to duty. These same less severely wounded cases, on the other hand, if kept waiting too long, or if evacuated to the base without operation, often develop gas gangrene, requiring possibly amputation or resulting in death.

Although it may be a surgical triumph to operate successfully on a penetrating abdomen, it is an expensive triumph, and not surgical efficiency, until means are provided for concentrating at short notice enough surgeons at stations near the fighting to take care of everyone in "push" conditions.

Unless, then, we can isolate from the rest the uncomplicated injuries to the urinary tract, which of course show a much smaller mortality than general abdominal cases, the question of whether they will ever get to the operating table at all has in the past, at least, depended upon the considerations named.

There are also special indications urging operation. In the case of wounds involving the kidney, the diaphragm may be lacerated or the chest cavity opened. Wholly aside from the kidney indications, the respiratory balance must be restored as quickly as possible by repair of the diaphragm and by closure of "sucking" chest wounds. In these combination "chest-abdomen" cases, the indications for the restoration of the intrathoracic pressure are even more insistent than the abdominal condition. The presence of hematuria, or the absence of voiding urine for a long period with relaxed bladder, pointing to probable rupture with infiltration, are also special indications, but here too the general condition of the patient and complicating injuries influence the time of operation.

Treatment: It is impossible to do more than indicate general principles for the treatment of wounds and injuries of the genitourinary tract in war surgery for two reasons: The first is that war surgery is far from being a settled matter. An evidence of this is the fact that the English have practically had to revise their treatises on war surgery two or three times, and no one knows what will be considered the best practice six months from now. The second reason is that after the patient gets on the operating table, what the surgeon will do will depend on the patient's general condition, the length of time since he has been wounded,

and the presence of complicating wounds which may be so severe as to make the genitourinary lesion the least important feature of the case. Bearing these facts in mind then, lacerated, dirty wounds require immediate operation with complete revision and excision of damaged tissue. Penetrating or perforating bullet wounds which cause less laceration and consequently less danger of gas infection are not of so urgent a nature, and unless they are causing continued hemorrhage, or have penetrated viscera, may be more safely left for later operation.

Kidney: Kidney wounds are not seen as frequently as one might expect. In through and through bullet wounds of the kidney, unless some large artery has been affected and hemorrhage is continuing the kidney condition will be less important than the damage to adjacent organs which the missile may have caused, as, for instance, a hole in the stomach or intestine, and the kidney may well be left alone. Where large lacerated shell wounds affect the kidney, nephrectomy is the only logical treatment. If only a small portion of the organ is affected, cleaning the wound, with packing and drainage, is preferable to an attempt at section and closure. A secondary nephrectomy may be necessary later on.

Bladder: In bladder wounds two cords should be sought for; to close off the poutoneal cavity from the bladder and to prevent infiltration of urine through extra-abdominal tissues by providing for drainage for the urine, either suprapubically or by perineum. Bladder wounds are frequently caused by large shell fragments and may be complicated by puncture of the pelvis and laceration of the rectum and perineum, so that many of the cases live only a few hours after reaching the hospital. Each case must be treated as the presenting conditions demand and often tax the ingenuity of the surgeon.

Simple bullet wounds penetrating or perforating the bladder do very well and are sometimes unrecognized at the time, the bullet later being removed from the cavity of the bladder or its neighborhood. Here again the important element of the case is the question of perforation of adjacent intestine.

Urethra: Attempts at primary closure of lacerations or ruptures of the urethra are usually unsuccessful. The wound is nearly always dirty and stitches around an in-dwelling catheter usually slough, and this occurs even when the urine is sidetracked through an artificial suprapubic or perineal opening. Repair of these lacerations is much more successful when done later on after the wound has cleaned up.

Wounds of the penis, scrotum, testicles: On account of the psychic effect upon patients who become sexually mutilated as the result of war wounds, the surgeon's main object in cases of this sort should be directed toward the conservation of as much tissue as possible, even though it seems hopelessly lacerated. This lacerated tissue can later be removed if non-viable, and much of it will surprise the surgeon by reestablished circulation. Since the war the French have developed surprising ingenuity and success in their plastic reconstruction of mutilated genital organs, a result which they say has greatly contributed to sustaining the morale of these patients, who otherwise tend to become greatly depressed concerning their condition.

Army Sanitary School No. 17.

TRANSLATION OF LECTURE BY DOCTOR LEMAITRE, GIVEN AT THE ARMY SANITARY SCHOOL,
A. E. F.

CHAPTER 1

I have practiced primary suture of war wounds since the month of July, 1915. After 29 months' experience it seems interesting to publish the results I have obtained, the reasons that led me to treat war wounds in this fashion, and the technique I have used. Having had the advantage of working in an army ambulance immobilized in a large hospital center, the activity of which in a majority of cases allowed me to keep the wounded until recovery; later on in a more active center, with a capacity allowing me to keep the patient for a prolonged period, I can give these results as definite for the majority of the cases I have treated, almost all in fact, outside of fracture cases, joining their regiment directly after leaving the hospital, from 15 days to 2 months after operation and having a leave of absence varying from 15 days to 3 months. During this time, 2,283 wounded have been treated within 24 hours after their injury; the immense majority, 1,862, between the seventh hour and the fifteenth 295 before the seventh hour, and 126 after the fifteenth following their injury.

We believe it to be preferable in any large number of cases, and with multiple wounds, to speak of wounds rather than of wounded. Each one can be considered from the point of view of treatment and evolution as though it were unique. We shall, therefore, speak of wounds and not of wounded. These 2,283 wounded presented 4,227 wounds. Amongst these wounds 323 were not treated surgically on account of their small size (very small fragments, especially in the face, perforating rifle bullet wounds with entrance and exit—openings equally small, without fracture, without injury to the blood vessels or the nerves, and without any sign of infection). Of 3,904 wounds treated surgically, 2,537 were united by primary suture and 307 by secondary suture; 851 wounds were not sutured at all, either because the wounds closed progressively of themselves, because the wounded died, or, finally, because in a period of great activity wounded had to be evacuated too soon to be sutured. In our statistics we will only consider 2,537 primary sutures and we will leave aside 209 delayed primary sutures and 307 secondary sutures; also 851 wounds which were not sutured at all.

Wounds of the soft parts:

1. Wounds of the soft parts of medium importance, 718, with 3 total failures and 8 partial failures.

(NOTE.—We understand by complete failures, cases where it was necessary to remove all the stitches; and by partial failures, those where sooner or later after the operation we had to remove a few stitches, the rest remaining in place and the infection being eliminated and superficial.)

2. Wounds of the soft parts of greater importance, 106, with 12 complete failures and 19 incomplete failures.

3. Wounds of the bone without complete fracture, 148, with 5 complete failures and 4 partial ones.

4. Wounds of the soft parts with injury to a large blood vessel, 68, with 2 complete failures and 5 partial ones.

5. Wounds of the soft parts with injury to a large nerve trunk, 34, without any complete failures and 4 partial ones.

Wounds of the large joints:

1. Wounds of the tibio-tarsal (with 4 cases of astragalectomy), 15, without complete failure and 2 partial ones.

2. Wounds of the knee (with 3 immediate resections of the knee joint), 22, with 1 complete failure (cured after secondary resection).

3. Wounds of the wrist (of which 3 presented limited bone lesions of the wrist necessitating partial excision of the carpus), 19, without complete failure, but 2 partial ones.

4. Wounds of the elbow joint (of which 12 underwent partial resection), 19, without complete failure, but 3 partial ones.

5. Wounds of the shoulder joint (of which 12 were treated by immediate resection of the head of the humerus), 12, without complete failure and 1 partial failure.

Wounds of complete fracture of the bone shaft:

1. Femur, 24, without complete failure, 2 partial failures.

2. Bones of the leg, 64, with 2 complete failures.

3. Humerus, 47, with 1 failure and 3 partial ones.

4. Forearm, 26, without complete failure, 2 partial ones.

5. Clavicle, 3, without failure.

6. Ulna alone, 24, without complete failure, but with 3 partial failures.

7. Radius alone, 29, without total failure and 2 incomplete failures.

8. Fibula alone, 44, without complete failure, 5 partial failures.

9. Tibia alone, 2, with 1 complete failure.

Wounds of the hand and foot:

1. Wounds of the hand: Injury to tendons, bones, or joints, 60, with 2 complete failures.

2. Wounds of the foot with lesions of tendons, bones, or joints, 50, without complete failure and 5 partial failures.

Wounds of the skull:

1. Wounds of the skull without injury to the brain, 14, without complete failure as far as union is concerned, but with 3 deaths and 2 partial failures.

(NOTE.—One of these died from progressive meningoencephalitis. We did not suture the skull wounds when the foreign body had not been removed from the brain.)

Wounds of the chest: Penetrating wounds, 7, without fracture as far as union is concerned, but with 1 death. (Wounds of the chest walls are included in the list of wounds of the soft parts.)

It is easy to understand that it is impossible for us to study in detail each one of these cases and give a complete history. However, it seems useful, to avoid any kind of confusion, to give a few words of explanation. First of all, these statistics include two distinct periods. During the first, extending from July, 1915, to July, 1917, our service was not specialized and received all kinds of wounds, the patients not being fit for evacuation. During this period also—at least during the first six months—we were beginning to use primary suturing; and it is during this period that we had the greatest number of cases in which we did not attempt suture. Out of 851 wounds that were not sutured (mentioned above), 768 belong to this first period and 83 only to the second period. During the second period, July, 1917, to the end of December, 1917, the service was changed and received only wounds of the soft parts. It is true that, by mistake, a certain number of bone wounds, a few wounds of joints, and a few fractures have been treated. Furthermore, this service being larger than the preceding one, and the conditions in the army being relatively calm, it was possible for us to keep the wounded all the time necessary. The feeling of confidence in the technique used by us increased daily, which led us to extend primary suturing to a number of wounds, and the percentage is therefore much greater during the second period than during the first. During the first period we primarily sutured 1,046 wounds out of 2,336, a little more than 44 per cent, whereas during the second period we sutured 1,491 out of 1,891 wounds, nearly 79 per cent.

During the first period the wounds not sutured primarily subdivide as follows: Non-operated, 216, a little more than 9 per cent; delayed primary suture, or secondary suture, 306, a little more than 13 per cent; nonsutured, 768, about 32 per cent.

During the second period wounds not primarily sutured subdivided as follows: Non-operated, 107, or 5 to 6 per cent; treated by delayed primary suture, or secondary suture, 210, a little more than 11 per cent; and nonsutured, 83, or 4 to 5 per cent.

A glance at the following table shows this difference:

	First period		Second period	
	Number	Per cent	Number	Per cent
Total wounds received in hospital.....	2,336		1,891	
Nontreated surgically.....	216	9-10	107	5-6
Primary suture.....	1,046	44-45	1,491	79
Delayed primary or secondary suture.....	306	13-14	210	11-12
Nonsutured.....	768	32	83	4-5

It is extremely difficult, if not impossible, to draw conclusions from these statistics as far as the percentage of wounds that ought to be amenable to primary suture is concerned, and those that ought to be united by delayed primary suture or secondary suture, or, lastly, treated as open wounds until they spontaneously heal. For each one of these two periods corresponds to a different nature of wounds and to a different period of evolution of this surgical technique. During the first period, which includes the last six months of 1915, we sutured from 15 to 30 per cent of all wounds; during 1916 and the first six months of 1917, treating the same kind of wounded, we sutured from 55 to 60 per cent; and during the period, July, 1917, to January, 1918, we have treated almost only wounds of the soft parts. The primary sutures were almost 79 per cent, but there are three other important factors which influenced this:

1. The time elapsing between the injury and operation.
2. The feasibility of keeping the patient sufficiently long in the hospital, enabling us to discharge the patients only a few days after removing the stitches.
3. The operative capacity in relation to the number of wounded that are awaiting operation.

It is also necessary to say that the first period of our activity concerned almost exclusively wounded operated on by ourselves, whereas, during the second period, it included the wounded operated by ourselves and by our assistants working under our direction.

Lastly, we want to note the following points:

1. We do not include in these statistics wounds of the abdomen, where the abdominal wound was primarily sutured, as we consider them foreign to our subject.

2. Joint wounds, as far as primary suture is concerned, for the greater part of these joint wounds were only diagnosed during operation and the majority only concerned wounds of the capsule or the synovial membrane. It would not be fair to compare these with war wounds in general, for we have only had light cases to treat. Those with bone lesions and those where diagnosis was made before operation were treated in the service of Doctor Leriche.

3. The fractures included in our statistical report correspond mostly to the first period. They are far from representing the total number of fractures we have had to treat, and they concern the most favorable cases amongst the latter. Lastly, the statistical report only includes sutured wounds sutured because the cases were considered suitable, and we warn against the mistake it would mean to draw conclusions applying to any particular class of wounds in general.

CHAPTER 2

We think it useful to relate the phases which gradually brought us to the primary closing of wounds and thus to relate our surgical progress during the war. We must begin by stating that the circumstances were favorable. After two months of traveling—corresponding to the retreat from Belgium, the Battle of the Marne, and the beginning of the Battle of the Aisne, a period during which we had no surgical work to do—we settled in a small town a few miles from the line. There we were able to treat a certain number of gravely wounded and to follow them sufficiently to enable us to note the outcome of our treatment and what war surgery ought to be.

1. *Period of surgical expectation.*—Initially we were under the optimistic reports of the innocuous character of war missiles as far as surgery was concerned, and we were satisfied with the disinfection of entrance of the wound with tinctures of iodine, removal of the foreign bodies which were visible, and applying a good aseptic dressing. The only cases where we operated at once were vascular injuries attended by hemorrhage, great injuries necessitating amputation of the limbs, penetrating wounds of the skull or abdomen, and those injured a few days before and arriving with a fully developed infection. All other cases, after dressing, were placed under observation. In the majority of cases after 24 or 48 hours fever started, pain became more and more acute, and an abundant flow of purulent and foul fluid started and very violent inflammation became obvious. Surgery was then resorted to. Notwithstanding incisions, pus appeared in intermuscular spaces, necessitating new and frequent incisions. The general condition of the patient declined rapidly. During this period, gas gangrene, secondary hemorrhage were frequent, and in the most favorable cases suppuration persisted. The wounded man was sick for a long time and was not in condition to be transported, and very often became a cripple. This nefarious period lasted from October to the middle of November, 1914.

2. *Period of incision.*—In view of these facts we no longer dressed the wound, but operated immediately on all patients without waiting the symptoms or appearance of infection, firmly believing that their wounds were inoculated, although there were not yet any clinical signs of infection. (NOTE.—During this period we only received severe injuries, rendering evacuation of the patient by rail impossible.)

In what did this operation consist? Incision of the wounds, removal of foreign bodies (projectiles, fragments of clothing, etc.), and packing the wound with sterile gauze. This period corresponds to the first half of November and the first half of December, 1914. It marked a great improvement. But at this moment we observed in our wounds a period of suppuration, elimination of muscle, fascia, and bone splinters, attended by fever during a fortnight, this necessitated changing the dressings two or three times a week. For dressings we used exclusively sterile gauze and never irrigated the wounds.

3. *Period of wound trimming.*—We therefore thought it might be possible to do away with this elimination attended by suppuration by removal of the foreign bodies and all the tissues dead or destined to die. The operation consisted in following the projectile exactly along its track through the tissues; in removing the skin, the connective tissues, the fascia the muscle, and the bones; all that experience had taught us was doomed to elimination, provoking infection, and keeping up suppuration; ending the operation by packing with sterile gauze. This period corresponds to the second half of December, 1914, and January, 1915. A slight fever, between 37.5 and 38, lasted four or five days and very soon the wound became pink and healed normally.

4. *Fixation with iodine.*—We then understood that during the operation we reinoculated the wound surface. For this reason, trying to destroy by fixation these germs on the surface, the idea occurred to us to use tincture of iodine, the result of which for fixation of germs in the skin had for a long time been demonstrated; but in order to have fixation it is necessary that the wound should be dry, just like the skin itself. Therefore, after a complete hemostasis, we for some time used hot air to dry the wound; then we gave this practice up and merely used dry gauze firmly pressed on the wound surface, applying tincture of iodine instantly after removing the gauze. This period corresponds to the months of February, March, April, and May, 1915. We may say that it corresponded to the suppression of pus in the wound; the wound granulated and healed without suppuration and without loss of tissue.

5. *Carrel method, first technique.*—Toward the end of the month of May, 1915, we became acquainted with the method of Doctor Carrel (first technique described). During the month of June, 1915, we tried his procedure; but, probably through a mistake on our part, this technique brought back the evil days of 1914.

6. *Primary suturing.*—We, therefore, in July, 1915, definitely gave up the use of antiseptics and came back to operative surgery. Encouraged by the preceding period of four months, we began to use primary suture in war wounds, doing away with slow healing up by granulation and spontaneous formation of the scar. The results were such that gradually and rapidly we increased the number of cases where we practiced primary suture, and that in the cases where we did not try to suture immediately we placed stitches, which were tied on a few days later, thus realizing delayed primary suture. Then when we were able to keep the patient long under our direction, we practiced secondary suture in the cases where we had been unable or unwilling to close by primary or delayed primary suture. At this time we had no laboratory at our disposal, and clinical signs alone guided us as well for primary sutures as for secondary sutures. We can not here enter into the detail of the clinical signs allowing us to decide this question. This point is, furthermore, of only historical interest at present. Often when the laboratory enumeration of germs (smear) is in contradiction with the clinical information, we ask the laboratory to make a culture to decide, and generally it is the clinical information which is proved correct. We were led to insist on these successive stages of the evolution of our technique because we consider them instructive. The different moments of our technique correspond to the different phases of improvement we are obliged to go through, and they follow each other in the course of the operation in the same chronological order as in our surgical evolution. Each one of them is of essential importance before taking up the following one.

In the practice of war surgery, according to opportunity, we can stop after the first operation, or at any stage, to take up later the successive steps when opportunity presents. We can thus enumerate at once the different steps of our technique. They are:

1. Incision.
2. Following the track of the projectile and making an inventory of the lesions produced by the same.
3. Excision of the dead tissues or those destined to necrosis, including, of course, the removal of foreign bodies.
4. Hemostasis, completed by fixation of the wound by tincture of iodine.
5. Repair.

In general it is very exceptional that one is not able to carry out these different steps up to No. 4, inclusive. If, however, because of material circumstances at the moment of the operation, excision of the tissues is not completely performed at this time, one must, with curved scissors, effect their removal at a subsequent dressing to avoid their spontaneous elimination.

When all the steps of the operation excepting the last (suturing) have been performed, clinical examination helped by the laboratory indicates with precision the moment when one can close the wound, either by delayed primary or secondary suture. We insist upon this point: That war surgery has a twofold duty—first and foremost, to prevent infection; and, second, to repair carefully the disorders caused by the wound and by the operation itself.

CHAPTER 3. TECHNIQUE

1. CONDITIONS UNDER WHICH IT CAN BE CONTEMPLATED.—Before taking up the technique in detail, it seems useful to indicate briefly the conditions which make it possible.

First. An efficient surgical organization is indispensable. It is a mistake which has lasted too long to believe that a war wound, contaminated by the missile and the fragment of clothing it carries along with it, is fatally doomed to suppuration. Correctly and aseptically operated at the right moment, all war wounds, with very few exceptions, will unite as though they were aseptic. One must, therefore, give due attention to operate with as perfect aseptic technique as in ordinary practice.

Second. Sterile rubber gloves are indispensable. It is hardly necessary to say that a surgeon in an ordinary aseptic operation takes a certain pride in not soiling his gloves by contact with the wound; there is all the more reason to avoid contact with the young colonies of germs that are beginning to develop on the surface of the war wound. He must therefore operate with the tip of his instruments, forceps, scissors, and knife, and he must only use his index finger for exploring the wound in those very rare cases where he has lost the track.

Third. The assistant must do likewise, and when he holds the retractors or mops the blood from the wound he must avoid as far as possible the contamination of his gloves during the whole operation. The point on which we insist frequently is to wipe the blood by pressure without rubbing. Friction of the wound has two great drawbacks: (1) It contaminates the sterile parts of the wound; (2) it runs the risk of causing the operator to lose sight of the little track caused by the missile, which he may have a great deal of difficulty to find afterward.

Fourth. The ideal would be to set aside every instrument that has served once, and take up a fresh one. Practically, however, if those instruments which have come in contact with the parts contaminated are wiped carefully with a piece of sterile gauze at once (smooth instruments, like knives, scissors, and retractors), one can, without great risk, use the same instruments during the operation until the moment comes for suturing.

The instruments most frequently necessary are small in number and in general for each operation a box of instruments sterilized in formalin vapors at 50° C. is used and it contains 8 Kocher forceps, 6 Terrier of Pian forceps, 4 towel holders, with sharp points, 1 grooved director, 1 knife, 2 thumb forceps, a medium-sized curette, a raspatorium, 1 long forceps and 1 Rongeur forceps, 2 pairs of scissors, straight and curved. Generally the latter are of small dimensions.

When, in the course of the operation, we need supplementary instruments, we make use of a special box from which we take the necessary ones. When we come to the suturing of the wound we take the necessary instruments precisely at this moment. Each operation requires a separate set of instruments. Sterilization by means of formalin vapors has always given full satisfaction. Three boxes of instruments are necessary for every operating table working without interruption, provided an orderly is entirely devoted to preparing them. The rotation of the boxes is as follows: One box is in use in the hands of the surgeon, another is in the hands of the orderly who cleans the instruments and prepares them, and the third is in the thermostat.

We can not emphasize the fact too much that the war surgeon who wishes to succeed in primary suture must understand that it is a difficult, minute, and no brilliant task which he has to take up; but he may be convinced that his results will be in direct proportion to the care he pays in following carefully the track of the projectile; in investigating the injuries produced; in doing away with the culture media; removing minutely the foreign bodies and all the bone fragments; and in excising with great care the skin, the connective tissue, the fascia and the muscles forming what has been called the chamber of attrition. Then he will end his operation after careful hemostasis, carefully drying the wound and fixating it with tincture of iodine, by the repair of the injuries due to the wound and the surgical operation. We can affirm that in this work, more than in any other, success rewards effort.

Fifth. In general the patient requires general anesthesia, for one never knows where the wound may lead to, and local anesthesia decreases the resistance of tissues already contaminated by germs. Spinal anesthesia can be used in a number of cases.

Sixth. The most delicate point consists in following step by step the track of the projectile; it is indispensable to see very well, and the light should be so arranged that the progressively extending field of operation may be seen step by step in such a way as never to remove anything without seeing it well. A frontal mirror with electric light can render service.

Seventh. It is hardly necessary to say that the surgeon must have always present in his mind the topographical anatomy of the region he is operating on. The projectile does not follow ordinary surgical paths, and as we will have to follow it, it is a point of capital importance to always know exactly where we are working from an anatomical viewpoint. The track of the vessels and nerves must be well in mind before hand; when the wound starting far from them takes us gradually in their vicinity, very often by a quite different path than that followed in ordinary surgical operations: Projectiles take no heed of classical anatomical paths to reach an organ, and, furthermore, they often meet a bone in their path which sends them in another direction and thereby creates a new path. All of this creates difficulty, from an anatomical view point; and yet the surgeon must know how to conquer this difficulty without causing more than a minimum of damage to tissues.

This is not all. Muscles underlying each other are not necessarily at the same point of contraction at the time of the injury. At the moment of the operation, under the influence of a general anesthesia, the perforations, in each one of them do not correspond with the others. We have therefore a broken line to follow in these cases, a real difficulty for the operator. Often a matter of capital importance for the war surgeon is a knowledge of the innervation and blood supply of the muscles. We will also have to revert to this point later on.

Eighth. But let us repeat it once more; it is an absolute necessity that the surgeon should have the firm will to attain his aim.

2. INVESTIGATION BEFORE THE OPERATION.—(1) *Radioscopy*.—For a long time we operated our patients without the help of the X-ray outfit. We were thus thrown back on our own resources, to follow the missile step by step, and we can affirm that we succeeded comparatively easily in thus removing projectiles, the situation of which was unknown to us. This necessity of not losing sight of the track leads the surgeon to follow it very closely. It trains his judgment and gives him sufficient dexterity to perform easily a surgical operation which at first is not without difficulty. Thus we believe that in the immense majority of cases radioscopy examination is sufficient. It indicates about where the projectile has remained, consequently about the direction it has traveled. It indicates the size and the number, if there are several. All of this is not without interest. One entrance may lead to two projectiles in the tissues, especially when a bone has been met in its path. In this case radioscopy examination will warn the surgeon that he will have to follow a Y-shaped track, the bifurcation taking place at the point where the vulnerating agent has broken up. In other cases it will reveal the existence of a wound or fracture which had escaped clinical examination or merely been surmised.

Lastly, in the case of multiple wounds by fragments of hand grenade we have often been forced to do away completely with a radioscopy examination, operating on an aluminum table and advised only from time to time by the radiograph with his frontal screen, without however, allowing ourselves to be guided entirely by him; for here, as well as in other cases, one must follow the track of the fragment, and not, as one is too often tempted to do, go directly for the foreign body by the shortest path. This mode of doing has a twofold advantage: Firstly, it saves time, the time necessary for the radioscopy examination, and, secondly, it enables the surgeon to be constantly informed of the number and size of the projectiles that still remain to be extracted, both of which are important, if one remembers that wounded with multiple wounds are often in a condition of shock preceding their infecting, and that the operation must be always in proportion to the resistance of the wounded.

(2) *Clinical examination of the wounded*.—(a) General examination: We believe it necessary to insist on the importance of complete clinical examination of the wounded before deciding to operate. At once wounds too slight and those which we know to be rarely infected can be eliminated from the operation. Amongst the latter we can mention minute fragments

in the face and hands, without injury to the bone and tendons or the joints. For wounds of this kind, produced without the projectile having gone through the clothing, contain no fragments of cloth which are always loaded with bacteria and which are far more dangerous than the projectile itself. In the same category are included through-and-through wounds by rifle bullets when the wounds of penetration and exit are both very small, without bone, joint, vessel, or nerve injury, and the track of which is neither tympanic nor painful. One can always eliminate—but for contrary reasons—moribunds and those whose general condition contraindicates any kind of operation. It is a delicate question and it is difficult to say when and where the surgeon must take the risk and operate just the same, but he must know at once that the first contraindication to any kind of primary suture is a bad general condition. These cases do not form a part of our subject matter and we only mention them in order to emphasize the following principle: Wounded whose general condition is not satisfactory must never be primarily sutured.

The pulse must be examined. It will, far better than the temperature, enable us to foresee at once whether one will do primary suture or not. We have never sutured primarily a patient whose pulse was above 120 when he entered the hospital, and often we have done so, and with success, for others who had a rectal temperature of 38.5°.

One has attached a great deal of importance to the time elapsing between the injury and the operation; one has gone so far as to prohibit primary suture for wounded whose injury dated back more than 8 hours. In the cases related above, a large proportion was sutured more than 12 hours after the injury, certain cases 24 hours after the injury, and we are sure that in a few cases one can further increase this time. However, it remains an established fact that time is a factor of great importance in making a decision and that the percentage of cases suitable for suture decreases as the time elapses after the injury.

(b) Local examination: Local examination will also give us information.

First. It is not a long time since we have drawn the attention of surgeons to the importance of recognizing gas wounds before the operation. This can be accomplished by nail percussion (filiping) in their neighborhood and we advise strongly once more to make this examination systematically in the region surrounding the wound. Very often we will be surprised to hear a tympanic sound, and this mode of investigation alone produces this symptom tympanitis that will reach away from the entrance of the wound, far from the projectile, and far from the track. We have noticed also that this mode of investigation frequently produces exquisite pain at the point of greatest tympanitis. Research and the injuries invariably found in the course of an operation have proven to us that these tympanic wounds attended by pain always correspond to gas infection by anaerobic germs. What action must we take as far as primary suturing is concerned? We advise, at least until full information is obtained, not to suture primarily those wounds. They are, however, in the majority of cases, suitable for delayed primary suture. We must say that amongst the 2,537 cases primarily sutured, related above, there are more than 200 where we did not find this symptom before operation and where, in the course of the operation, we found and excised gelatinous infiltration of a pink color in the connective tissue, both subcutaneous and inter-muscular, and yet these wounds united without suppuration, the way an aseptic wound would have done.

Second. We must also mention the importance there is in a clinical examination to determine motor or sensory paralysis. This investigation allows us to diagnose before operation of nerve lesions which we must not forget to repair whenever it is possible.

Third. Vascular lesions, which are often overlooked, must likewise be thought of. They may influence the technique followed in the pursuit of the wound track and likewise the decision one takes at the moment of closing the wound. We may say at once that it is an absolute rule never to suture a wound underlying another one which has caused an injury leading to the ligation of the main artery, irrigating the territory first. Let it be well understood that the great risk of primary suture—gas gangrene—finds its principal factor in the existence of necrotic or badly irrigated muscles, and only a secondary factor in their contamination by anaerobic germs.

A war wound cleared of this necrotic tissue, the cells of which are copiously irrigated by oxygenated blood can be sutured. The surgeon is warned in sufficient time, by symptoms of which we shall speak later on, to remove the stitches and pack the wound without causing undue risk to the patient.

So much for the wound underlying the arterial lesions. What position must be taken as far as the wound which has caused the lesion is concerned? The factor of the general condition due to hemorrhage being eliminated, two cases must be considered: Either the limb is infiltrated with blood, tense, almost double in volume, an abundant hemorrhage having taken place in the depth and produced an internal tourniquet. In that case no suture must be attempted. It is often necessary to split widely, even to split the muscle fascia distended by this hematoma. The muscle must be freed, every source of compression removed, that would hamper its proper circulation under penalty of having it contaminated by anaerobic germs, to see it become the prey of gas gangrene prepared by the enormous decrease in its vitality and its lack of oxygen. In another case the arterial wound has caused but a little hemorrhage. It is really a dry wound. The limb is not distended. There is no diffuse hematoma. Under these conditions the wound can be sutured.

Fourth. Clinical examination will also give us information concerning muscular destruction and bone injury.

There are certain wounds of the soft parts offering such an aspect that from the start every surgeon knows that he can not—and that, even if he could, he should not—perform primary suture. The same holds true in the case of fractures.

Fifth. There are also frequent cases where the patient has multiple wounds. It is perhaps in these cases more than anywhere else that the clinician must take precedent over the surgeon. Sometimes, judging the capacity of resistance of the wounded, he will hesitate to add further shock due to the operation or he will be obliged to decide which one of the wounds claim immediate operation. In these cases he will limit himself to a careful laying open of the wound, sometimes even leaving without operation the less important injuries which he would have completely operated and sutured if they had been alone. All this the clinician can learn from examination of the wounded before taking up his instruments, but even in the course of the operation the surgeon must rectify the initial decision, deciding for or against suture according to the aspect of the lesions, which he sees in the course of the operation, although he might initially have expected to close the wound.

3. THE OPERATION ITSELF.—(1) *The incision.*—The first moment of the operation consists in incising the skin, excising at the same time the cutaneous border of the wound and the track in the subcutaneous connective down to the fascia.

But if in peace time surgical operations are always well regulated, the surgeon knowing from the start what he will have to do; it is not so in war surgery. In the first case one knows from the start the length and direction necessary for the incision and it is very exceptional that one is obliged to prolong or to deflect it in the course of the operation. In the second case, on the contrary, one does not know beforehand what lesions or infiltrations will be met in the course of the operation. For this reason with data collected by clinical examination and by radioscopic examination concerning the direction of the wound track and its depth, and also the underlying organs, we decide on a general direction more commonly parallel to the axis of the limb and the length of the incision which will initially be relatively limited.

Having immobilized the skin in a position which produces concordance between the skin wound and the track in the underlying subcutaneous tissue, we excise a small skin flap with the subcutaneous tissue, oblong in its shape, by two slightly curved incisions passing one centimeter about from the lips of the wound, and joining each other three centimeters approximately further away. Thus suture will enable us to get a linear scar.

We insist at once on the point that it is unnecessary to excise too much skin. Generally one centimeter outside of the wound is sufficient. It is, however, necessary in certain cases to be less economic in this excision. Let us repeat it, economy of tissue must be the rule of the war surgeon. No more for the skin than the muscles, must be considered, the war wound like a malignant tumor that must be taken out in one block and as extensively as possible. We can not insist too much on the fact that dead tissue must be removed and the same for tissue destined to die. But this only must be removed; and we are convinced that in the matter of removal many often having sinned by being too conservative are at present sinning in the opposite direction.

The skin and underlying adipose layer in the initial portion of the track we remove without any instrument becoming contaminated. We now have a little gap five or six centimeters in length, except in cases where a large skin wound has already obliged us to make a greater excision. However, it is exceptionally that we give it greater dimensions at the start. We prefer increasing it as the need arises, inwards or outwards, transforming it in a flap as in the course of the operation and necessity or utility arises. In this way the ultimate incision will never be greater than necessary.

(2) *Following the path of the missile.*—With a few clips of the curved scissors we remove, if necessary, a few fibers of connective tissue, expose the fascia, and we easily recognize the perforation through which the projectile has passed.

Two clips of the curved scissors, often very economical, increase this opening and remove its débris. Two Kocher forceps grasp the lips of the opening and lift in the form of a cone that already allows us to see a certain depth into the muscle the path followed by the missile. The split fascia and underlying muscle in the direction of the track allows us to see better and to bring to the surface this part of the tunnel. If bleeding occurs, it is immediately sponged. The small arteries are ligated with very fine catgut, the strands being cut very short. This can often be done by a single knot; often, even if the ligature has included some muscle tissue, we remove with the scissors the small stump thus formed.

We note the aspect of the muscle surrounding the track laid bare. One has thus a clear sight of the track through the first muscular layer. With the aid of curved scissors cutting sharply, we excise this muscle, removing only dead muscle fibers, which do not bleed, which have lost their normal color, and which do not react by fibrillary contraction under the influence of pinching with the forceps. It is well understood that we will have to remove in the course of the operation all foreign bodies and fragments of clothing found in the operation. Hemostasis is then carried out. Retractors spread the wound, and very often one sees the track of the projectile continuing in the underlying muscle. One pursues in the same way. Retractors expose to the eye and the instruments of the surgeon greater and greater depths of the wound track. Very often we have followed a projectile the size of a pea through the thigh or through the buttock down to the bone through a cutaneous opening of not more than 8 to 10 cm. and we affirm that with careful hemostasis one can complete the operation in the immense majority of cases. When we deal with a through-and-through wound, situated, for instance, in the thigh, and occupying the greatest diameter of the limb; we follow the track through one of the wounds, the one which appears to be the least traumatized; then about midway leave at this point a small gauze packing and start at the other extremity until we join the first. In a case where projectile has almost gone through the thigh, but has become lodged a few centimeters from the skin on the opposite side, we follow the track from the entrance until we reach the axis of the limb and after opening on the opposite side we go directly to the projectile until we reach the path we initially excised. This following of the track is often easy, but not always so. It is possible to lose one's way, and in this case one must avoid, above all things, to utilize the grooved director for exploration. It will merely create artefacts. It is by careful inspection of the point where the track has been lost sight of that one has the greatest chance of picking it up again. It will appear in the shape of a little blood clot or an adherent fragment of clothing, or a simple ecchymotic spot of the muscle. It is by lifting, by drawing a little sideways a few muscular fibers, that one will find one's way again. If we lose our way at the deep surface of a muscle, let us recall the physiology of the underlying muscle and see if shifting of the two muscles has not caused the formation of a broken line which we have mentioned. Let us therefore retract a little above and below the first muscle; ask the assistant to impart a few slight movements to the limb, and we will often have the agreeable surprise to see the lost trace reappear. If all this leads to nothing, let us find the nearest edge of the muscle, detach its surface from the underlying tissues and thus we will find the injury to the underlying muscle either by its new path or by taking up the first, but we will be careful not to infect the sliding surface of the two muscles, for sometimes we will discover here a few fragments of cloth that the projectile had left there and the sliding muscle had dispersed.

Sometimes things are more complicated yet. Let us suppose the case of a projectile which, instead of traveling in a perpendicular direction to the axis of the limb, has traveled

in a longitudinal direction. We begin as follows: After following the track as far as possible through a sufficiently large opening but without its being excessive, we mark the point where we stop by a little gauze mop, and then by a second incision underlying the first one we go back to this gauze mop and then continue the pursuit of the wound track. If this second opening does not allow us to reach the projectile, it is very rare that a third incision, taking us directly down to this foreign body, does not allow us by retrograde progression to find the second stopping point, thus having exposed the whole wound track. Several times we have utilized these ladder incisions and our objective has always been attained. We can not repeat too often that the track must be followed, that is must have been seen in its entirety, passing everywhere the projectile has passed, and it is one of the important factors of success in primary suture. Certainly it may succeed in other cases where the track has not been followed, for the whole extent of the track is not contaminated. We have noted that the wound track was contaminated by fragments of clothing, especially in the initial centimeters of its length and where it went through the fasciae and bone. We, therefore, sometimes, in order to avoid anatomical injuries out of proportion with the gravity of the lesion, wipe out part of the track with a sterile piece of gauze, pulled through by forceps, going exactly through the track and dragging it through in the direction supposedly followed by the projectile; but it is necessary to remember at the time of closing by suture that this slight deviation of the rule has been made, and not to forget it either, in carefully watching the patient after the operation if one has notwithstanding decided to suture primarily.

(3) *Inspection of the track; inventory of the damage done; excision.*—We have now followed the wound track completely. We have already removed all foreign bodies and bone splinters, if there were any. We have excised the cutaneous wounds. We have removed the majority of the muscle which is dead; excised when necessary; and we have investigated all the damage done.

(a) Nerve lesions will be immediately repaired, by suturing any nerve that happens to be cut. If there is only a partial wound to the nerve without complete section it is sometimes well to reinforce the union by a stitch bringing together the neurilemma. Unless there is a special indication, such as the proximity of fracture, we do not inclose the nerve in muscle or other protective tissue.

(b) Vascular injuries will be treated later on.

In the majority of cases double ligature will be necessary, taking care to place the ligature 1 cm. above the injury and to excise the injured portion of the blood vessel. It is seldom that the vessel can be sutured. However, in small lateral wounds we recommend suturing the vessel provided the neighborhood is healthy. But we know the nefarious effect of projectiles in the neighborhood, producing secondary hemorrhage, of the development of aneurism, and must therefore be very circumspect in this regard. Very often arterial lesions, even if important vessels are concerned, are disclosed only in the course of the pursuit of the wound track. They had bled very little, the perforation being momentarily and very rapidly obliterated by blood clot or reflex vasoconstriction, or in the cases of complete section by retraction of the middle tunie, become manifest in those cases when we detached the blood clot covering the opening. Often, it is possible to treat these lesions easily through the path followed, but sometimes also one meets with very great difficulties and often absolute impossibility. Therefore we always have in our service a tourniquet within reach of each operating table.

Often, also, the artery lesions are recognized at the time of the clinical examination. From the viewpoint of the technique that is to be carried out, two cases may occur. Either we consider the direction of the track will enable us to easily expose the arterial injury and we follow this path, or considering at once that this path is impossible or too risky we begin the operation by an incision which leads us directly to the artery. We treat this and primarily suture this aseptic wound. Then as though there had been no arterial injury we treat the track of the missile. When the lesion affects a large venous trunk we incise in the same way, but in such a case the tourniquet is unnecessary; compressive packing of the wound is sufficient until the ligature has been completed.

(d) *Bone injuries*.—It is necessary to remove all the splinters met. With the Rongeur forceps we must freshen the bone wound when there is only an incomplete fracture. When there is a complete fracture it is necessary to remove the splinters as completely as possible, taking particular pains to preserve the periosteum and the underlying osteo-genetic tissue, the importance of which has been so well emphasized by Doctor Leriche. It is necessary to inspect the bone marrow to remove that which is in the vicinity of the focus of the fracture but not remove the marrow extensively, as we have seen it done sometimes.

Articular bone lesions must be treated according to their importance, either by classical excision of the joint at once or by regularization of the focus of the fracture when that is possible.

We do not want to insist on this point, as it would involve lengthy explanations, and we can only repeat what has been said by Doctor Leriche on the subject.

(e) We think it is advisable, on the contrary, to insist on what must be done in the way of muscular and fascial excision.

In general the aponeurosis, which is resisting, is simply perforated by the projectile. Sometimes the tear extends a little beyond the perforation, which is always fringed by shredded tissue. These shreds must be excised for a distance of a few millimeters, but the most important thing is to inspect them carefully, for often one here finds minute fragments of clothing adhering to the tissues which are most important factors of infections. Intermuscular fascia must likewise be inspected with particular care, and we advise the removal of a little layer of muscular fibers, often healthy, which adhere to the fascia at this point in order to have a clearer sight and not allow those little fragments of clothing to escape, for they are very much to be feared. Sometimes it is necessary to inspect both faces of this tendinous layer, to split above and below the opening, and to turn out the two margins of Kocher forceps, thus exposing its deep aspect to the eyes of the surgeon. This is likewise necessary to enable one to follow the track later on.

(f) Tendons which are in the way of the projectile must likewise be minutely inspected. When they are cut they must be sutured after freshening. When suturing is impossible, they must be sutured to a neighboring tendon; in a word one must at once perform in their case the operation necessary for the best functional repair. If they have only been brushed by the projectile they must be cleansed of minute fragments of clothing which may adhere to them. Their wound must be treated the way old surgeons used to do with an amputation stump, and they must be reinforced with a catgut stitch if this treatment has increased their initial injury rendering them weak enough to jeopardize their solidity.

Sometimes, in wounds of the wrist and the ankle we have been in the necessity of dissecting, to cleanse and repair them, the extensor or flexor tendons the way we would have done for the removal of tuberculous synovitis, and thus to obtain, after primary suture, a perfect functional repair.

(g) We must not forget to excise as completely as possible this subcutaneous or intermuscular tissue infiltrated by dark blood or transformed into a kind of pink or brownish green gelatinous substance. Surgeons do not like to meet with this condition for it is often a prelude of grave infection and accompanies generally the tympanitic tracks already mentioned.

(h) Lastly, the muscles (soft tissues gorged with blood) explode very often under the influence of the impact. The asperities of the artillery projectile and especially the enormous speed which all war projectiles acquire, produce in these tissues lesions of explosion and commotion which stupefy and kill these organs which are of a relatively delicate texture. Experience has shown that grave infection occurs in war wounds, owing to a twofold factor: (1) Mortification of the muscle, which becomes an excellent culture medium in the well-regulated thermostat of the human body; (2) microorganisms are introduced by fragments of clothing carried by the missile. The first of these factors is by far the most to be feared, and the second, without the help of the first, is very often not able to produce its effect.

We must therefore remove all the necrotic portion of the muscle, but only that part that represents the culture medium. Certainly, in the beginning, the surgeon must hesitate in determining exactly what he must remove and what he must leave. Sometimes, he removes too much, sometimes he does not remove enough, and it is only his personal experience which will teach him, his judgment improving little by little, the exact line of separation between the two. It is essentially a question varying according to the nature of the case,

varying also with the nature of the wound and the depth of the track. There are some cases when any muscular excision is unnecessary. There are others where it is necessary in the extremities of the track. There are others, finally, where removing a few out febrils may be sufficient, but there are others where it will be necessary to remove considerable masses of muscle; even, in certain wounds already the prey of gas gangrene, whole muscles at a time. There are, however, certain signs which can guide the surgeon. These signs are three in number: (1) Normal coloration of the muscle; (2) bleeding of muscle, when tested by a minute clip of the scissors; (3) fibrillary contraction, when the muscle is stimulated by pinching with the forceps.

Sometimes the muscular track presents normal coloration. It is sufficient then to inspect it to remove little fragments of cloth that may exist, and to freshen it by a few scissors clips. In this case muscular excision is practically unnecessary. Very often the track is of a graying hue, even black. In such a case the superficial layer of the track must be removed. In general it is unnecessary to remove a thick layer; half a centimeter is often sufficient, sometimes less. It is rare that more be necessary, unless there is gas infection. In those cases we recommend to examine carefully the fresh section of the muscle thus produced, to see whether there is any open space between the muscular fibers, or a few cut fibers the extremity of which retracted at once after the injury may have carried with them little fragments of clothing.

Sometimes one finds the muscle paler than usual—pinkish in hue or coppery—and very often on this case the first excision, always performed with curved scissors, and about 1 cm. from the surface, offers a section which presents the same aspect.

The blood oozing on the surface similar to a pinkish dew is not to be seen. True, we can see a little blood jet from a little intramuscular artery which we have cut, but that is not the sign enabling us to say the muscle is normal. Moreover, if the muscle is stimulated by pinching slightly with the dissecting forceps it does not react by the little fibrillary contraction which is so characteristic.

What do we do in such a case? We advise splitting the fascia of the muscle about which we are in doubt, giving it breathing space and allowing it to spread out freely; then wait a few minutes, taking up another part of the wound. One will then be surprised to see this muscle, pale a few moments ago, the section of which did not bleed, that did not react when pinched by the forceps, offer now simultaneously these three symptoms. The muscle was apparently suffocated and the scissors freed the tissue, allowing it to recover life. It is really a live muscle and its excision would have been useless.

If, on the contrary, after this trial, it does not manifest its vitality we must excise it progressively, still using the curved scissors, and taking off a layer of a few millimeters at a time until the necessary characteristics appear beyond a doubt. That is precisely the reason why we repeat the quantity of muscle to be removed varies essentially according to the case, and we appeal to the tact of the surgeon, who, thanks to these symptoms, very soon acquires sufficient judgment to decide what must be removed and what can be left.

In other cases the small artery has infiltrated a muscle with blood. With a few clips of the scissors we detach the principal clots. It is often possible to leave a few dark spots resulting from this infiltration of blood without risking to compromise the primary suture.

We have already specified, but judge necessary to repeat once more, that by bleeding muscle we must not understand bleeding from a cut artery, but that little capillary oozing that appears like a pinkish dew on the whole surface of the section.

We will not insist any more on the sign of fibrillary contraction in response to stimulation by pinching. It must be constant at the proximal end of muscular fascicles which we examine, but it may fail at the distal end, depending on the condition of the nerve supply. Let it be well understood, what is important is to free the wound of all tissues whose life is finished. We must therefore leave in the wound no fragment of dead muscle and instruct our assistant not to traumatize with retractors or Kocher forceps the delicate muscular tissue, the vitality of which is easily compromised, creating one of the important factors of grave infection following war wounds.

One has doubtless noticed how much we insist on the use of curved scissors. They must cut sharply, not with their point but with their belly, cutting tangentially to the surface and for this work they are infinitely superior to the knife. The latter may prick with its point, and thus inoculate; and the stimulation it produces in the muscular fibers it cuts often causes the

underlying ones to have reflex contraction, sometimes even carrying with them into the depth of the muscle little fragments of clothing, their contaminated extremity not having been excised. We apologize for repeating once more that muscular excision must be economical, muscle may compensate and adapt itself to a new function, but it does not regenerate. Therefore, in the immense majority of cases—we would almost say in all cases—one must avoid cutting the muscles transversely. Apart from the interruption in the muscle itself, which may be restored by primary suture, one must not forget that, by so doing, one cuts as well the nerve, the blood supply of the underlying part, and the dangerous consequence is obvious. Without its being necessary to insist on the fact, it is obvious that the distal end will no longer receive its proper nerve supply, and suppression of the arterial blood jeopardizes the vitality of the distal end, being capable sometimes of causing necrosis, with formation of gas infection, and at the least causing a failure of the primary suture. For instance; we know how grave from a functional viewpoint are transfixing wounds of the calf, and yet we can affirm that if they are judiciously treated they almost always heal by primary suture. The difficulty the surgeon so frequently meets in these cases is due to a twofold cause: The blood supply of the calf muscles and the presence of the thick intramuscular aponeurosis of the soleus muscle (the large muscle bodies of the first named are irrigated almost exclusively, each one independently, by a single artery). If one of these arteries is cut, either by the projectile or in the course of the operation, the vitality of this muscular mass is so much lessened that the worst disasters may be feared and one must withhold from primary suture in all of these cases.

As to the intramuscular flat tendon of the soleus, it is situated in a deep portion of the limb, concealed by a thick layer of tissue, and the projectile often carries to this point the fragments of clothing.

One sees at once what risk would involve a wound of this region, if it were sutured without the surgeon being certain not to have left any foreign body unnoticed.

If, notwithstanding, in certain cases one feels compelled to cut a muscle crosswise, one must not do so unless one has to deal with a muscle receiving its nerve and blood supply at several points so that one can afterwards by suture restore its anatomical continuity. It is in a majority of cases preferable, if the thing be feasible, to work round the muscle, passing in that way the obstacle which it presents, and take up the track through this new path, without omitting the examination of the small portion of the track that could not be investigated by the direct path.

We admit, however, that there are cases where one must expect functional sacrifice of muscle, but at least it is a very rare exception indeed, and only to be made when cutting crosswise would involve a graver risk still. Two words can sum up what this excision of muscle tissue ought to be: No avarice; no prodigality.

(4) *Drying and fixation with tincture of iodine.*—The inventory we have made has allowed us to recognize unavoidable losses of tissue and to clear the situation. Let us now say a word in regard to repairing as well as possible without causing the patient to run any risk.

As we have said, hemostasis has been insured in the course of the operation. This hemostasis must be very thorough for two reasons: First, it must prevent the formation of hematoma, so favorable for suppuration; secondly, the wound must be completely dried so the fixation of its surface can take place under the action of tincture of iodine. We therefore completely dry each wound with gauze pressed on the wound surface and rapidly removed at the precise moment when the wound is abundantly swabbed with tincture of iodine. Immediately another dry gauze mop wipes up the excess of tincture of iodine. If the fixation has been well done, the whole wound surface becomes dry as though varnished and assumes a coppery hue which is absolutely characteristic. This procedure, if correctly carried out, is of great importance. Certainly, we do not pretend that a wound which has not been treated in this way will necessarily suppurate. Numerous facts would contradict our statement at once, and ourselves we do not resort to this mode of action in simple cases, where the pursuit of the wound track has shown us healthy tissues which require no excision, and also in superficial wounds, which are totally excised; but, on the one hand, we have already explained how we were led to this treatment, and, on the other, we believe that the small number of failures shown in our statistical report, is due partly at least to the careful carrying out of this step in the operation.

We took up tincture of iodine (5 per cent) as a fixating agent because we used it before the operation for fixation of the superficial layer of the skin before the operation and because it is a simple way of doing, and we always have this solution at hand; but we are ready to abandon it for any other fixating agent which will offer more advantages, and which will not have the drawback we are about to mention.

Tincture of iodine fixes not only the superficial microorganisms but also the underlying superficial cells of the wound. As a result a slight secretion of serum takes place, turbid, which oozes out between the stitches of the wound or along the capillary drainage when there is one, which produces no drawback, not even that of having to renew the dressing, as it drains in the deepest layer of the same. It is only necessary when capillary drainage has been used and one inspects the wound to remove this drainage on the third or fourth day. Furthermore, the slight serum elimination delays the cicatrization for four or five days. It is for this reason that we advise to remove the stitches on the 12th or even the 13th day only.

This slight drawback has a favorable consequence: It allows, when one judges it necessary, to put off the primary suture till the eighth or ninth day. We have even some cases of delayed primary suture performed on the tenth and twelfth day.

(5) *Suturing*.—As the words "primary suture," "delayed primary suture," and "secondary suture" are coming more and more into use, it is necessary to understand clearly the meaning attached to each one of them, to avoid designating the same thing by two different names. For our part, we understand by immediate primary suture the normal termination of the operation we have just described. The suture takes place immediately after the excision and treatment of the wound.

Delayed primary suture consists, without further excision or freshening of any kind, to repair the anatomical layers (when the gap in the fascia is not too great to bring them together), or the skin alone. It consists, therefore, in taking up the operation, which is at this time carried to its end, after an interruption of a variable number of days.

On the contrary, secondary suture consists in closing the wound after excision either of all the scar tissue in one mass or only an epithelial border and a narrow strip of skin in the neighborhood, and part only of the granulation tissue, when one can not do likewise.

We therefore think it advisable to distinguish two kinds of secondary suture. In one, one removes the scar tissue as a whole, and reconstructs all the layers of the flesh wound thus produced. This might be called secondary suture with anatomical reconstruction. In the other, which might be called secondary suture of the skin, one limits oneself to excision of the epithelial border, allowing the granulation tissue, entirely or in part, according to circumstances, to remain.

As far as we are concerned we always suture the wound primarily when we deem it advisable; when we do not do so, our patients are followed clinically and bacteriologically in view of delayed primary suture. When we can not perform the latter, we strive to perform secondary suture as far as possible. In these cases we prefer an anatomical repair of the wound except when it is impossible for one reason or another, and in this last case we perform a secondary suture of the skin alone.

We do not propose taking up the technique of secondary suture. The only reason we mentioned it was to emphasize the following fact: When we can not suture primarily, the treatment of the wound consists in a simple, dry aseptic dressing, without the use of any antiseptic, the dressing being renewed every five or six days. At each dressing it is necessary to make sure there are no necrotic fragments to be removed; should there be any they are detached by a snip of the curved scissors. Then we wash the skin surrounding the wound, with oleate of sodium, we dry with a gauze mop imbibed with ether, and paint the surrounding skin with a little tincture of iodine.

We can affirm that wounds treated in this way do not suppurate, or very slightly. Sometimes during a week in the interval between two dressings the wound is slightly grayish, but very soon becomes pink. In a word, when primary suture and delayed primary suture are both impossible we trust to the vital power of the patient for the disinfection of the wound—without striving to destroy the microorganisms, leaving this to the phagocytes and being very careful not to interfere with the process of autoimmunization of the patient.

Laboratory examination can be used as to the cellular and microbic condition, of the wound, more by cultures than by smears. It is the general condition of the patient, on the one hand, the aspect and evolution of the wound, on the other, and, furthermore, the absence of streptococcus that will enable us to decide when it is possible to suture.

We are convinced that treated in this way our patients are ready for secondary suture as soon as if they had been treated by the Carrel method.

It is unnecessary to describe in detail the technique of the primary suture of the wound. Suffice it to say that the different anatomical layers are repaired whenever possible and that the security can be increased by using the capillary drain, composed of three or four silkworm guts which are removed on the third or fourth day; but there are often cases where we do not place any at all.

It is useful to note that for the repair of the different layers with buried sutures, one must use nothing but fine catgut, starting from the principle that every foreign body and animal tissue favors suppuration of the wound even if it contains very few germs. For the same reasons, we cut the strands of the ligature very short and avoid strangulation of the tissues.

We end by applying dry sterile dressing and immobilizing the operated region as far as possible.

4. POSTOPERATIVE CARE OF THE PATIENT.—This is very simple. Unless there be a special indication, the dressing is changed at the end of 12 or 13 days, in order to remove the stitches when there is no capillary drainage. At the end of three or four days to remove this drainage, if one has been made; in such cases a second dressing is necessary to remove the stitches. In the great majority of cases the wound unites by first intention, and from the fifteenth to the eighteenth day no more dressing is required.

We must also mention that after the suture the mobilization of the operated region must be avoided, for, as we have already said, and as we repeat, we close wounds which are not sterile from a bacteriological point of view. Their evolution is that of a sterile wound because we have removed by operation the great factor of infection, and the defense of the organism does the rest. Nature has foresight and realizes immobilization of an infected region. We must imitate it in immobilizing the region we have operated upon. It is for this reason the results of primary suture would not be as good were one obliged to evacuate the patient and make him travel prematurely. However, this period is relatively short and taking place in the region of the wound.

We attach greater importance to the symptoms of pain. In principle, 12 hours after the operation the patient ought no longer to suffer. We don't refer, of course, to pain produced by motion or pressure on the wound. It is spontaneous pain which must call our attention, and in particular when the patient complains that the dressing is too tight. If the wounded complains, being very careful in eliminating the nervous susceptibility of the patient, we must remove the dressing. Often one discovers the cause of the complaint of the patient to be either hematoma, and stitches must be removed, the bleeding vessel sought for ligature, and the wound packed with gauze, delayed primary suture being performed two or three days later, or else we have to do with beginning infection and then all the stitches must be removed, the wound completely laid open, and packed.

This spontaneous pain is in our judgment the capital symptom to indicate that primary suture was unduly performed.

5. CONTRAINDICATIONS.—This is the most delicate point of the method. We mean discussion of the indications and contraindications to the primary suturing of war wounds.

From the start we must say that all, or almost all, war wounds which can be correctly treated in due time should be sutured as soon as possible. In other words, a suture is four or five days after the removal of the stitches the patient may travel. Many of our wounded leave the hospital, on convalescence leave, around the twentieth day, sometimes even a little earlier.

Let us now see what points deserve attention in the days that follow the operation. Three points are important—temperature, pulse, pain.

Very often there is a certain rise in temperature 38, 38.5 rectally—during the first two days, sometimes during the first three days; then rapidly the temperature falls to normal.

We must say that certain of our cases reach a temperature of 39°. This does not trouble us especially, and nothing unfavorable takes place. It is only a prolonged rise of temperature that calls for an examination of the wound. If in examining the wound there is found a little redness over one of the stitches, gentle pressure over the surrounding zone is made. If this pressure is painful, it is better to remove the stitch. If, on the contrary, pressure is painless we can leave the stitch in.

The pulse of the patient gives more precise information. In general the pulse ought to be normal, between 72 and 80. If it is more frequent, even without rise in temperature, one must watch the wound very carefully, but one need not be alarmed. More commonly, the pulse becomes rapidly normal. In the contrary case other symptoms (pain, temperature, general condition) warn the surgeon that something abnormal is indicated in all cases. We will, therefore, not speak of indications but of contraindications. These are based on manifold reasons.

Some have no relation to the patient, or the wound, or the surgeon; they are not based on technical reasons, but rather depend on the material circumstances which can not be modified. Thus, for instance, when the influx of wounded is clearly out of proportion with the limited operative capacity. Contraindications of this nature we will leave out of our discussion.

Other contraindications of a purely technical order, on the contrary, we must examine with care. We will divide them in two groups. First, absolute contraindications; second, relative contraindication.

a. Absolute contraindications.—They are the following:

First. The patient reaches the surgeon at a relatively late period after the injury. He is already suppurating or presents a zone of lymphangitis around the wound, a little streak of lymphangitis a certain distance from this, and swelling of the lymph gland in the neighborhood. We need not insist on this contraindication, which is obvious.

Second. The same applies evidently to patients who arrive, sometimes only a few hours after their wound, in our experience, but already with confirmed and extensive gas gangrene.

Third. One must in no case, excepting joint wounds (and often in this case the suture must be limited to the synovial membrane and the capsule), suture primarily a patient whose general condition is bad. But what must be understood by bad general condition? Whenever a patient is shocked, whatever may be the cause of this condition. Now, in a majority of cases of shock, except these due to hemorrhage or shock due to intoxication, the wounded should be watched and given general treatment before deciding to operate. A wounded man who is very anemic, owing to much loss of blood, whose pulse is equal to or above 120 beats a minute, emotive causes of this acceleration being eliminated, should not be primarily sutured. This is the meaning we give to the words bad general condition contraindication any primary suture.

Fourth. When one has to deal with a shattered limb, or even certain injuries of the soft parts, and one hesitates about the advisability of a primary amputation.

Fifth. We have already said that no wound underlying another wound which involves arterial injury necessitating the ligature of a vessel and a limb, ought ever to be sutured primarily.

These are the absolute contraindications, and we see that they can be reduced to two general ones: Either the wounded presents an infection too advanced to enable one to think of primary union, or else the circulation, general or local, is so impaired that by suturing the wound one would cause the patient to run the greatest risk on account of the favoring factors for the development of anaerobic germs.

b. Relative contraindications.—Let us now see what contraindications may exist in individual cases. It is here especially that the tact and clinical sense of the surgeon must guide him and where the clinician can in certain cases stop the hand of the surgeon who might be too anxious to close his wound at once.

These contraindications are numerous. Let us examine them successively.

First. The time elapsed since the injury has been noted when we examined the patient before operation. We do not attach absolute value to this factor to decide at what precise moment primary suture ought no longer to be practiced. Certain surgeons have spoken of

eight hours as being the limit. We are not of this opinion. There are cases where one must not suture primarily, even if one can operate within the first two or three hours. There are others where one can suture much later, about the twenty-fourth hour. However, the result of the study of the flora of the wounds shows in a prepotent manner that the longer time elapsed since the injury the greater becomes the importance of the microorganisms, and it is natural to take into account for final determination the time that has elapsed since the injury; but we can not and will not fix any precise moment.

Second. The same applies to the temperature taken before the operation. Initially we have never sutured any patient whose temperature was above 38. Our personal experience has taught us that one can with impunity close the wound in a patient whose temperature reaches 39, provided there be no other contraindication. These patients must be followed with special care, and the fever presented before the operation will really be of more importance in guiding the surgeon after the operation than it had at the moment of the suture itself.

Third. Does the finding of a painful, tympanitic zone around the wound before the operation, and the presence of a gelatinous and pinkish or greenish connective tissue at the time of the operation, constitute a contraindication to primary suture? When one is certain to have seen the whole of the track, to have excised all this gelatinous edema, and to have found tissues having normal characteristics of vitality. In a word, when the surgeon is well satisfied with his work the wound may be closed; but we advise being very prudent and, until one has gained experience, preferably resort to delayed primary suture in such cases.

Fourth. We have already said what we think of wounds having produced an arterial lesion, and we have mentioned that they can be sutured primarily, first, when the general condition of the patient is favorable, and, secondly, when the wound is not infiltrated by blood. When the wound is infiltrated by blood it ought not to be sutured—more with a view of preserving nutrition of the limb than from fear of infection.

Fifth. One must not suture cases where one has found in the course of the operation lesions of explosion, mortification, large quantities of clothing, not forgetting; however, that it is often possible in these cases to perform a delayed primary suture if they have been correctly operated. It is simply a question of prudence.

Sixth. When one finds in the course of the operation the whole wound track with a grayish appearance it is preferable to postpone the suture.

Seventh. When the wound is prepared with a multitude of little fragments, as frequently occurs when a hand grenade explodes in the vicinity, the vitality, if not jeopardized, is at least markedly lessened. Greater care is necessary in suturing such cases.

Eighth. When the whole wound track has not been seen, either because the guidance thread has been lost or other anatomical reasons, one has to be very circumspect. It is true that primary suture may succeed, but if it fails it is unnecessary to seek an explanation elsewhere than in this fact.

Ninth. If one is in doubt about asepsis of instruments and material used, it is obviously necessary to leave the wound open in these cases and resort to delayed primary suture.

Tenth. When the surgeon is in doubt of himself. This is a purely psychological contraindication, but it has in our eyes a capital importance and we permit ourselves to give the following advice:

Let the surgeon operate as minutely, as carefully as though he intended to perform a primary suture, but in his first operations he will only attempt the delayed suture. It is only after a certain time when he will have seen his wounded with normal temperatures, all his wounds without pus, that he will regret not having performed primary suture. Having gained confidence in himself, feeling that he has mastered infection, he will begin attempting primary suture. Thus he will avoid many disappointments.

Like the absolute contraindications these relative contraindications are based, as we have seen, on the antecedents of the wound, on the clinical examination of the patient, on the clinical examination of the wound, the anatomical condition of the lesions during the operation, the blood supply, and, lastly, the principle of general pathology which states that the same quantity of the same germ with the same degree of virulence will produce very different effects according to whether it has been inoculated in healthy, live tissues or in tissues that are dead or with decreased vitality.

RÔLE OF THE LABORATORY.—We have not mentioned so far bacteriological examination, and we have placed ourselves in the situation of a surgeon not having any laboratory at his disposal.

However, the laboratory can and must help our judgment in this matter. It is of first importance—we may say it is indispensable—for delayed primary suture and for secondary sutures. The work of Tissier has shown us how it may apply to primary sutures. In the course of a trip to La Panne in the month of March, 1917, we had the good fortune to meet him, and we remember the deep impression his opinion on streptococcus in wound infection produced upon us. This gave up the key to certain failures which we could not understand. In these cases clinical examination of the lesions found in the course of the operation had led us to perform primary suture, which we were later obliged to remove. Since then we have been able to control bacteriologically the nefarious action of the streptococcus, always in our cases of complete failure, and often in those of partial failure it was the streptococcus we found as cause of the infection.

In our partial failures where we found no streptococcus we found staphylococcus.

We, therefore, accept fully the first part of the dictum of Tissier: That every primary suture of a wound, based on correct anatomical and clinical principles, where no mistake has been made in the operation, ought to unite, and that if union fails this failure is due to streptococcus.

But basing ourselves on a practice of 30 months and the very small number of our failures, we do not for the moment consider demonstrated the fact that every wound contaminated by streptococcus is fatally doomed to suppuration and suture to failure. We can not believe that in the very large number of our primary sutures the number of streptococcus contaminations of the wound can have been so slight, and we likewise do not deem it possible that we should have eliminated from primary suture all of such cases. Continuing our present practice, we hope that laboratory investigation will soon clear up the subject.

CONCLUSION

This method is in contradiction with the general ideas accepted before the war. It was not conceived then that they could operate a wound already strongly contaminated by microbes which were developing and close it as though it were aseptic. The method has, however, no original element. It is the result of a combination of surgical acts, which are logical and have been known for a long time.

Based on observation and common sense, the method has been perfected step by step. We have often been criticized for not publishing our technique sooner, for it is now, with the exception of slight improvements, what it was two and a half years ago. Our reasons for refraining from publication are the following:

1. A technique is taught by example and not by books or words. It is understood and learned much more by seeing the surgeon act than by reading or listening to his description. Then our first publication on the subject, in the months of March, April, and May, 1916, at the Medico-Surgical Society of the ——— Army were not precisely met with encouragement, although we already had the experience of 10 months and gave the histories of 218 cases, with 2 failures. But our report was premature; ideas were not directed in this direction at that moment.

We thought there must be at the front surgeons who had been influenced by the same reasons as ourselves and were carrying out the same practice. At present this way of treating war wounds is becoming classical, and if we publish our statistics and our technique it is, on the one hand, to bring our contribution to the subject; on the other, to express our opinion on points where surgeons do not seem to be in accord in practice, if not in principle, causing the method prejudice.

Opponents of primary suture claim that it necessitates a considerable excision of tissues at the least more important than that which would be necessary for disinfection by chemical means. We are not of this opinion. Excision sufficient to make a primary suture successful is exactly equal to that which is necessary when the other method is used.

Those who excise more excise too much. Primary suture does not require to be vindicated; it does not fear the attacks of its opponents; and is capable of defending itself. The creature of French surgery will grow and extend owing to its own virtues without needing the protection of a father or an adoptive father.

Army Sanitary School No. 18.

TRIP TO THE TRENCHES—GROUP UNDER MAJOR BURNETT

Accompanied by Majors Hugo, Farris, Boswell, and Haskins, and Captain Taylor

On the morning of December 13, 1917, six medical officers left the casualty clearing station for a visit to the front-line sector, about 5 miles distant. We proceeded to the advance dressing station by ambulance; this station being located in a completely destroyed town. The advance station is in indirect command of a lieutenant colonel of the R. A. M. C., who is commanding officer of the entire field ambulance unit. The station was located in the cellar of an old demolished brewery, in which there was good protection from shell fire, in this sector practically continuous. The approach to the cellar, camouflaged and protected by two gas-proof curtains, which led into a spacious corridor, off which there were a store-room, a dressing room, a ward, an operating room, quarters for the personnel, a dining room, a laundry, a kitchen, a storeroom, and an additional waiting room for wounded, with bunks for 50 patients. Upstairs there was a bath and quarters for officers, with dining room and sleeping room. The personnel consisted of 2 medical officers, 1 American and 1 English. Additional personnel of 45 enlisted men, the bearer section entire of the field ambulance, including none commissioned officers, were on duty as dressers, litter bearers, and attendants. The supplies consisted of 3 surgical boxes, 3 medical field panniers, medical companion, surgical instruments in a sufficient quantity, changes of clothing, water tank, and a variety of splints, including the Thomas. Besides there were boxes containing various sponge basins and jars for dressings—in short, all the necessary equipment for dressing room and emergency operation purposes. There was besides a reserve supply of clothing for the personnel of the station itself. The dressing room and operating room were well equipped with an improvised operating table, with sterile dressings in glass jars, and with solution for disinfecting. No definite number of hand litters were kept at this place, but approximately 15 litters were on hand for use. The kitchen was well appointed in every way and clean. A chute is arranged into the cellar so that a loaded litter may be slid down or drawn up. The officers' quarters were clean and well protected. There was sufficient ward space, including a reserve for 135 cases to be temporarily placed if necessary. Only two ambulances were kept in front of the station, in a protected position, as experience had taught that more would result in drawing fire and consequent casualties in personnel. The function of this station was to receive wounded from the front lines; to give them proper shock treatment by external heat, and hot drinks and proper application, if not already accomplished, of the Thomas splints for suitable cases; to make a proper record for the wounded by filling out the field medical card and by entering the patient's name in admittance and discharge book for the benefit of the records of the station itself. Antitetanic serum was given at this station to all wounded, from 500 to 1,000 units being administered. Personnel was detached from this station to aid battalion medical personnel in times of "strafe." Patients are sent from there to the M. D. S. or C. C. S. as rapidly as possible, but endeavor is made to send sitting with recumbent cases. Stretcher bearers need to be very strong men. Folding litters have not proved satisfactory. This station was located about 2,500 yards in the rear of the trenches. Extreme care was used to have good protection from shell fire by means of sandbags around sides in direct line of fire. Gas curtains were kept wet with water, and the frames of dugout entrances and exit were tightly fitted. A small but excellent engine furnished electric light, but oil lamps were also installed. The station was heated by small stoves.

From this station we proceeded along a road pitted with shell holes from a gas attack of the night before, to the entrance of a communicating trench leading to the reserve and support trenches. This trench was about $1\frac{1}{4}$ miles in length, well drained, with duck-board flooring. It was wide at the top and had been severely shelled so that the parapets were in

bad condition and furnished imperfect protection. Close to and parallel to the trench was a good road, down which stretcher bearers from the trenches brought wounded by wheel litters, by hand litters, and by trolley. Apparently an understanding with the boche had successfully protected litter bearers on this road for several months, none having been fired on while carrying wounded. Instantaneous fire was drawn by any other party on this road. There were along this communicating trench three relay stations for changing of battalion litter bearers. These were slightly protected positions dug into the sides of the trench, with an outlet toward the right to the road. One noncommissioned officer, four litter bearers, and two hand litters were in each of these posts.

We passed from the communicating trench to the rear line support trench by means of another communicating trench, and here saw the first battalion aid post, designated a regimental aid post. This was near the battalion headquarters' dugout, and was itself located in a dugout directly off the support trench. We were told that the Medical Department often has to dig its own dugouts, and that they should have capacity for at least 30 recumbent patients. The entrance had a gas-proof curtain beyond which a 45° stairway led to the dugout proper; another gas curtain being placed at the foot of the stairs. This dugout had one entrance and one exit, protected in the same manner. The space was divided into living quarters for personnel, a section for the medical officer, a reception, dressing room, and ward combined, and a small accessory room in which cooking was done when cooked rations were not brought up. The lighting was by means of lanterns and candles; and the overhead protection was insufficient for direct hits by shell fire, not more than 5 feet of corrugated iron and sandbags, and timber and earth forming the roof. Those articles noted as being necessary for a regimental aid post are: Lights, operating table, litter supports, buckets, stools, gas-proof containers for stores (food and supplies), extra blankets, plenty of hot water for hot drinks and surgical use, sterilizer, instruments, ligatures, chloroform, cocaine, iodine, picric acid, sterile dressings and bandages, Thomas and other splints, including Gooch splint, adhesive plaster, plaster of Paris, instruments for emergency surgery, supply of common medicine, usually in tablet form.

No formal requisition is needed for supplies which are brought up by returning litter bearers.

The medical officer must always leave word where he is to be found. If a man is brought in who can evidently live but a short while, he is made comfortable and kept. Walking cases are dressed, given a hot drink, and are sent down. A plan of the trenches is kept here showing location of dugouts, headquarters, latrines, kitchens, and rest rooms.

The personnel consisted of one R. A. M. C. medical officer—a lieutenant, 16 stretcher bearers, 8 being actually present at the station and 8 being on duty with the companies of the battalion—2 to each company; also 1 orderly, a corporal, assistant to the surgeon, and 1 water-cart man with 4 assistants. One driver for the battalion medical cart was not present, but was on duty as a part of the organization. There were two sanitary men with each company of this battalion to look after the sanitary conditions under the direction of the medical officer of the battalion. The stretcher bearers were assigned permanently to the battalion post. The orderly was a R. A. M. C. man; the battalion cart driver was an Army Service Corps man. The equipment consisted of the personal equipment of the enlisted man, a surgical box of dressings, a field medical pannier, a medical companion, and a few additional dressings for special use. Emergency surgery of a minor nature can be carried on at this station. Additional equipment consisted of a Primus stove, a small operating table, improvised, with 8 litters, extra blankets, 4 Thomas splints, bunk racks for 8 patients, and a supply of gas masks for patients. Each stretcher bearer carried a pouch with shell dressings. A sufficient quantity of morphine in small rubber bottles was on hand. The work at this station consisted in the application of Thomas splints, temporary dressings or adjustment of dressings of all wounds; of shock treatment by warming with hot drinks and injection of morphine and of transportation of wounded through the relay stations to the advance dressing station. The records here were, first, the placing of a tally card upon the wounded, with name of the organization, rank, and any medication administered, especially morphine; also the keeping of admittance and discharge book of all sick or wounded. This was for the benefit of the records of the station itself. The medical officer should visit his sector in detail every day.

The second battalion aid post, similar in construction and personnel and function, was visited in another support trench section.

The third battalion post was located in a spacious compartment of a vast tunnel system, tunneled out of solid chalk formation. This tunnel, with its ramifications, was miles in extent and from 60 to 80 feet under the surface. Wounded and sick unable to walk were removed through this tunnel and up a shaft. The removal at the exit was accomplished by means of an overhead trolley. Ventilation of this tunnel and of the battalion post in this section was excellent. The latrines for the two first-aid posts were in a protected part of the trench, pails being used, which are daily emptied into pits 100 yards from trenches and then cleaned. All three battalion posts took particular pains in seeing that the wounded were given hot drinks, were thoroughly warmed and rested before being sent back. In times of stress there is no room for resting cases. Battalion dugouts are too small (usually about 10 feet in width and 20 to 25 feet in length) to accommodate more than 8 patients at a time. All medical officers agreed that there should be room for at least 25 or 30 cases at a time, for in battle it frequently becomes otherwise necessary to leave wounded men in the trenches outside of the dugouts. Improvised stoves burning coke were used, as little or no smoke resulted. All dugouts seen and nearly all trenches in this sector, support, and front line, were in bad state of repair, but duck boards were placed along trenches and all were well drained. Every effort was apparently made by the commanding officers to secure good personal hygiene. The drinking water was all hyperchlorited under the supervision of the water personnel of the battalion aid post. In this sector the front line fire trench was 50 yards from the German lines and stretcher bearers were continually exposed to fire, both shell and machine gun; in carrying out their work. Among the medical personnel there was everywhere a spirit of dogged and even cheerful determination to do the duty they were called upon to do. Discipline was excellent. American medical officers are apparently efficient and well liked.

The return trip was made to the advance dressing station three hours after leaving for the trenches. The commanding officer of the field ambulance, whose M. D. S. we visited, stated that additional personnel from the advance dressing station, including medical officers, was furnished battalion units whenever occasion demanded. He also stated that when an advance was made battalion medical officers did not go "over the top" until after the trenches attacked had been consolidated sufficiently to prevent a successful counterattack; that he might go over with the battalion commander, who usually did not go with his men, but that the field ambulance officer in charge of stretcher bearers usually did go over the top directly after the battalion unit. Battalion medical officers move their stations forward to the front-line trenches from the support trenches when advances are made and only take their equipment to newly consolidated trenches when there is protection in dugouts against counterattacks. Stretcher bearers from battalion units wear the symbol "S. B." in red on yellow on the arm and bring the wounded from No Man's Land to the front-line trenches. It was stated that large numbers of wounded found their own way back to the battalion post during actual battle.

The return trip to the casualty clearing station was made without incident.

ADDITIONAL NOTES

The chest for medicines is known as "the monkey." Morphine in liquid form is carried at the R. A. P., where also three Thomas splints are kept.

The trench latrines were of the pail type.

Rubber boots are provided for all men obliged to stand or work in water. Straps are furnished to prevent excoriation of the feet.

Single-wheel litters are practicable in the trench, but overhead trolley and rail at night are favorite methods of evacuation.

Two of three R. A. P.'s were poorly lighted and protected and were about 15 by 15 feet.

Daily sick call of the battalion was held at the R. A. P.

A. D. S. in brewery cellar. This is the ambulance head. Antitoxin given here and such emergency cases as can not wait an hour are here operated upon. This station only replenishes supplies at a R. A. P. in emergency. The waiting room for patients needing transportation could hold 50 patients in bunks. The personnel of this station was being

used at the time of the visit of this party to dig dugouts, under an Australian engineer. From A. D. S. men are evacuated direct to M. D. S., C. C. S., or rest station. Fourteen hundred have been handled through this station in one day.

Army Sanitary School No. 19.

TRIP TO THE TRENCHES—GROUP UNDER COLONEL WILLIAMS

Accompanied by Majors Lawrence, Wilkins, McIvor, and Bogan

This group was conducted by Lieutenant Colonel Miller, commanding the 46th Field Ambulance.

The party first proceeded to an advance dressing station, badly placed, as it was within a hundred feet of an ammunition dump, near a main road swept by machine-gun fire, and under a church tower which served as an excellent target for German shells. It was in a dugout 8 feet under the ground, and had two entrances, with gas curtains of the usual type. Patients awaiting transportation were in a large house, which was quite comfortable, near by. The station was a very comfortable one and well supplied with drugs, Thomas splints, and a kitchen from which they were serving hot coffee. The entrance was camouflaged and was protected by sandbags. There were accommodations for 24 patients in 3 tiers of litters on racks. There were warming appliances for patients and materials for stimulation, and it was well heated and lighted. The station consisted of three rooms. The dressing room was about 12 feet square; there was another room for the personnel. It was usually reached by autos, which can be sheltered behind several ruined houses. The kitchen, latrines, and waiting room were upstairs, above ground, as the dugout was improvised from a cellar. The kitchen was located directly next to a bucket latrine, and there was a dining room for the personnel. One medical officer and 8 enlisted men were in attendance here. Everything about the place was immaculate. It was 3,000 yards from the firing line.

From here the party walked across an open field to a communicating trench, and through it for about a thousand yards to a relay bearer post. These posts are for the relief of bearers coming down the trench and will accommodate 4 men and 6 patients in an emergency. From here, about 500 yards farther on, was a R. A. P. in a support trench, connected with the A. D. S. telephone. This station is about 20 feet underground. It was capable of caring for 24 patients and was adjacent to battalion headquarters. It had two exits, with the usual double gas curtains at each entrance. This post was to be abandoned shortly for another one farther front which was more commodious. Gas curtains were weighted and there was a vestibule of about 9 feet on a level, between two curtains. Curtains are soaked in solution every second day. There was some gas cases at the R. A. P. at the time. They were treated as stretcher cases and given hot coffee. There were two rooms, one a dressing room and men's quarters and one for the medical officer, 10 feet wide and 15 feet long. Drugs and dressings were few, and the latter were kept in gas-proof boxes. Supplies were kept in small quantities and frequently replaced. Two Thomas splints always on hand. There were four or more litters, blankets, appliances for heating patients, and a small stove in each room. At this station were 1 medical officer and 4 men. The wounded are carried back in the daytime by hand to the bearer post, and from there by hand to the A. D. S., where they are shipped on ambulances. At night they are taken back on the narrow-gauge railroad, if possible, as the narrow-gauge railroad parallels the communicating trench. Bearers are given a ration at the R. A. P. forward, as are combatants, but the R. A. M. C. men to the rear are not, as their work is slightly less hazardous. The latrines in the trenches are of the pail variety and their contents are buried in shell holes at night. The urinal had a splash back. The men are tagged at the R. A. P. and the A. D. S. starts the white "field medical card" carried on the buttonhole in a brown envelope. The battalion water system was under the supervision of a noncommissioned officer and 4 men, who had no other duties.

The latrines left the communicating trench at right angles and were approached by a gallery about 6 paces long, which turned to the right 4 paces and then to the left about the same distance. The pails were disinfected by 5 per cent cresol and were at all times fly proof.

The fuel used up here was coke, which was burned in an improvised stove made of an oil drum.

Sanitation in the trenches seemed very satisfactory. There was no rubbish on the ground, the water was chlorinated, and all garbage was buried in the same manner as feces, in shell holes at night.

The party now passed through a tunnel to the first-line trench, situated 50 yards from the German line. This tunnel was about a thousand yards long, was equipped with electric light, and men were quartered on all sides. Kitchens were found in the tunnel. A section of this trench had been blown in the previous night. There was a small tramway running the entire length, and there were carpenter shops, electrical shops, ammunition stores, quarter-master storerooms, etc. The material removed during the excavation of this tunnel was used to fill sandbags. The tunnel was well warmed. It was noticeable that the trenches were kept clean and in good repair, men being at work upon them constantly. Trench duck boards were installed everywhere. The drainage was excellent, and everything had the appearance of being absolutely clean. The water supply in the trenches was by cart, and it was also piped to battalion headquarters. Antitetanic serum is given at the A. D. S., where the white card giving the history of the patient, to be fastened to his buttonhole, is begun. Men at the front are examined weekly for contagious diseases and lice.

When a new medical officer takes over a station he goes up the day before to check up and sign for the property. He also acquaints himself with the sector he is serving and is given instructions as to water, sanitation, etc.

Trench foot is not so prevalent now as heretofore, owing to the severe disciplinary measures taken. Clean socks come up nightly with the rations. Dry boots are supplied, and whale oil is rubbed into the feet by groups of two, one man massaging the other's feet.

A gas guard of two men is kept on duty at all times, and a Klaxon horn is used for gas signal.

During an attack the medical officer is moved to the front-line trenches and the medical officer at the A. D. S. comes up to the R. A. P. The M. O. of the regiment is in constant touch with the C. O. and goes over the top with him in the third or fourth wave. Listening posts were shown and apparatus for detecting the direction and velocity of the wind explained.

From this place the party returned to the A. D. S., passing a bearer relay post en route, where the personnel had made very comfortable living quarters. At the A. D. S. was a British cemetery, each grave being marked where possible. Here there were dugouts for gas cases, protected by double doors, and the blankets were soaked every third day. Latrines of the bucket type and emptied into a pit every night. Stoves were improvised. At this post two ambulances were on duty, and here the surgeon told us that he believed that every R. A. P. should have accommodations for 30 patients.

From here the party proceeded to the M. D. S., located in a very old building, with dressing room, operating room, and all the equipment of a tent section. A ward for officers, noncommissioned officers, and soldiers, dining rooms for same, kitchen, and latrines of the bucket type; canteen, baths, saddlery, tailor shop, harness-maker shop, and a beautifully kept animal corral, with a transportation park near by. All leather goods were in perfect condition and clean, and the metal parts were well polished. There was a Thresh disinfector, and they were told that by working from 9 a. m. to 9 p. m. they could sterilize a thousand blankets, and that the cost of the machine is \$3,500. The storeroom, carpenter shop, and other dependent buildings were also seen. The operating room was equipped for performing operations of a major character. While arrangements had been made for earing for the patients 48 hours, they were passed to the C. C. S. before that time, as a rule. There was a good drying room for clothing and an office.

GENERAL REMARKS ON THE TRENCHES

The water used was from an artesian well and was pumped up, even to the fire trench, but it was also carried in water carts on narrow-gauge railroad.

Latrines were of both bucket and deep-trench type, but the latter was preferred.

In all gas cases the clothing was immediately removed and new clothing supplied.

The duck boards had a clear space of from 9 inches to 2 feet under them at all places allowing drainage. No broken slats were observed until one got out of the trench proper.

Trench foot was considered a matter of discipline more than anything else.

Medical records: Proper to make at the A. D. S. and M. D. S. In a rush may be made at the C. C. S.

Army Sanitary School No. 22.

VISIT TO BRITISH CASUALTY CLEARING STATIONS

December 15, 1917

The whole class left in four auto ambulances to make a tour of some 70 miles for the inspection of casualty clearing stations.

Casualty Clearing Station 18.—This hospital was of the old type and consisted of double-walled marquee tents. It was pleasantly situated amongst some trees at the side of a canal. It was well parked, laid out with good, hard roads, walks, flower gardens, sod, etc. It was a most cheerful and pleasant looking place, as well as being in the most orderly and neat condition. There was no rubbish, as there were boxes in conspicuous places labeled for trash, for newspapers, etc. Whitewash was liberally used. There were no things left lying around.

A broad road led up to two entrances—one for sitting patients and one on the other side of the road, for lying patients. The receiving tent, grouped for the ambulatory cases, consisted of four marquee tents. Three of them formed a reception room and the fourth was for dressing the cases. At the other entrance was a number of these tents for the reception and dressing of recumbent cases. These tents were double walled, had celluloid windows, and were electrically lighted, as they were dark within. They look like small circus tents, and the union between them was accomplished by lacing the doors together and placing a tarpaulin over the joint to prevent the rain from getting in. They were well heated by stoves. Behind these two receiving departments were 4 lines of wards, consisting of 3 wards of 3 tents each. Two lines were for medical cases and two for surgical. Each ward held 30 bed patients, but by removing the beds and replacing them by stretchers they can be made, with crowding, to hold 50. The wards are joined together by covered passageways, sides of canvas, and roofs of corrugated iron on wooden frames. These wards have wooden floors covered with linoleum. There are two stoves to each ward and they were comfortably heated. The beds were enameled iron, well made up, with good sheets, blankets, and mattresses, and were models of cleanliness and neatness. Each ward had a sitting room and library. There were easy chairs, washstands, and comforts. Each bed had a bedside table. All patients in good-enough condition to be up were required to be washed and shaved before breakfast at 8 a. m. R. A. M. C. men live in conical tents. Fire buckets are kept in the wards.

The tents are said to be much warmer than a hut, but are expensive and can not be depended on to last over one season.

While in these wards we were shown a German litter captured at Viny Ridge. It was joined in the middle for easy shipping, but was heavy and cumbersome. It was a clumsy affair.

At the exit all ambulances stopped in front of a "store" which was kept supplied with blankets, litters, Thomas splints, hot-water bags, etc., to replace those left with patients.

We now saw the building used for the reception of dirty clothing for disinfecting. This consisted of a large drying room, heated by the body of a single-cylinder animal-drawn Thresh disinfecter. The opening to the disinfecting cage was left outside of the building, but the heat for the drying room was supplied by the hot machine and the stack, which was laid across the top under the ceiling. This drying room is used for wet clothing and shoes. The temperature within this disinfecter reaches 240° F. and 40 blankets can be disinfected at a time, or 30 kits. The address of this sterilizer is as follows: Thresh Disinfecting Co., No. 4 Central Building, Westminster, Southwest. It burns 200 pounds of coal a day and is very heavy, but is the best type I have seen.

The kitchens were very clean, walls whitewashed, all stoves blacked, utensils neatly hung up, and only the barely necessary articles were visible. The cooks were uniformed, with white aprons and caps. There are six Soyer stoves, which were simply large caldrons with tops. These Soyer stoves are of Germau origin and have been adopted by the British because they are excellent for soups, stews, and coffee. In addition, they had improvised a range with 16 ovens, 4 double ovens on each side, each oven containing 2 roasting pans. It was made of brick and earth, metal ovens being set in which were part of the field equipment of the old British field ambulance. The floor of the kitchen was of concrete. They gave roast meat twice a week, stew three times a week, and the bread came from the base. One reason why this kitchen was so clean and neat was that the things we usually see hanging around a kitchen

were kept in a separate building outside. For instance, there was a room for cook's clothing to hang in, there was a separate meat safe, and there was a storehouse for all cooking utensils and unused material. Connected with this kitchen by a covered passageway was the dining room, consisting of two marquee tents. This was neat and clean. They had a large tank, which was kept outside the kitchen, for drinking water. An interesting feature of the kitchen was the systematic recovery of all fats. Old scraps of meat were boiled and the fats skimmed off. All the greasy salvage water ran from the kitchen sink over a washboard into a series of grease recovering oil drums. The kitchen was located on the bank of a canal and the fall of the water was taken advantage of to create a siphon system in a series of three cans placed one above the other, into which was led, through pipes, the greasy water. The incoming pipe discharged at the bottom of the can, the outgoing pipe leading to the next can below it, was led off below the grease layer, which formed by solidification of the grease in contact with cold water. This was skimmed off once a day and the ultimate effluent was practically free from grease and clean, and was discharged into the canal.

(NOTE.—This conserved grease was sent to ordnance depot to be manufactured into explosives, and the cooks took a great pride in stating that the amount of grease saved produced so many pounds of ammunition.)

The garbage was given to the farmers, but all refuse not taken away was burned in the incinerator.

The latrines were not far away from the kitchen and were an illustration of how the squatting system could be made the most sanitary of all systems simply by good discipline and cleanliness. The latrine proper was a well-protected shed, facing a clump of trees on the canal and within 20 feet was a Horsfall incinerator. The system is known as the MacPherson. The floor of the latrine was cement. Upon this cement floor were 8 or 10 accommodations for the men who were to use it. These consisted of two halves of biscuit tins placed one behind the other and raised by a block at the center, thus slightly tilting the front one forward and the back one backward. The latter tin contained a square of newspaper a little larger than the floor of the tin. Immediately in front of this system was a urine trough, which led down into a urine pit which I was told would last for months without becoming obnoxious. A man entering would squat over the rear tin and evacuate upon the newspaper the residual urine being passed into the front tin. Toilet paper was provided and after cleansing himself the man arose, emptied the front urine tin, which was kept in contact with the rear tin by a flange bent over backward, and then took up his evacuation by bringing together the four corners of the newspaper, and carried it across to the incinerator, the door of which he opened and casting the material in. All men were required to urinate in the urine trough before defecation. One orderly, neatly dressed, was kept on duty at this latrine to insure its proper working and to keep up the fire in the incinerator, which he did by means of camp sweepings and trash dumped there for that purpose throughout the day. The incinerator needed only two pounds of coke a day to start the fire, and from that time on it was kept up by the camp trash. This orderly was required to compel men to observe all of the details of cleanliness required by this system. If any man failed to do so, he had to do it for him. Consequently the place was a model of cleanliness. The commanding officer remarked that it was a system which worked very well for small commands constantly under supervision but would not do, as a general thing, for large aggregations of troops. He also remarked that to make this system work it was wise to always have a very husky orderly on duty. He recommended it as a very good means of educating the sanitary conscience for disciplinary purposes in small, dirty commands. He stated that a pail was provided in this latrine for men with diarrhea. We were all impressed with the absolute cleanliness of this latrine. There was absolutely no odor about it and the tins were bright and shiny. When they get rusty they can be easily thrown away, as biscuit tins are cheap and plentiful. The boards were whitewashed; tarred paint was used on the outside. Everything seemed to work perfectly. Anybody that can run a latrine like this has evidence of being a good administrative officer. It should be remarked that the orderly on duty was always selected because he was a good man and was paid extra—4 pence a day. Charcoal seems to be the proper fuel to insure the proper running of an incinerator. Near the latrine was a large truck garden from which most of the vegetables used at this hospital came, and farther away was a large athletic field for convalescent patients.

The operating theater was in a frame building, and separate buildings—some distance away, and therefore inconvenient—were used for sterilizing and X-ray rooms. Normally this operating room had six tables, but three had been sent away to reinforce another part of the line by operating teams. It was lighted by electricity, but had acetylene for emergency. Normally three teams worked there, and near by there was a ward of eight tents holding 120 patients. All dependencies of this hospital—pack stores, quartermaster's stores, etc.—were neat and clean.

Before leaving we were taken a few yards away to a railroad siding and given a very practical talk on the method of loading and entraining patients. Ten minutes before the train starts the commanding officer of the train is given a correct list of patients in the following order: Recumbent cases requiring Carrel's treatment, recumbent cases seriously wounded, sitting cases, and cases of mental diseases. Infectious cases are always separated. Cases should be loaded deliberately but rapidly in batches of sixes. Carrel cases are loaded first, then the recumbent seriously wounded, then the sitting cases. One of the chief duties of the entraining officer is to see that no man is put aboard the train who is likely to die en route, as this is considered the greatest crime of a casualty clearing station. We were cautioned to exact of all commanding officers of hospital trains a receipt for documents concerning sick and wounded turned over to him. This siding was used not only for casualty clearing station 18, but also for casualty clearing station 23, 4 miles away and reached by motor ambulance over good road. One hundred complete changes of clothing and equipment are always kept on hand in the pack store.

Casualty Clearing Station 23.—This is run by Colonel Safford. This is of old style and is practically a rest station and a station for ophthalmic and gassed cases. It was not on a railroad.

This hospital, old style as it was, was a perfect model of good administration, cleanliness, and attractiveness. It was situated in the grounds of an old chateau, on a high hill, well wooded, well parked, with flower gardens and hard roads. The grounds were taken care of by the convalescent patients. Colonel Safford called special attention to the fact that the road leading up to the entrance of the receiving rooms for sitting and lying cases should be wide and that only two ambulances should be allowed to move up at a time. They usually came in batches of four. As they moved out of the grounds, after unloading, they stopped at a little storehouse for the replenishment of their supplies, as heretofore noted for casualty clearing station 18, but this should be sufficiently remote so as not to cause any blocking of the road near the entrances to the receiving tents. The receiving tents were grouped in bunches of three. Lying cases were received in five marquee tents joined together. We saw here the admission of a recumbent patient. The clerk who took the "particulars" had a little board strapped to his wrist upon which he wrote. The buff ticket when made out is sent to the office and entered up in the admission and discharge book. The counterfoil or stub bears the same number as the ticket and is pinned on the envelope containing the man's history. All dressing tents are provided with the apparatus for heating litters. In this case the heating apparatus was made of a frame of half hoops, covered with canvas and fitted out inside with electric lights. When a man is very much shocked blankets are laid on the floor, the man is laid on them, and a heavy cylinder placed over him, as this gives a high degree of heat. The head is left outside. In the dressing room of the recumbent side was what Colonel Safford calls his "fire-alarm box." It was the inevitable busenit tin, with the open face sealed in by paper and was affixed to the wall. In this box there were the instruments and dressings already sterilized for such emergency cases as could not wait for the hunting up of instruments and their sterilization. Upon the paper was typewritten a list of the contents of the box, which contains the following articles: Tourniquet, rubber gloves, tracheotomy tube, hemostats, scalpel, scissors, trocar, hypodermic syringes and needles, surgical needles, silkworm gut, dressings.

As soon as this box has been opened by putting the fist through the paper, it is taken down and another box similar to it replaces it.

The preoperating room was next seen. It accommodated 40 to 50 patients, and contained trestles upon which to place the litters. Here the patient was washed up, put into pajamas, and heated.

The next room was the X-ray room; and the next the operating room. This room contained 6 tables with 2 tables to a team. It is fitted up with the Wallace-Cowell operating-room furniture and equipment, all of which can be put on a trailer within an hour. It all fits into light, hardwood boxes with trays, one set above the other, very much like the Globe-Wernicke bookcases. When they go on this trailer they are not jumbled in, but are packed up neatly and can be taken out deliberately. The anesthetic tables and instrument tables are enameled iron with glass tops and the operating tables are folding. One of them was a special operating table, also folding, for abdominal cases, under which a compartment containing electric lights was found to heat the patient continuously while on the table. The clerk who takes the "particulars" of the patient and of the operation keeps an eye out for the valuables, or Dorothy bag, of the patient. He sees that it comes into the operating room with him and goes out with him. In this operating room the tables were supplied with irrigating solutions by overhead trolley, which conducted the bottles from one table to another.

We saw a group of tents set apart for venereal cases and one shed, well whitewashed, with a concrete floor and a central stand with large 5-gallon bottles, from which solutions were piped by rubber tubes to hang over a trough in which patients could take their daily irrigation. This place was immaculately clean, and contained also a table with the equipment necessary for the passage of sounds. The commanding officer stated that he had 60 cases of chronic gonorrhea to help him around the hospital. They were used for the rough work in cleaning up. Everything connected with these venereal patients is separated from the other patients. They have their own latrines, baths, and dispensary. The nearest they ever come to the patients is when they are used at times as litter bearers.

If a man comes in without a "T" marked on his forehead he is given antitetanic serum in the dressing room. Here, also, we heard that morphine was also marked on the forehead. A dose of a quarter of a grain being marked as follows: "M $\frac{1}{4}$." The heating of patients was accomplished not only by the canvas-covered frame with electric lights but also by the Cowell method (blanket litter) and by the half-cylinder hood heated from the outside through a stovepipe under which is placed a lamp.

The latrine here was of the MacPherson type also, and Colonel Safford preferred it to all others. The orderly stayed on duty 12 hours.

Officers had a pail system and were provided with a wash basin and soap and towels.

There were two Horsfall incinerators, and it was repeated here that they needed only 2 pounds of fuel a day and that this should be charecoal, but the chief fuel, of course, was camp refuse.

The kitchen was widely open to the air and was most neat—whitewashed and stoves blacked, and cooks were uniformed with white aprons and caps. The floor was of brick.

A special-duty man was kept as a painter; and he must have been a strong man from the amount of paint that we saw.

A Thresh disinfector of the same type as casualty clearing station 18, and similarly housed and used, was seen.

The pack store.—This is a storehouse in which the clothing is kept, and at least 50 full complements of clothing and equipment were constantly on hand to fit out soldiers returning to the front. The usual method is that when the patient is undressed and put to bed his property is brought by an orderly to this storehouse, marked with the wounded man's name and serial number. If the man is evacuated to the rear, and therefore lost to the division, this property is opened and distributed to the various departments for reissue. This includes his ordnance, rifle, etc. If he goes to duty he presents his receipt for his equipment and gets it back. This includes his own rifle. The rifles are cleaned daily by a P. B. soldier of the line; that is to say, a man incapacitated for duty at the front.

All officers leaving the hospital are required to sign a statement that they have received all of their property brought there.

The quartermaster in charge of this storehouse is not an officer of the Quartermaster Corps, but is always an ex-R. A. M. C. man, a sergeant of long service. Colonel Safford said it was very hard to get these positions, as they were very good ones and were kept for medical department men only.

The wards were made of five marquee tents joined together. They were very neat and in general can be compared with this already described for casualty clearing station 18.

The laundry was given out at the rate of 2,000 pieces a week to civilians. The beds were furnished by the British Red Cross, as were most of the comforts. The wards were provided with chairs, tables, reading and writing materials, etc. There was an officers' ward of 18 beds, with a good stove. They had a lounging room, washroom, and reading and writing material.

Other wards hold 22 beds. Wards were classified into bed wards and stretcher wards. Stretcher wards hold 24 patients.

Another feature of this hospital was the accommodations provided for gas cases. There are wards for their reception for cold weather, but in pleasant summer weather they are placed in a long shed, open on the lee side of the wind and sheltered by burlap at the ends and other side. They hold 58 stretcher cases and 8 bed cases for more seriously asphyxiated cases. All gas cases are treated as recumbent cases and are not allowed to walk. It should be added in connection with the shed for gas cases that the stretchers are arranged in fours, with their heads all toward a central oxygen tank, from which tubes lead off to each patient using the Haldane oxygen apparatus.

In going through this hospital I found in a small room a tiny stove which did not hold half a hodful of coal.

There was a hut built for the ophthalmic cases. This contained a dark room, an examining room, and a room for work to be done on the eye. This was a model of completeness and was furnished not only with modern instruments and appliances but had a good dark room. The hut was supplied with electric light.

Colonel Safford called our attention to the fact that a special examination of each patient is made by the orderly officer before the patient leaves the hospital, and yet again at the railway station to prevent moribund cases being put on.

At this hospital we also saw the usual dependencies, including a tailor shop, barber shop, medical comfort storehouse, etc.

We now visited three casualty clearing stations, grouped, in the Canadian sector. This is going to be a very handsome installment, the largest we have seen, as eventually there will be room for 10,000 patients. Each of four casualty clearing stations holds 2,500. While there were some tents and barrack huts, the Nissen hut was the type used. The site was an unfortunate one as far as the soil was concerned. It was on a muddy plain, and roads had to be made at great cost and difficulty. Duck boards were used between wards because the French object to so many paths. There was nothing to be seen inside, as it was not yet finished; but the arrangement for receiving, operating, and housing, as well as for evacuation, was on the plan already laid down by Colonel Safford. We saw here one of the great advantages of a Nissen hut. It was put up rapidly. This enormous hospital was about finished as far as construction went, and it had only taken six weeks. The earth was banked up on either side of each hut and the wooden floors were flat on the ground, allowing no air space beneath, which made them warm. This entire group was sewered and had a general water supply through piping. Each casualty clearing station forming this group had a separate administration. There were no trees and the place was perfectly bare and unattractive, but the Canadians are building to stay and be comfortable.

Casualty Clearing Stations 57 and 30.—This was a group near Arras. These buildings were of the new type. One of them at least was chiefly constructed of Nissen huts, the other mainly of tents; but both followed Colonel Safford's idea of construction and arrangement, and, while much more stable, did not differ greatly from the others. They are on a hill near a railroad station and yet are centrally located, but there are too many ammunition dumps and repair shops around them to make for safety. They have an electric lighting power in common. It was rather late when we reached there, and for this reason we were unable to see everything which we might have seen if earlier.

The capacity of these hospitals is a thousand apiece. The only difference in the plan of admitting and discharging patients was that at these hospitals the entrance and exit were at the same end. The marquee tents very well by the commanding officer. The marquee wards hold 44 patients, while the Nissen huts hold 20, but the cost was tremendously in favor

of the Nissen huts. The Nissen huts were rather hard to heat. In one of the wards a cement heater of our "Franklin" type had been built by the engineers and seemed very good. Officers' wards were lined with tongue-and-grooved lumber, which is painted. They had wooden floors. There was linoleum on the floor, and all wards were models of cleanliness and comfort. It was noticed that some of the Nissen huts have a ventilator running the length of the building, with louvred windows, while others have windows cut in their sides. If beds are taken out they will accommodate 30 litter patients on the floor. The main object of having these casualty clearing stations grouped is because the chief function of a casualty clearing station is to reduce the number of patients to be transported and to keep men at the front. It was noticed that the end ward tents had two end rooms—one for attendants and one for urinals and bedpans and ward utensils. Some of the Nissen huts had 24 beds. All wards were well heated.

There was a dental department in Casualty Clearing Station 57, and it was well equipped. Royal Army Medical Corps men were located in conical tents with boarded floors, 8 to 10 men to a tent. A few barrack wards were found with 40 beds, and a stretcher ward contained 60 of the same type. The baths were excellent. There was always an undressing room and a dressing room, and hot water was obtained not from the "secours-aux-soldats," but from an iron boiler in a stack of the same general pattern but more solid. They had a tank for cooling the water and preventing it being turned on too hot. The baths, hot-water heaters, and sterilizers were all under the control of the quartermaster, who was here, as in the others, an officer of administration appointed from among the old sergeants of the Royal Army Medical Corps. The bathroom had 12 spray heads and a thousand can bathe in two hours, we were told. Each shower head is large enough for four to get under at once. They make a drill out of it. Men stand under the water for a minute, then soap themselves for a minute, then wash off the soap another minute, then they get out and dress. Their clothing is disinfected as heretofore described. We were told that the Infantry in the British Army has a bath and a change of clothing here every 8 to 10 days. At both these hospitals separate baths for officers and for skin cases were kept.

We saw tubs, basins, and shower baths in this hospital. The bucket system with fly-proof top was here used, and all camp refuse and feces burned, but the commanding officer preferred the deep pit, as in this soil it works very well, there being much chalk. They do not care much here for the MacPherson type. At these two hospitals defaulters were required to do this sanitary work, such as emptying pails. Other sanitary men get 4 pence extra per day, but only supervise.

The laundry was washed by civilians with portable equipment.

The arrangement of the operating room in both of these hospitals was by means of Nissen huts. A plan is appended giving the main features, Figure 14. It was lighted and ventilated by a louvred ventilator running the length of the building. It was well lighted with electric light, and there were good closet room, instrument cabinets, hot sterile water in wash basins, with racks for solution bottles, etc. It was lined with tongue and grooved lumber and painted with white enamel paint. There was linoleum on the floor, and they were models of cleanliness. Surgeons of teams here operate 12 hours, spend 4 hours visiting their cases, and sleep 8 hours. At both these hospitals there were 12 tables for six teams. They count upon two teams for every 100 admitted. They keep 3 medical officers in the reception room and dressing room, 2 in the resuscitation room, and 1 for entraining. Same system of taking care of the kit and reissuing was observed here as hereinbefore described. Cases are always redressed for evacuation. Personnel for the ward is 1 nurse and 3 orderlies, but in a push this has to be doubled.

The steward storehouse was really a commissary storehouse with additional medical comforts, such as port wine, canned meat, olives, fruits, etc. None of the latter articles were for sale. It was very well supplied. The officers, nurses, and servants (soldiers) are all messed alike. The waiters are all enlisted men. The noncommissioned officers have a separate mess hall, bath, and rest room. The kitchens were excellent, the best we have seen yet. The lavatory was all whitewashed and black painted. Absence of things lying around. Soyer stoves used.

In Casualty Clearing Station No. 30 we saw the Nissen stove. It was constructed of corrugated iron with interior oven. It will bake for 500 men and needs 120 gallons of water

a day. The floors of this kitchen were cement. The oven was of brick, with sheet-iron sides. There was a special sink with grease traps on the plan hereinbefore described as the Jacobs grease trap, and the water runs out clear into the ground. The incinerator here is used to heat water which is utilized in the kitchen, 4 pounds of charcoal used for the fire a day. One side of the kitchen was entirely open to the air. There was a large Thresh sterilizer here whose heat was conserved to heat the drying room.

We saw in the other hospital a kitchen with two ranges which supplied hot water by coils which ran through the improvised ranges to be used for ablution benches and washing water in the kitchen. There were also 10 Soyer stoves here. The capacity of this kitchen is 500 meals at present. There was a carpenter shop, tinsmith, barber shop, etc., as in other casualty clearing stations.

The two hospitals had one radiologist and one laboratory in common. Gassed cases were in a separate ward. They all have to be warmed because they are very anemic.

Army Sanitary School No. 31.

SICK WASTAGE

By Captain Parkinson, December 11, 1917

In the good old days the division sanitary personnel moved with the division. This made a break in which sanitary conditions were more or less wiped out every time the division left a sector until the new incoming division had adjusted itself. To remedy this the army areas are now divided into sanitary areas which have the same sanitary personnel at all times regardless of the division surgeon who may occupy the area. Indeed the area may take in terrain occupied by other divisions, and even other corps. All these sanitary areas in each army are under the sanitary A. D. M. S. for the army. He is not a corps officer. This is a good system because it keeps the area under the same officer, who has about the same responsibility as a civil health officer back home. In 1914 there were 17 officers in the sanitary department and now there are 200 of these officers and 2,000 of other ranks. Each corps has a sanitary section manned by army troops assigned for duty with the corps. It was the constant change of divisions that led to this area sanitation, as well as the bewilderment of the civil population, who, after seeing contradictory ideas of incoming sanitary officers, lost interest in cleaning up. The sanitary officer is by no means always a doctor. He is often a sanitary engineer. Captain Parkinson strongly deprecates excessive letter writing. He states that the whole matter of sanitation is one of individual effort anyway, and a sanitary officer should not merely come up and "look at things" when something goes wrong, but he must do something to remedy it. It is necessary to have good none commissioned officers as inspectors, and to praise them where for any successful effort praise is due. There must be constant supervision of the sanitary area. The sanitary officer should get the sympathy of his commanding officer. If he doesn't he has failed. He must get to know the men, especially the none commissioned officers, and work not only on their sympathies but on their pride.

Food dumps.—These are raised platforms for supplies at the rear, but toward the front and on the marches the food often has to be dumped on oilcloth spread on the ground. Food must be looked after personally to see how it is handled. Food should not be condemned en masse, but only the parts of it which are unfit. Don't condemn a whole carload of cans of milk because one can is bad; try to salvage all you can. As a matter of fact most epidemics of intestinal diseases are due to civilians. The storehouses of food should have correct ventilation. The doors should be flyproof. The bread should be put on racks and meat should be kept away from other food in meat safes, protected against flies, vermin, and animals. It is just as important to protect clean food as to attend to garbage disposal.

Cookhouses.—It makes no difference how close a cookhouse is to a latrine, provided the latter is clean and fly proof. It is better to have a battalion cookhouse than company cookhouses. It is more economical, there being less wastage, and can be kept clean better. There should be 12 additional pairs of overalls to allow of frequent washing and change in uniform. The medical history of cooks should be kept and care should be taken that they are not carriers of typhoid, paratyphoid, or dysentery. Keep the kitchen clean without the

use of lime, but whitewash the walls constantly in order to make it look the part. Don't have a lot of truck lying around—boxes, cleaning material, rags, dirty cans, waiting until some one has time to dispose of it or some use comes for it, and all that sort of thing. Only have the utensils out that are absolutely necessary for constant employment. Especially look out for the officers' cookhouses. The cookhouse should have impervious floors and metal receptacles should be on hand, one for empty tins, one for solids, and one for liquids. It is well to have tins for scraps of meat and fats. There is no excuse for a cook being dirty if he is allowed enough clothes to keep clean. You should see that there is a variety about the food. Don't give the men stew every day. Save the fats from waste meats and the grease from greasy water. Enough fat was saved from this source last year to provide 10,000 rounds of cordite ammunition. Above all, do not allow the men to keep their personal equipment in the kitchen. A cook can serve 250 men with 4 or 5 pounds of coal daily. Meat blocks are better than tables because they can be kept cleaner and there are no cracks for meat to rot in. Wooden-handled knives and forks are a positive danger and should be tabooed. Bread 10 to 12 days old, if warmed in a damp cloth, will be fit to eat. The rolling kitchen is excellent—cooks for 200. One should always avoid jumping on the transportation corps any more than possible. They have their troubles.

Diseases.—The greatest cause of sick wastage is reduced vitality from overwork and poor food, constant cold, and insufficient sleep. It is an ill-conceived idea of a commanding officer that troops to be efficient should do arduous service and be deprived of comforts and necessities. This is not the time nor the place to weed out the unfit and the wise commanding officer will endeavor to keep all his men and not only select few who can rise above his silly selective processes. It is vicious to get men up before sunrise, give them their breakfast in the dark, and start them out in the cold morning mist, chilled, underfed, and usually with wet clothing, to do an arduous day's work, terminating again in cold and wet. Such men, after supper, with clothes still wet, even have lectures running into the night. This is called "intensive training."

At the outset we should recognize that the allied armies are composed of troops from many countries, who generally bring their diseases with them.

At the very head of diseases that actually cause loss of efficiency is scabies and its frequent sequela, impetigo. It is a very bad thing to have scabies started in a command. The men are shunned who have it, and this breaks their spirit. Old cases are apt to end in impetigo (I believe that this name should be changed to ecthyma). Scabies is mainly spread by blankets, which should be regularly disinfected for all the command, and dry heat will get rid of it. The Thresh disinfector is not the best way to disinfest blankets, and dry heat is preferred. Now impetigo means a loss of from 10 days to 3 weeks at the base; and scabies means a loss of good 50 per cent of a man's efficiency from loss of sleep by itching and scratching. By far the most serious ectoparasite is the one causing the last. Nearly all cases of pyrexia of unknown origin (p. u. o.) are accompanied by lice. This p. u. o. is a serious cause of sick wastage among the English. In fact one should look upon the louse as a winter pest and danger as we look on the fly in the summer. The disinfestation of clothes for lice and scabies with dry heat is accomplished at 60° C. for half an hour, and the plant should be attached to the baths and the men's clothing disinfested while they are bathing. At this bath there is a noncommissioned officer of the Medical Department, trained to recognize scabies, lice and the leading points in skin diseases, and he notes the name of any man whom he thinks ought to go before the medical officer. Scabies should be isolated. The bathing facilities ought to be good and they should be divisional. Bathing should be made a parade.

Intestinal diseases.—Ninety per cent of the British are inoculated against typhoid fever and paratyphoid, but such inoculation is unfortunately not compulsory. The Germans inoculate for typhoid fever and cholera every six months. In the British Army last year there have been 33 cases of typhoid out of 250,000 men. The mortality is low—1 to 30. Typhoid fever epidemics amongst civilians have often been a source of serious alarm amongst the British. Vaccination of them ought to be compulsory. Captain Parkinson considers the typhoid is usually spread by carriers. He also believes that it lives in water three weeks (which I do certainly not believe). The water detail is composed of 1 noncommissioned

officer and 4 men of the Royal Army Medical Corps. They hypo the water and leave it stand all night, but it is necessary to remember that the hypo should be kept in a dry place and kept dry.

In running the water-cart system do not use the rule of thumb in doing the hypoing, but establish the dose of bleaching powder in test by the Horrick apparatus. A water detail should never be changed and should be examined to see whether there are any typhoid, paratyphoid, or dysentery carriers. The cart should be cleansed before adding the water to be chlorinated. It should stand every night for use the next day.

Typhoid inoculation is compulsory in the Canadian Army.

Dysentery.—Amebic dysentery is rare, but there were 188 cases of Shigo and Flexner in six months in this army. To avoid Flexner and Shiga dysentery, when men go into a place where the water can not be properly sterilized they are given each a bisulphate of iron tablet to drop into their canteens, and thus sterilize their water. Dysentery, in fact, causes more trouble than typhoid fever.

Captain Parkinson has tremendous faith in the use of portable laboratories and strongly recommended them.

Better sanitation has left its mark on the infant mortality of France, which has decreased in these parts of the country occupied by the English.

Other infectious diseases.—The exanthemata; one rarely finds it necessary to quarantine suspects, but instead of this they are examined every day between the eighth and fourteenth day after contact. In diphtheria and cerebral spinal fever three swabs are taken before discharging the patient. The Levick spray has not proved itself to be of any value, using chlora-mines T in the case of mumps. In fact, in a case of diphtheria, it had produced no effect at all on the bacteria after five exposures of the carriers to the spray.

Trench foot.—This is largely a matter of discipline. The cause is constant standing in wet, and impaired circulation. Twenty-four hours is the limit for a tour of duty in a water-logged trench. Gum boots are useful when actually at work in the trenches, but they are to be used only for this purpose and are to be removed when the necessity is passed. Rubber boots are not suitable for dry cold.

To prevent trench foot they wash the feet frequently, dry them, and rub in whale oil. This massage is the chief thing. Every man should be required to carry an extra pair of dry socks, and in addition to this dry socks are sent up with the food to the trenches. There is sick wastage for trench foot and it has been as high as 0.765. Dry socks should really be put on twice daily, when boots should be removed and toes exercised. When the feet are cold, heat should be avoided. Feet should be kept moving all the time, the shoes two sizes too large and kept as dry as possible. Puttees should not be worn. The powder used for trench foot is as follows: Potash soap, 300 pounds; camphor, 32 pounds; sodium borate, 35 pounds; talcum powder, 500 pounds. The trenches should be well drained and kept so.

If trench foot develops in a command the commanding officer has to be grilled on the following questions, in the form of a report which he makes out every time for each man acquiring trench foot.

1. Frequency of baths.
2. Frequency of changes of socks.
3. Length of time on duty and where.
4. Condition of trenches.
5. Efforts made to improve trench conditions.
6. Reason for failure to attain improvement.
7. Were unfavorable conditions reported? If not, why?
8. With what result?
9. Condition of dugouts.
10. Condition of other men of platoon.

This army evacuated in 1915-16, 3,311 trench feet. In 1916-17 there were 395 evacuated for this trouble. This is due to better care of the feet and better trenches. One should remember always that in the case of trench foot you should use antitetanic serum.

Army Sanitary School No. 33.

LECTURES

By Lieut. Col. W. L. Keller, M. C., United States Army, commanding Hospital V. R. 76.
December 4, 1917

Class took 7.10 a. m. train, Gare du Nord, for Ris-Orangis to visit Hospital Complementary, V. R. 76, commanded by Lieut. Col. W. L. Keller, M. C., instructor in war surgery of the Army Sanitary School. Arriving at 8.30 a. m., they were met by Colonel Keller and conducted to his hospital.

It is of brick, of five stories, architecturally agreeable to the eye, and surrounded by extensive and well-parked grounds. It is provided with electric lights, piped water supply, and central heating, and compares favorably with a good type of Paris hospitals. The arrangement of wards, operating rooms, etc., was good, and the neatness and cleanliness of the institution was striking, as was the provision made for comfort of patients and for the necessary medical and surgical supplies. The staff was sufficient but not top-heavy. The nurses were English speaking as a rule and everyone had his or her duty cut out, and the director generally saw to it that this duty was rapidly and efficiently performed. The administration of this hospital was excellent.

The hospital was one of those special surgical hospitals of the French for the treatment of complicated fractures and was formerly under Doctor Blake, of New York. As a matter of fact, 100 per cent of the fracture cases were infected when they arrived, generally in quiet periods, from the hospitals nearer the front and in time of activity from the battlefield sanitary units. Hence the director received his cases from two weeks to two months after receipt of their injury, or, in time of activity, from several days to two weeks after an advance. There were some 200 patients at the time we made our visit, some of which were convalescing from fresh wounds received in a recent push. The normal capacity was 450. All were French, in excellent general condition and high spirits, and it was noticed that they had the most profound respects for Colonel Keller. Most of the cases were handled by front-line organizations before they reached Colonel Keller, and they appeared to be either exceedingly serious cases of compound fractures of thigh, arm, hip, and shoulder, or they were serious cases unsuccessfully handled in less elaborately equipped hospitals.

There were a very few details worthy of special mention which concern the general administration of the hospital. The arrangement for washing ward utensils was unique. On each floor in the corridor and in full view of passersby there were slop sinks, capacious and clean. Overhead was placed a short hose with nozzle and stream of water sufficient in itself to dislodge material which had adhered to vessels. All patients had attached to their histories, on a board upon the bed, a drawing or tracing of not only the last X-ray picture made, bringing out clearly the position of bones, fragments, and bits of projectiles, but of all previous ones. The clerical work connected with the case is done chiefly in the wards. It is not too much to say that Colonel Keller knows everything that goes on in his hospital at all times, is familiar with the daily condition of each patient, and is tireless in his efforts to get the most out of the machine. It was interesting to hear him describe himself what, after all, was the secret of his success:

"The surgeon, being the party responsible, must not only order things done, but he must see that they are done properly."

THE FRENCH SYSTEM OF EVACUATION

In general it differs from the English, "a horizontal system," in that its control is vertical; i. e., the wounded man is under the same supervision from front to rear, from start to finish. Colonel Keller evidently believes in the famous French "triage," so bitterly criticised by many of the French surgeons who have to use it at the front.

THE GENERAL TREATMENT OF WOUNDS OF WAR

All war wounds now can be considered to be infected. Consequently the earlier we attack a contaminated wound, the less chance there is of subsequent infection. The chemical sterilization of wounds in war was until recently all we possessed to not only combat the danger of infection, but the infection itself. To-day we accomplish by means of excision of

the tract of the projectile, removal of foreign bodies, and subsequent primitive suture in wounds of soft parts what until now was accomplished by débridement and Carrel's irrigation of the open wound in an intermittent current of the hypochlorite solution of Dakin. But primary suture can thus be accomplished only before real infection has begun; i. e., before 8 hours have elapsed after the receipt of the wound. After 8 hours up to 12, such sutures are exposed to failure from infection and after 12 hours Carrel's method must be adopted. If primitive suture is applied, the patient must be kept in the hospital where it is performed until two weeks have elapsed. To transfer them before subjected them to great danger of failure to avoid infection.

The primary suture of wounds is only practicable when they are received in small number and within the first 10 or 12 hours. The primary suture retarded can be practiced when they are received in large numbers; that is, during a big offensive. In this case, the wound is excised, all foreign bodies removed, and a flat dressing applied. The patient is then ready for transportation to the other formations in the rear where he can be sutured on the first, second, third, or fourth day without further sterilization. There are some cases on record which have been done as late as 24 hours with considerable success, but that delay should be avoided.

After the battle of the Aisne, 30 per cent of the men suffering from wounds of the soft parts were given 10 days' leave, 32 per cent three weeks' leave, and 38 per cent two months' leave, and so all these men returned to their regiments in a short time. All wounds that had not been excised within the infective period were subjected to progressive sterilization and secondary suture practiced. The great majority of these wounds can be closed and a large proportion can be so reduced in size as to decrease the dressings and discomfort of the patient. Secondary suture is usually performed after a bacteriological examination of the discharge shows a count of 1 organism to 3 to 5 fields, or a pure mucoid discharge for five days when laboratory facilities are not at hand. The superficial carpet of granulating tissue with the cicatricial margins is usually excised in one mass, the wound is undercut, and an effort is made to bring the underlying surfaces in correct anatomical position by a modified figure-of-eight suture which lowers the tension and allows perfect apposition of the skin and in many cases, leaves a movable scar.

The use of catgut is to be avoided in these cases, for if it should become necessary to use Carrel-Dakin at a later period it is immediately dissolved and fails to hold the structures in place. Colonel Keller states that few skin flaps die from lack of arterial blood supply, but many from venous congestion, and consequently he makes multiple stab wounds in the skin to reduce the tension and provide additional drainage.

He laid special stress on the use of methylene blue as an aid to map out the sinuses leading to sequestra and, in some cases, to projectiles with discharging sinuses.

Fractures of long bones.—The main point is in securing traction from the first and sustaining it until union takes place. The possibilities of primitive and retarded primitive suture, reducing infection in compound fractures, is giving promise of great success, but great care must be observed in the débridement to spare as much bone as possible when there is great loss of substance. Any bone attached to the periosteum must be left to bridge over the space which would otherwise result in a pseudoarthrosis. In these cases the sequestra can be removed by operation at a later date if necessary.

In fractures of the long bones, Depage starts immediate progressive sterilization with Carrel-Dakin as soon as the wound is excised, and his success has been beyond all expectations. Before secondary bone operations always give antitetanic serum.

There are in France 168,000 men who are walking around with sinuses at the present time, four-fifths of which might have been avoided if progressive sterilization had been started.

The Thomas splint, or some modification, is the one which seemed to be most used for traction purposes, and a demonstration was made of the splints which are commonly used to-day.

No. 1, Thomas, most used; the padded ring fits well into the gluteal fold, and counter-extension is secured against the tuberosity of the ischium. A long rod of iron descends on the inner aspect of the lower extremity, passes under the arch of the foot at some distance,

forming like a stirrup, ascends along the outer aspect of the lower extremity, both ends being fixed in the rim of the ring. An anklet over the shoe is attached to the stirrup and tightened with the Spanish windlass to get traction during transportation. A cradle is formed by a double bandage passing under the extremity, two under the thigh and two under the leg, and a fifth one passing under the flexure of the knee. The latter must be taught to secure a slight flexion at the knee.

No. 2, Blake splint, easily applied as it does not have to be threaded over the limb, but it gives more or less uncertain traction during transportation as the screws of the sides are jarred loose when the splint is bent. Rights and lefts are required.

The Keller splint, or half ring hinged to set an angle of 55° and padded to rest against the ischial tuberosity. It has the following advantages: Small cost, easy to transport (10 of these splints can be in the same space as 2 Thomas splints), it is easily applied, and can be used for either right or left extremity.

Thomas arm splint, used mostly for transport.

Jones humerus traction splint, is a padded half ring which permits extension of the humerus with flexion of the elbow.

Jones crab splint, mostly used for holding the hand in dorsi-flexed position as in cases of wrist drop.

Posterior wire splint.

Hodgens splint.

Sinclair's modification of Thomas arm splint.

Ladder splint.

Wallace splint.

Spinal splints.

Plaster of Paris is not much used and seldom advocated in the fractures of war wounds owing to the possibility of gas infection escaping detection in the area covered. Wooden splints are also supplied to be used in emergency for fracture cases. When a patient with a fracture of femur or humerus reaches a well-equipped hospital where he is to stay, he retains his Thomas or Jones humerus splint, but the hospital exchanges a similar one for that applied to his limb. The Spanish windlass is removed and traction is procured by the lateral strips on the sides of the limb, or adhesive plaster, Heussner's or Sinclair's glue being the two favorite preparations used to attach the flannel bandages to the limb. The strips are attached to a small perforated board, which in turn is connected with the rope and pulleys as described in the Splint Manual issued by the medical board of which Colonel Keller was president.

All cases of overriding fractures of long duration and without consolidation are immediately put on sufficient traction to paralyze the contracted muscles. This varies with the individual and the condition of the limb, but 20 to 35 pounds for the first 8 to 15 hours, accompanied by morphin or codein to relieve pain, will result in complete relaxation in many cases. In those cases which are not improvable by this method, a tongs or a Steinman pin for traction from the knee is used. Great care must be exercised with some patients in regard to the ligaments of the knee joint, as excessive weight will injure them about the third week in many cases.

After the traction has resulted in bringing down the fragments to normal position, they are easily maintained by a weight of 15 pounds in the average cases. All patients in apparatus are X rayed by a portable machine as often as is necessary to convince the surgeon that the fragments are in good apposition. It is not necessarily a cabinetmaker's approximation, as the main object is to strive for alignment and a plumb joint that will give a good functional result even if there is some deformity at the seat of fracture.

In going through Colonel Keller's wards, the application of all these splints was seen. Each bed had its elaborate frame, making a forest of rings, ropes, pulleys, and crossbeams. The apparatus is so arranged that the patient can move himself in bed in almost any direction with great ease by a handgrip. The weights and counterweights and ropes leading through the pulleys enable the limb to be swung in mid-air, thus permitting easy and rapid dressing of wounds with a minimum of pain.

Many cases of fractures had united in bad position before being admitted. These cases are not interfered with for several months and until all infection has disappeared, and

then only after administration of tetanus antitoxin before any operative procedure is instituted. In many cases of compound comminuted fractures any effort to bring the bony ends in position may result in tetanus, gas gangrene, or metastatic infection if attempted during the active stage.

Sequestrectomies are often performed in these cases when the wounds fail to heal after prolonged use of Dakin's solution.

One point emphasized by Colonel Keller in this demonstration was the great importance of early traction from the time the man is wounded, and this can be accomplished by a Thomas or hinge splint, which we hope to have at all places close to the front, as well as in a certain proportion of ambulances.

The most important part of the after treatment of fractures is the daily movement of the joints, but not necessarily movement to a degree that would cause the inflamed muscles in the vicinity of the fracture to be irritated by motion over the infected areas. Muscles of the limb are massaged, tendons are moved within their sheaths, all having one object in view; that is, of preserving a muscle from the degeneration of disuse against the time when it must move the joint in the vicinity of the fracture, and this is only possible by daily massage and motion.

Joints.—In fractures involving the elbow joint, after the foreign body has been removed, mobilization is now practiced instead of immobilization, and this is immediately started after the patient comes out from under the anesthetic.

The same treatment applies to the knee joint where the destruction has not been too great, and Wilhelm has procured exceptional results in even extreme cases.

Special fractures.—Femur: The mortality is exceedingly high in fractures at the neck of the femur, and few of these cases reach a base hospital. They should be usually treated by extreme abduction and suspension. Subtrochanteric fractures also call for extreme abduction and traction (as well as abduction of the other limb).

Fractures of the shaft can be treated by traction and suspension, and the amount of abduction used is very slight, but this depends on muscular injuries and exact location. The Hodgen's splint or straight splint can be also used in these cases. In supracondylar fractures of the femur the displacement is such that it may be more easily controlled by a double inclined plane and a Steineman pin if infection is not too great; if the infection is severe, a straight pull without flexion may be necessary to avoid gravitating of septic material through the muscular planes into the upper part of the thigh.

Fractures of both bones of the leg are usually treated in a Hodgen's or in a straight splint, with traction by lateral bands attached by Heussner's glue. The foot is maintained at a right-angle position by a strap going from the sole to a pulley which holds it at proper angle.

Fractures of one bone of the leg are treated in the same manner.

Humerus: Treatment of the surgical neck. The right-angle abduction of the arm is practiced in the treatment of these cases, the line of traction being that of the latissimus dorsi and pectoralis major, which makes it in the axis of the limb.

In fractures below the insertion of the latissimus dorsi and pectoralis major, or above the deltoid, traction and suspension with abduction is used, but the degree of abduction is reduced.

Fractures of the middle third require little abduction and can be treated by direct pull in the axis of the limb with a cuff at the elbow or lateral straps attached by Heussner's glue; 5 to 6 pounds is the maximum weight.

Supracondylar fractures are usually treated by pull in almost the same axis; little abduction is required.

In fractures of the middle of the humerus, after healing is complete, they can be treated with the Jones's humerus splint with the greatest satisfaction.

Forearm: Position depends on location of fracture of either bone. Fractures of both bones with infection is usually treated in supination with extension.

Shoulder joint: He advocated saving the head of the humerus, or as much of it as possible, as in cases with comminuted fractures he procured good results from ankylosis to the scapula at right angle. This allows full play and a greater range of motion of the shoulder. He showed cases of resection of the head which left the patient in almost a helpless condition.

In conclusion of the remarks on the fractures, Colonel Keller made clear that bone grafting should not be attempted as a rule until one year after healing of the wound. This, of course, applies to infected cases, and regardless of this statement, he showed 4 successful cases of bone graft in the hospital treated in a shorter space of time. He also mentioned the futility of bone plating in early pseudoarthrosis, where the ends brought together usually fail to unite, owing to the absorption of the upper end of the distal fragment.

Special surgery.—Colonel Keller's experience was by no means limited to fractures. Many wounds of the chest and severe wounds of muscles, nerves, and, in fact at times, most other parts of the body complicated these fractures. His remarks on surgical conditions in certain regions included the following:

Brain and skull: Previous experience of operating at the front in all injuries of the skull and brain, especially by those not trained for this class of work, has led to more conservatism. Decompression is no longer looked upon as a cure for all brain conditions and is avoided as an early procedure in infected war wounds of the skull, except in progressive hemorrhage or when the X-ray leaves no doubt as to the real operative indications. Do not transport grave cases; use local anesthetic if possible. Sitting posture when practicable except in shock. Remove only superficial projectiles and bone débris which are easily reached. Through and through wounds of the brain, drain with rubber tissue; never with gauze.

In fractures with injury to the dura, no foreign body present, early excision to sterilize wound should be limited to the removal of contaminated tissues. All cases that may be due to edema incident to the traumatism of a high-explosive missile should be treated conservatively and no extensive work should be done except at a properly equipped hospital with X-ray facilities, a surgeon who has had special experience in this line of work, and the services of a neurologist at his call.

Chest cases: Chest cases are treated in the semisitting position except when there is extreme shock. It is generally considered that the sooner a wound is relieved of its infection-carrying agents, the better; i. e., clothing, missiles, blood clots, the latter being a suitable media for the growth of bacteria. Excise tract, clean wound, remove foreign bodies easily reached, and reset fractured ribs; sew pleura, muscles, and skin when possible; if unable to close pleura, muscles and skin when possible; if unable to close pleura, close muscles; if unable to close muscles, close skin; if unable to close skin, close with gauze as it lessens shock by steadying the mediastinum and permits the sound lung to functionate normally. The mortality is much lower with early closure; in 99 cases where the pleura was drained, 50 per cent died; in 57 cases completely closed, 29 per cent died.

Group "A": (1) Entrance and exit bullet wound; (2) entrance and exit wound (shrapnel ball); (3) wounds caused by small fragments of high-explosive missile. These cases do well when treated conservatively; results good.

Group "B": (1) Wounds caused by large irregular fragments of high-explosive shell which have lodged in the thorax and carried in clothing and other infected material into the cavity; (2) tangential wound of the thorax, enfilading ribs and driving portion of bone into the pleura and lung; (3) entrance and exit bullet wound—exit explosive in character.

Group (1) needs immediate radical surgical procedures as close to the firing line as practicable; (2) and (3) more frequently developing hemothorax or pyothorax, can be drained later.

Hemothorax: Some cases bleed freely for many days, whilst others go on fighting; rest in bed; do not aspirate for two weeks as hemorrhage would recur.

In the large sucking wounds of the chest, the shock is great and the wounds should be closed in every case if possible for the reasons already stated. Always keep patient under observation for two weeks after operation. If empyema develops, treat by the Carrel-Dakin method until the bacteriological count shows but 1 organism to from 3 to 5 fields and then close.

Abdominal operations.—No class of surgical work taxes the judgment of the military surgeon more than a decision as to the proper procedure to be followed in abdominal cases. Symptoms are unreliable; surgeons differ as to results of operation; many patients are beyond help of surgery when they are first seen. Of those in a condition where operation might be beneficial, some would recover if left alone; and whilst the tide might be turned

in a broad proportion of cases by operating, the patients also might die from shock incident to operative measures. In many of these cases operated upon during this war, it was perfectly evident that men died from shock, as there was no sign of peritonitis at the post-mortem, and consequently deciding when to refrain from operating in such cases taxes the discretion of the ablest surgeons.

Wounds of the middle section of the abdomen are much more fatal than those of the lateral, and those of the umbilical more than those of the epigastrium or hypogastrium.

Wounds of the liver frequently call for surgical interference in cases of hemorrhage. The same may be said relative to the kidneys and spleen.

Stomach.—Prognosis in stomach cases when the organ is empty is often good when treated by conservative methods. In wounds of the duodenum and colon, the prognosis is better as the paralytic distension met in wounds of the ileum is not encountered. Colostomy is frequently necessary in wounds of the rectum and cecum. When possible, close abdomen after operation, do not drain, do not operate after 36 hours.

In thoraco-abdominal wounds, make incision over the wound; section the ribs down to diaphragm and incise diaphragm to the point where missile has passed through it; remove foreign bodies and suture abdominal organs which have been injured; remove all clots in pleura, dry cavity and close without drainage; less shock than in the double operation.

Tendons.—Unless prompt massage is instituted, there is danger of fibro-fatty degeneration of muscle and adhesion of tendons to sheaths.

The class was now shown a large number of X-ray plates and received a lecture on the method of rapid localization of shell fragments by Mr. Gage.

Army Sanitary School, No. 36.

VISIT TO MOTOR AMBULANCE CONVOY, RED CROSS DEPOT, STATIONARY AMBULANCE 39, GENERAL HOSPITAL 70, AND THIRD CORPS MOBILE LABORATORY

MOTOR AMBULANCE CONVOY

This consisted of 50 ambulances of the usual type, 2 truck repair shops, 1 field truck, 4 motor lorries, and 7 motor cycles. There was a captain of the Medical Corps in command and an administrative officer in charge of the repair shop. There were 129 men, mostly Army Service Corps. There are three of these convoys to each army—one to each corps and one in reserve. They are usually divided into three groups and thus they serve groups of casualty clearing stations under the orders of the commanding officer of the ambulance convoy who has the location and name of the driver of every car under him. The method of keeping track of the cars is ingenious. There are boards hung up on the wall with hooks. The number of the car and the name of the driver are painted on a clothespin, which is placed on the board corresponding to its location; that is to say, for every date the whereabouts of a certain ambulance is on that board in its place. If in the shop it will be on the board corresponding. The cars are sent up as needed to the sections they serve, and their runs are sometimes long. They never travel in groups of over three owing to danger from shell fire. The cars are in excellent condition. The repair shop repairs all breakdowns, as well as tires and tubes. The machinists are experts and they state that they can repair any car within six hours no matter what is the matter with it—a general statement which, while it may not be exact, shows that they can certainly promptly handle the ordinary repairs needed. This is greatly facilitated by having one type of car and spare parts for same. There were several cases of broken axles being repaired while I was there. There is not much breaking down of cars, as the men are very careful with them and they are kept immaculately clean. No car is allowed to stand muddy, either here or elsewhere. They are free from scratches and always look as if brand new. The men are quartered in Nissen huts where there is also a small dispensary for them and a medical officer. Here, also, an improvised Turkish bath had been rigged up by the men themselves. This organization was very alert. There was a good deal of work done in the office in keeping track of cars and official correspondence, but all of their records were kept in boxes, in which they were packed, and they stated that they could get out of the place with all their records in half an hour. This headquarters is 26 miles behind the line at ———. This organization had a place for amateur theatricals.

The power and light for the repair shop come from a dynamo run by one of the machines.

THE RED CROSS DEPOT

This is in the Army area near an old church in a quiet town, occupying several buildings and filled with tons and tons of supplies. There was a very close watch kept on the output of articles, and the office had a very fine system of filing in special cubby-holes the requisitions from each of the units they serve. It was stated by the representative of the Red Cross in charge that he promptly gets out these supplies on approved requisitions by the A. D. M. S. They provide all material which may be of value in the treatment and for the comfort of the sick, wounded, and personnel of the medical department. That this was a pretty extensive list can be seen from the variety of articles kept. Storehouses were filled with clothing, in which were seen pajamas, sheets, towels, bed linens, bath robes, sweaters, mufflers, blankets and pillows, cigarettes, games, fancy foods, toilet articles, soap, polish, brushes, phonograph records, chairs, chinaware, glassware, cutlery, and surgical dressings and auxiliaries. The Red Cross storehouse had also Fowler bed frames, tin buckets, etc.

At the time of our visit they were making up an enormous number of packages of Christmas presents, with many little luxuries, cigarettes, candy, bouillons, nuts, etc., for the men.

One of the things which interested us was the matter of transportation. This is facilitated by the quartermaster, but they have some transportation of their own. The great difficulty they have is knowing where to find these organizations, as the area which they serve is very large. We were struck by the very small number of personnel at this big depot and the lack of confusion, although it was a very busy place.

STATIONARY HOSPITAL NO. 39

This was chiefly a center for nervous affections, especially shell shock, and we were given a little talk on the subject of war neuroses by Lieutenant Colonel Irwin, in command of the hospital. It is well behind the lines. When cases of shell shock are admitted they are immediately put to bed after examination, kept absolutely quiet and given very little medication, but baths and massages are liberally used. A good force of nursing sisters is on hand here. Later on the men are gotten out and are given a mixture of recreation, light work, exercises, outdoor sports, etc. As a result of this kind of treatment the greater part return to their regiments in six weeks. As a matter of fact, patients usually remain here from 10 to 14 days only. Only five of several hundred have been readmitted; and it is the rarest thing to have shell shock initiate any mental disease, which seems to indicate that there is some pathological change caused in the nervous system by the bursting of shells. The capacity of the hospital is from 400 to 450, but they can expand to accommodate a thousand men. The hospital is mainly in the buildings of an old fort, used as a prison, a very picturesque station and in very neat condition. It is expanded by Nissen huts and other buildings. There is a bomb-proof corral, which really is not bombproof at all but only splinter-proof, but it furnished enough protection to prevent the men from worrying in case of a night attack by avions. The stationary hospital is a frame unit, but the personnel and the character of the cases treated is not fixed. There are the hospitals at which specialists are found, and at this one there were 13 officers, 17 nursing sisters, and 200 of other ranks. There was an X ray and operating theater. The bucket latrine was used. Around the firebox of the incinerators of these latrines hot-water coils were wound which communicated with large storage tanks for hot water. The nursing sisters were quartered in Nissen huts. There was a section of the hospital turned over to the Portuguese medical department for treatment of their cases, as they were in a sector near by. The whole atmosphere of the place was cheerful; and although outdoor sports are obligatory, the men seemed to take to them very kindly. We found several groups playing ball, and Colonel Irwin seemed very confident that most cases of shell shock could be coaxed back into shape by a combination of rest, recreation, and exercise alone. We saw some very interesting cases of shell shock, one of which seemed to be hysteria, and in another diagnosed hysteria there seemed to be a definite lesion.

Case No. 1.—Man admitted two or three hours before was lying in bed with chronic convulsions and apparently unconscious. Colonel Irwin said he would be down playing ball in a couple of days. The pulse was rapid in this case.

Case No. 2.—Man entirely unconscious and apparently very much shocked. Just admitted four or five hours before. He was curled up and his pulse was slow and weak.

The pupils in both these cases were dilated.

Case No. 3.—Said to be hysterical paralysis of left hand, extending over six months. They said he was getting better, but it was noticed that he had some fibrosis of the muscles of the forearm and some false ankylosis of the joints.

Before a man leaves the hospital his case is summed up and the commanding officer personally examines him in the office. When the sum total of evidence points to malingering, a report is made to the commanding officer of the regiment from which he came that he may be disciplined at the source.

The colonel states that some men discharged from the hospital are never good for service at the front again and are only fit to be P. B. men. Still others have to be gotten out of the army. An interesting sidelight on the methods of the hospital in treating these cases is seen in that they have retained certain men who have been encouraged to develop a specialty which made them useful around the place. As an example, there was one who had a knack for charging soda-water bottles. A plant was provided for him and he is producing the aerated waters used at the hospital.

GENERAL HOSPITAL NO. 70

This was a fine hospital in a quiet town 25 miles from the front; situated in a monastery and school. The hospital itself had 600 beds, but with its infectious diseases camp and out-buildings held 1,500. There were only 300 patients at present in the hospital. The attendants were in tents, as they could not get labor to put up huts. This hospital would be called a base hospital in our Army, but the English are very much more careful with the use of their terms than we are. They reserve the name "base hospital," with a few exceptions, those being near ports. This hospital made a specialty of receiving chest, brain, and fracture cases. The personnel consisted of 20 medical officers and 78 enlisted men, but there were a large number of nursing sisters.

We first visited the wards devoted to fracture cases. We were reminded of Colonel Keller's remark that the English had a better comprehension of the subject of extension of fractures than any other army, and it is true. In many cases the Thomas splint had been left on, but extension, of course, had been secured by adhesive straps to the sides of legs and afterwards suspended by ropes through pulleys on the usual bed frame. The handgrip for patients was noticeably frequent here and allowed free movement of patient in bed and change of position. Plaster was not used to any extent. One of the most interesting apparatuses that we saw was one for the treatment of fracture at or near the neck of the femur, with involvement of the buttock, rectum, bladder, and pelvic bones. It was a mesh sloping back from the foot at an angle of 25° and swung on a bed frame by hooking the mesh over one of the bunks. Underneath there was a portion corresponding to the position of the buttock which could be let down, allowing dressing to proceed without moving the patient. The feet were fastened in this way by the weight of the body, both limbs being widely abducted. Patients are said to very readily accommodate themselves to having their head lower than their feet. They were very fond of b. i. p. (bismuth-iodiform powder). They stated that while they occasionally got iodiform poisoning from it and sore and swollen gums, they believed that in some way or other the duration of sepsis was lessened. Carrel's treatment was not much used, but it was employed to a certain extent. All of the officers repeated that the ideal was to close wounds by primary suture, or at least make an effort to get primary retarded, and this spirit pervaded everywhere.

We saw a guillotine amputation of the thigh, high up, performed for gas gangrene.

There was a ward for brain cases which was very interesting, as they received all the bad ones that lived.

One case was that of a young man in excellent physical condition who was brought in with what appeared to be a scalp wound. It was carefully examined, no fracture was detected, and after primary excision was sewed up, but in three weeks he began to be very quiet (we were cautioned to be suspicious always of a head case that becomes progressively quiet). Soon the temperature began to rise and localizing symptoms became evident. He was operated upon and a small fracture, which had been overlooked but was not depressed, was discovered. He was trephined, the abscess was evacuated, and all symptoms disappeared.

Another case was seen in which there was a good deal of loss of bone and brain substance in the right posterior, upper quarter. The wound was cleaned out and closed. Recovery followed, with motion returning to the left hand, which had been lost previously, but there was loss of sensation still.

The third case was an exceedingly bad one, in which a large portion of the bone from the occipital and posterior parietal regions was involved. In this case severe infection followed and the man's life was despaired of, but he gradually improved physically and the infection was overcome. A brain hernia now developed that was cut out, and an osteoplastic operation was done; but as in all of these very severe cases the man is a perfect dement—his mind is permanently gone. Most of their brain cases were doing very well and, strange to say insanity does not seem to be a frequent sequela.

The wounds of the chest were almost universally recovering, but there was one case, that of a young boy not over 18 years of age, who had just received the Victoria Cross for distinguished bravery, and who was hit just as he was swinging on his pack to return on leave. He was a high-strung young man and, by one of those paradoxes of psychology, was very much alarmed about his condition. As a matter of fact he had a right to be because there was evidently some infectious process going on in the chest, his breathing was rapid and his temperature had risen.

When we left the hospital we stepped out into the large park surrounding the monastery to inspect the contagious-diseases camp. This was situated under some magnificent trees and was the most attractive place we have yet seen, the character of the grounds being in accord with the English custom. In this place the marquee tents were correctly pitched according to military custom and ample air space had been allowed between them. They were well heated, well furnished, and well cared for. All of the tents were being sandbagged and bombproofed, and dugouts were being built, as a casualty clearing station, only a few miles away, was raided a few nights ago and nine nurses and some orderlies were killed.

The infectious diseases-hospital had quarantined their cases in tents and groups of tents, by diseases. The prevailing infectious disease was mumps, and they complained very bitterly of it because they were obliged to keep a man 21 days before returning him to duty. They stated that there was a great deal of orchitis following this affection. They retained their scarlet fever cases generally, but they sometimes send them back to another hospital. They had a fair number of cases of measles. The medical officer stated that the old type of measles was ever present and was very bad, the usual complications being mastoiditis and bronchopneumonia. They had some cases of inflammatory rheumatism and gave a very unfavorable prognosis. They treat very few cases of diphtheria or cerebrospinal meningitis.

Army Sanitary School No. 37.

VISIT TO 11TH DIVISION DEPOT MEDICAL STORES, DIVISION BATHS, CORPS LAUNDRY, AND INSPECTION OF FIELD AMBULANCE EQUIPMENT

The advance medical supply depot was in the same town in which the casualty clearing station, in which we were quartered, was situated. It was in an old brick building with the windows all shattered from avions. Cold, neat, and cheerless. Supplies are furnished divisions and issued on indents (requisitions) from R. A. P., A. D. S., C. C. S., with approval of the D. D. M. S. Articles issued are automatically replaced from base depot. There is a room full of drugs, another with dressings, instruments, and complete chests of medical supplies, and still another with splints, oxygen tanks, nitrous oxide gas, etc. Most of the splints were of the modern Thomas type, but they had a large supply of all kinds of the old splints used previous to the extension method. They said that these splints—especially fracture boxes—were hardly ever called for. While this is a corps organization, the English Army provides for a divisional advance medical supply depot. There is no accountability in the transactions with front and rear. It takes a week to fill requisitions. The bandages noticed were of 2, 3, 4, and 6 inch widths. The English refer to absorbent cotton as "wool."

BATHS

This was at division headquarters, a half hour from the town at which we were quartered. The division baths in the English Army are under the A. D. M. S. and are run, in this particu-

lar instance, by the field ambulance stationed in the town where their headquarters were. There was a complete service for bathing, disinfection of clothing, and supply of clean clothing. All companies are bathed every 8 to 10 days and it is a military function; they come in a body. The bath in question was situated in a tumble-down house of this tumble-down town and it was wet, cold, and uncomfortable, but the baths were there all the same. There was a room for undressing, from which we passed to the bath and then to the dressing room. When the men stripped, their underclothes were all thrown in a pile to be carried off to the corps laundry the next day. Their outer clothing, except their shoes, was put in the hot-air sterilizer outside the building, to be deloused. If they brought a towel the towel was thrown in with the dirty clothing, as they were furnished here towels and soap. They then passed to the bathroom where they got under the hot shower bath. Then they passed to the dressing room where they were given clean underclothing from the general store and handed their disinfested outer clothing. The whole operation took about 20 minutes. The sterilization of the outer clothing was accomplished at 200° for 20 minutes. There was a Thresh sterilizer working here which was used chiefly for blankets, which is the chief source of scabies, and this did not seem to be used for underclothing at all. The hot water for the baths comes from the two boilers, and there is a separate bath for officers. They can put in 600 uniforms in their hot-air sterilizer in an hour. The disinfestation of the outer clothing was accomplished in a dry-heat room, improvised, as usual, with corrugated iron, through the floor of which ran, exposed, a flue which turned up in a stack at the end. It was pretty well air-tight. The fire was kindled outside and burned a great deal of coal. It was very hot. They kept a temperature of 200°. They said that 500 men could be bathed a day. The whole plant burns 1½ tons of coal a week for bathhouse and delousing. One R. A. M. C. corporal is in charge and he has five Army Service Corps men on duty under him. The Thresh puts through 50 blankets every 30 minutes, and stories vary as to the number of blankets they can do in a day—some say 1,000 and some venture 2,000. The blankets are steaming when removed to dry. They stated that they steam the blankets of the entire division every three weeks at the rate of one regiment a day. If they find scabies in a billet they take out all the blankets for delousing and issue fresh ones.

Walking a short distance away to a very much overbombed house, we entered the division canteen. Back of it, in a big room, was the division soup kitchen. There are three Soyer stoves here for hot soup and tea, and the man on duty was required to have hot drinks free of charge for all men who applied for them, night or day. This worked very well. Companies on the way to the trenches at night were served here.

Farther on we visited some of the billets. The town is just on the edge of falling down entirely from the nightly visits they receive, so the billets were not much. Most of them were badly ventilated, overcrowded, dark, and poorly furnished, with improvised bed frames made of old pieces of lumber and chicken wire, but it was the best they could do under the circumstances. It was a dingy town and very sad looking, but the men were the picture of health.

We now visited the field ambulance which runs the baths, where we found laid out in a room the entire equipment for a field ambulance section, with all the chests, panniers, and boxes open. It did not differ very materially from our own except in the following regard: Three small tents, three Primus stoves. They had a good many more blankets. Their field-going equipment was more liberal, and they had ovens of the kind described heretofore as being put into an improvised range at casualty clearing stations. They had a basket devoted to rubber goods only. Everything was neat and clean.

CORPS LAUNDRY

The corps laundry was immense, and poor. It looked like a ruined sugar mill and was about the same size. Everything practically was improvised and in certain parts there were pieces of modern equipment, like centrifugal tubs, which gave the impression of mahogany tables in a dugout. The laundry was in charge of a lieutenant colonel, and he was very unhappy. Said they wouldn't give him anything. He said he hoped the United States would start right because he wouldn't like anybody to have his troubles. He said the little machinery that he had only made him dissatisfied with the rest of it.

In the first place, the approach was over an awful road, muddy and filled with big stones. The laundry comes from the divisions daily and is thrown in a pile and counted. The driver is given a receipt which he takes over to the cleaning side and gets exactly the same number of pieces in exchange for his receipt. They take this laundry and immediately sterilize it in a double Thresh apparatus, and it is then washed, some in steam mangles and some by civilians (women) who were improperly housed and in a room filled with dirty clothes and streaming steam. A few centrifugal machines were seen. The clothing from hospitals is, in addition, sulphurized. Finally, when washed and dried, it is mended by an odd crew of women, done up in bundles and stored ready for issue. This laundry was the essence of overimprovisation; a good laundry would have cost much less to run and been far more efficient. It must be said, however, that the demonstration was really wonderful, as they actually made the thing work efficiently. It washes for 25,000 men. Two thousand sets of underwear can be sterilized and dried daily. There is an ironing department run by women. The drying room is large and new. They have cages in compartments which are heated by flues which pass around the room before they leave it. They are entered by tight-closing doors and have only a pipe for the escape of steam from the drying clothing. The steam laundry has to be up and going, as the division needs daily 5,000 pairs of socks and 2,500 units of clothing—shirts, drawers, undershirts, and towels.

I went away with a tremendous respect for the officer in charge, who had made a success out of a really insufficient plant.

FIELD AMBULANCE

The last place we visited was the rest station manned by the First North Cumberland Field Ambulance, 46th Division, in the town in which we were quartered. Here all cases of suspected self-inflicted injuries were sent for observation and investigation. One section of the field ambulance equipment was taken out and loaded on a wagon, which required four horses. To the wagon was attached a trailer which weighed 4,500 pounds. It was under the command of Colonel Writh. The wagon contained, among other things, when loaded, one acetylene outfit, medical comfort panniers, one food box, one operating table, and one fracture box, which had never been opened and in which the fracture mobilizing outfit was completely out of date, but they lug it around just the same.

The hospital was neat, especially the quartermaster's storehouse, which was really a commissary. Food was usually replenished there. The kitchen was excellent, and by the conservation of fats they got 70 pounds in two weeks to turn in. The grease traps in the kitchen alone yield $3\frac{1}{2}$ pounds a day.

Army Sanitary School No. 39.

VISIT TO SCABIES HOSPITAL AND CORPS REST STATION

This hospital was in huts and received all parasitic skin diseases. On admission the clothing is taken away and sterilized. The man is bathed and anointed with sulphur ointment and put to bed. This sulphur ointment is kept up for three or four days. He is then bathed and left three or four days without any treatment. If the infection still persists the treatment is repeated. If there is any inflammation of the skin he is treated with bland ointments, such as zinc oxide, 10 per cent; also use ammoniated mercury. The outer clothing is sterilized in a dry, hot-air sterilizer at 220° F. for half an hour, and this is repeated if the man stays there any time. A fair dermatitis is set up by overuse of sulphur. Scabies is one of the great causes of incapacitation of the soldier. It was extending throughout the army pretty rapidly. One of the complications of scabies which is counted serious is impetigo.

The scabies hospital here was a stationary hospital once. It is generally in Nissen huts and buildings—all well heated and lighted. The beds are improvised from frames and chicken wire. The hot-air sterilizer was the same as that used at division baths, already described. The kitchens were good and the grease trap was in use. The latrines were of the pail variety. The incinerator was brick.

Men to be discharged are always sent to the evacuation ward the day before they go out.

Tubs are used for bathing, which seems to be an error as if bathing at any place requires a shower bath this is the place for it.

CORPS REST STATION

The corps rest station used to be a divisional unit, but is now provided at the rate of two per corps. The cases sent here are those of the slightly sick and men who are worn out by overwork and need rest and sleep. The cases are received direct from the A. D. S., M. D. S., or C. C. S. At certain times slightly wounded are also sent here, as well as convalecents from all units, who will be able to return to the line in four weeks. The commander of the field hospital was a very experienced officer and said that he believed that at this place men should be allowed to take it easy and be freed from as much military routine as possible. He said that it was a place for them to forget about the war. He added that two days ago a bomb had struck the place and killed 4 and wounded 14. The exact capacity was not stated, but we understand it ran from 300 up and could expand even to 1,000. It was run by a field ambulance detailed in sequence from the division. The equipment came from the Red Cross chiefly, but there were some quartermaster's supplies. Medical and surgical supplies were furnished from the equipment of the field ambulance. When an ambulance was relieved it only took with it its own equipment; other supplies remain here. The object of the station is to save wastage to the division, which would occur if the men were sent farther back. At this hospital they also receive cases of trench foot and a great deal of P. U. O. (pyrexia of unknown origin, known more commonly as trench fever). No surgery was being done here. The treatment consisted of rest, recreation, sports, forced feeding, and open air. They tried to make the men forget they were soldiers and free them from war. In this way many men are prevented from getting sick who would otherwise break down if they kept on. About 80 per cent go back to their regiments in two weeks. They rest from three to six weeks, but some have to be sent eventually to a stationary hospital. Gas cases go to a special casualty clearing station for treatment, but the general causes of admission are coughs, fevers, and trivial wounds and disorders. One of the chief objects aimed at in this hospital is to provide a quiet, pretty, well-kept place, with good grounds, and they have succeeded. The police and neatness of the place is on a par with what has been said of other English medical stations. There is really room for 500 patients here in cosy, well-lighted huts. The whole object of the medical officer seems to be to make the men comfortable and give them plenty of entertainment. Amateur theatricals enter into this, and they have a very nice assembly hall for it. They also have a barrack building devoted to amusements, with carpeted floor, comfortable wicker chairs, writing material, and games. Bridge parties were quite the rage at this station. A number of pictures were seen on the wall of considerable merit. At the time they were making great preparations for Christmas, and a big theatrical entertainment was being planned. There is a gymnasium in another building, and the men were encouraged to take part in outdoor sports. The pail system of latrines, with incinerator and soakage pit, was in vogue here. The kitchen was excellent. The dining room was well decorated. There were the usual canteen, library, carpenter shops, barber shops, etc., and the place was self-sustaining. Much construction work was being done here by the men themselves.

The organization was $\frac{1}{3}$ No. Midland Field Ambulance, in command of Col. F. A. Hodders. Colonel Hodders explained that the slightly wounded usually go to the division collecting station.

Army Sanitary School No. 41.

DUGOUTS

Lecture by Captain Irving, February 16, 1918

CLASSIFICATION

The term "dugout" includes all varieties of shelter of whatever kind that involve excavation and the provision of overhead cover against enemy fire.

The deep underground excavations made by actual mining operations, and from which the natural overburden has never been removed, are known as cave shelters; the relatively superficial structures made by first digging an open cut and later providing a shell-proof roof, as cut-and-cover shelters; and the small splinter-proofs used in the front line for the protection of one or two men, as individual shelters.

LOCATION

Cave shelters are now generally prohibited in the first continuous trench facing the enemy, whether it be a fire or observation trench. It has been found—

(1) That the difficulty of knowing the exact moment of the passage of a creeping barrage frequently causes men to remain in them too long; and as the exit from them is slow, troops are frequently trapped in the shelters and either killed or captured.

(2) That they concentrate troops together in too large units to permit of all of them reaching their positions in line sufficiently quickly to take part in the defense against attack.

(3) That it is difficult to prevent troops, whose presence above ground is imperative to repel an attack, from taking shelter in them during preliminary shellfire.

Cave shelters become progressively less numerous and larger from front to rear since the farther the shelter is from the front the longer will be the time available for exit and deployment and the less will be the likelihood of sudden attack. It should, however, be borne in mind in locating back-area shelters that any line of trenches is liable to become a front line in case of retirement. Shelters should therefore always be so located and constructed as to be convertible to use under such conditions.

The entrance to cave shelters may be from a fire trench, from auxiliary trenches in the rear of the fire trench, or from naturally sheltered localities such as steep reverse slopes, old quarries, etc.

Entrances must invariably be placed so as to permit of easy passage from the shelter to the places where the occupants are to become effective.

Cut-and-cover shelters are located in or near the front line where cave shelters are prohibited or in localities where ground water, hardness of rock, or other causes make the construction of cave shelters impracticable.

Individual shelters are of light construction and are placed only in or near the front line.

CAVE SHELTERS

Necessity.—Cave shelters have become necessary in modern warfare on account of the increase in the duration of battles and the development of artillery of heavy calibers, while their construction has been made possible by the stabilization of opposing lines through long periods.

Troops must now frequently remain under shell fire for days and often weeks at a time and require rest, sleep, and relaxation from nervous strain. These are possible only when complete protection against shell fire is afforded. This protection must not only in itself be actually sufficient but must be one in whose adequacy the troops have implicit confidence. Without such protection the physical fitness and morale of troops can not be preserved.

Attacks occur only at intervals, but the occupancy of the cave shelter is continuous. Therefore maximum comfort consistent with proper protection must be secured for the inmates, comfortable bunks must be erected, water and dampness excluded, ventilation and proper sanitation secured, light furnished, and as far as possible space for the storage of personal effects and for amusement and relaxation provided.

Standardization.—A standardization of dimensions and structural materials is essential in order to—

- (1) Prevent the erection of unsuitable shelters by unskilled men.
- (2) Relieve supply depots of the necessity of preparing and keeping in stock a very large variety of different materials.
- (3) Establish a uniform system which may be readily learned and taught to a large number of men.
- (4) Insure the rapid provision of an abundant supply of materials.
- (5) Secure maximum economy of materials.
- (6) Minimum labor at the front.

The standards adopted are stated in the appropriate places under each of the following paragraphs dealing with particular portions of a dugout. They have been made sufficiently elastic to be applicable to a wide variety of conditions.

Cover.—The amount of cover required by a cave shelter depends upon the caliber of the artillery against which it is desired to provide protection, the explosive charge contained

in a shell of given caliber, the character of fuse employed to produce detonation, the depth of penetration before explosion, the nature of the soil or rock overhead, the extent to which the soil has been previously subjected to shell fire, and to a limited extent on the nature of the interior construction. The calibers in use by the enemy include the following.

37-mm. (1.46-inch) revolver gun.	150-mm. (5.89-inch) heavy field howitzer.
76-mm. (2.95-inch) light trench mortar.	170-mm. (6.69-inch) medium trench mortars.
77-mm. (3.03-inch) field gun.	210-mm. (8.30-inch) mortar.
88-mm. (3.45-inch) field gun.	240-mm. (9.45-inch) heavy ladungswerfer.
92-mm. (3.58-inch) Lanz trench mortar.	250-mm. (9.84-inch) heavy minenwerfer.
100-mm. (3.94-inch) gun.	305-mm. (10-inch) howitzer and gun.
105-mm. (4.13-inch) light field howitzer.	380-mm. (13.96-inch) gun.
120-mm. (4.73-inch) gun.	420-mm. (16.53-inch) mortar.
130-mm. (5.31-inch) gun.	

Of these guns the very heavy calibers, 305's, 380's, and 420's are not in common use, their transport and emplacement and the transport of ammunition for them offer extreme difficulties, and their manufacture in large numbers is impossible. They are therefore rarely employed unless the objective be a strong defense of some point which must be passed at all costs, a bridgehead or some vital and strongly defended obstacle. Such circumstances are rare, and when they do arise cave shelters of great depth must be made which will afford suitable protection against them. The following table will give some idea of the great depth of penetration and the extreme destructive effect of these very heavy caliber projectiles in ground consisting of earth mixed with pebbles.

Caliber	Explosive charge	Thickness to be given to the roofs of dugouts	Depth of penetration	Place of the experiences
		<i>Kilograms</i>	<i>Meters</i>	
210 (high charge)	18	6.50	3.00	Verdun.
305	35	8.50	4.50	Do.
380	68	8.50	3.50	Do.
420	106	14.50	8.75	Do.

Shelters deep enough to withstand the destructive effect of the last three very heavy calibers (305, 380, and 420) can be made only with great difficulty and require the services of skilled engineers. They may be regarded as a special job and should not properly be included in normal dugout work.

It is therefore clear that the amount of labor involved in constructing all cave shelters so as to furnish protection against them is not justified.

Of the first 14 or smaller calibers shown in the first table a few only are in common use, and it is for protection against them especially that necessary cover must be provided. These are the 77-mm. field gun, 105-mm. light field howitzer, 150-mm. heavy field howitzer, 210-mm. mortar.

The 210-mm. mortar shell is of two different varieties, that with a light charge and that with a heavy charge of 18 kgs. of high explosive. The heavy charge shell has a weight of 262 pounds, and a depth of penetration of from 9¼ feet in hard rocky ground to 11 feet in pebbly earth. Since both the charges and the penetration of the 210-mm. mortar far exceed those of the lighter calibers and its trajectory is so high as to permit of the maximum effect on cave shelters, it is clear that cover sufficient to furnish protection against it will likewise be much more than sufficient against the lower calibers. For these reasons it has become customary to consider protective cover in terms of the high-charge 210-mm. shell.

The 210-mm. shell is made both with an instantaneous fuze and a delay-action fuze, and it is the latter type which is especially used against the cave shelter.

For both classes of fuze, a layer of hard rock, broken brick, coarse gravel, concrete blocks, rails, logs, etc., covered with only a thin layer of earth and placed directly over the point to be protected, adds materially to the strength of the dugout since it causes the detonation of the shell nearer to the surface. When this hard layer is artificial it is termed a burster course.

The theory of the burster course is simple. The detonation of shells is brought about by their sudden retardation. Any such retardation of an instantaneous fuze produces immediate detonation so that no appreciable penetration can occur after retardation has taken place. In soft ground this retardation does not occur until after very considerable penetration. The shell therefore explodes below the surface not only at a reduced distance above the cave shelter chamber but with a much increased destructive power due to the tamping effect of the penetrated earth.

A burster course, though not opposing any appreciable obstacle to the passage of the shell, produces retardation nearer the surface and so prevents penetration and the consequent increased destruction.

With the delay-action fuze an appreciable delay occurs between retardation and detonation and thus permits a considerably greater penetration after retardation and before detonation. Consequently the delay-action shell will always penetrate deeper than the instantaneous, even when a bursting course is interposed, but for this very reason it is extremely important to produce retardation at the surface and thus to restrict the penetration after retardation to the space between the surface and the point of detonation.

Since a burster course can not generally be placed over a dugout chamber, but only above the entrance, care must be taken whenever possible to select ground where there is a natural burster course; i. e., ground that contains a hard layer of rock, not more than 16 inches below the surface.

The nature of the soil which forms the overburden materially affects the depth of cover necessary. Sodden, shell-plowed earth is the poorest of all covers and requires the greatest depth. Since it does not generally extend much more than 15 feet below the surface, it will usually form only a portion of any given cover. In such a case it is worse than nothing, for it so tamps the explosive that it renders insufficient the remaining cover even though the latter would otherwise have been sufficient. Next to shell-plowed earth, soft unturned earth, whether clay or loam, requires the greatest depth, chalk less depth, limestone still less, and very hard rock such as granite the least of all.

The following figures give minimum head cover for protection against the 210-mm. shell:

Sodden shell-plowed earth, upward of 30 feet (9 m.).

Soft unturned earth or loam, 23 feet (7 m.).

Chalk, 21 feet (6.4 m.).

Limestone and marl, 20 feet (6 m.).

Very hard limestone, 12 feet (3.7 m.).

Granite, 6 to 8 feet (1.8 to 2.4 m.).

Shelters are rarely made in granite or rocks of equivalent hardness, so that they need not be here considered. It is the practice of the French to place their cave shelters between 6 and 7 m. as a minimum, according to the character of the soil. The British go deeper and now generally consider 29 feet as the best practice both in earth and chalk.

While the minimum depths above given may perforce be employed when the ground water level is high or shortness of time and hardness of rock preclude the possibility of deeper work, it is now considered important to secure a cover of from 25 to 30 feet. The added excavation affects only the narrow entrances and involves but little added work, which is far more than compensated for by the increased security.

The timbers used in the interior construction of a cave shelter and the arrangement of chambers must be strong enough not only to support the ground but withstand the destructive force of high-explosive shells. For such depths as 25 feet or more, lighter timber is required than for shelters nearer to the surface, since the force of shell shock decreases much more rapidly with depth than the need for added support increases.

The size of underground chambers has some effect on the cover requisite for safe protection. Stronger support or deeper cover are necessary for large than for small chambers. It is therefore necessary to limit the size of chambers. The maximum span of cave shelters is limited by the available material employed in construction. Under ordinary conditions this span should not exceed 9 feet since timbers of sufficient size for greater spans are difficult to secure and structural steel girders must be too long and too heavy for easy transport.

INFANTRY CAVE SHELTERS

General plan.—A cave shelter consists of a number of relatively narrow entrances connected by galleries and chambers. Chambers furnish living quarters for the garrison. The arrangement of chambers, entrances, and galleries differs to some extent, according to whether they are designed to house Infantry, posts of command, Artillery personnel, machine-gun crews, or surgical dressing stations.

Cave shelters for infantry are made up of standard units, each unit to house 24 men. Each unit comprises a longitudinal chamber connected at opposite ends by galleries, with at least two entrances. Chambers are 9 feet in width and either 33 or 35 feet in length from wall to wall. These dimensions should not be exceeded.

Two standard units, joined together, will house 48 men or an Infantry platoon, with a 9 by 9 foot separate room for the platoon leader. The general plan for enlisted men, 10 will be detailed on special duty as cooks, orderlies, buglers, cyclists, liaison agents, etc., so that there will never be more than 48 men in a platoon shelter at any time nor more than 24 in a standard or one-half platoon units.

Larger shelters for companies, battalions, etc., are built up of these standard units by adding one to the other until the desired size is attained. The maximum number of men using a single entrance in a disconnected one-half platoon unit is 12, in a platoon shelter of two units, 16, and in a series of three or more connected units it is as high as 24, but it should never exceed this figure.

At the bottom of each entrance is a winze which forms a bomb pit, placed to catch grenades thrown into the entrance so that they may explode in it without injuring the occupants. It is also designed to catch mobile charges of from 10 to 20 pounds of high explosive rolled down the entrance, and should be made deep enough (at least 8 feet) to reduce the concussion to a minimum. This bomb pit is extremely important and should never be omitted from those shelters which are far enough forward to fall within range of raids or sudden attacks. To still further reduce the destructive effect of explosives, a right-angled bend or elbow is made in the gallery just before it joins the chamber. This causes a number of reflections of the wave of concussion before it enters the chamber and reduces its effect. The number of reflections is still further increased by excavating the chamber on the side of the gallery toward the mouths of entrances instead of away from them.

The commanding officer's chamber should always be built on the same plan as the main chamber where the men are quartered in order that it may be later expanded into a full-sized chamber in case it is desired to add another unit to the shelter.

In Infantry cave shelters designed for reserves the bomb pit and elbows may be omitted if desirable since the shelter is far enough in the rear to render attack extremely unlikely.

The width of the block of ground or pillar between each entrance and the adjacent chamber may vary in accordance with distance apart at which the entrances are placed, but it should never be reduced below 6 feet. Wherever possible it should have the width shown on the type plan (9 feet 4½ inches), since the greater width removes the chamber farther from the explosives in the bomb pits, affords a greater number of reflections to the wave of concussion, and furnishes a safer support to the ground between entrance and chambers.

On the type plan the two entrances of a unit cave shelter are spaced a number of feet apart, center to center. A uniform spacing of entrances can not, however, be adopted since topography, the position and relative length of traverses and the location of favorable surroundings may compel a considerable variation. Any variation from the spacing shown with type plan will be taken care of by expansion or contraction in the length of the gallery leading from the foot of the incline to the chamber, provided only that the width of the block of ground or pillar between entrance and adjacent chamber be not reduced to less than 6 feet. When the change in spacing of entrances is equal to the spacing of two gallery sets an additional set is added or subtracted from each of the two galleries connecting the two entrances and the chambers. When it is less or more than 6 feet the desired increase or decrease in length is provided by introducing closely spaced sets in the same galleries until the desired spacing is obtained.

The recessed type of cave shelter where successive rooms give off of one main gallery connecting the entrances should not be used for Infantry because the large number of men quartered in a single chamber renders satisfactory ventilation difficult.

STANDARD MATERIALS FOR GALLERIES AND INCLINES

Gallery sets.—Gallery frames are so constructed that they are of sufficient strength to serve both as frames and as eases. The uprights at the sides of the gallery shall be termed the posts, the cap sill at the top the cap, and the ground sill at the bottom the sill. When assembled the posts, cap, and sill of a single unit shall be collectively termed a gallery set, or simply a set.

Caps, sills, and posts are made of 9 by 8 inch softwood plank. All joints are solid butt joints. Posts are kept in position by 1-inch boards (—or 8 inches in width) called spreaders and nailed to the caps and sills as distance pieces. The use of the spreaders obviates the special framing of timbers for joints and permits caps and sills to be converted to any other desired use by the simple removal of spreaders.

Spreaders are nailed onto caps and sills before the latter are shipped to the front. Three small nails only are used so as to permit easy removal for correcting errors in cutting or for converting plank to other uses.

Gallery sets for cave shelters are of two different sizes, a smaller size for general use and a larger size for special. Standard gallery sets are used for timbering inclined entrances to cave shelters, where the timbers are set normal to the slope, for horizontal galleries connecting the bottoms of entrances with chambers, and for horizontal galleries used as third entrances. They are also extensively used for the closely timbered galleries employed on a large scale in mine warfare.

The special set is used for supporting the fire step when inclined entrances give off from the fire trench and for timbering those inclined entrances in which it is necessary to place the sets in a vertical position. It is sometimes employed for closely timbered Infantry subways.

(1) The small set is 6 feet in the clear from spreader to spreader by 3 feet in the clear between posts. Posts are 6 feet 2 inches long, caps and sills 3 feet 6 inches. The standard small gallery sets are made from 6 inch to 8 inch round logs 10 feet in length. Logs are first sawed in two lengthwise, then crosswise, so as to yield two posts 6 feet 2 inches in length and a cap and sill 3 feet 10 inches in length. They are then set with the flat faces inward and separated by the usual spreaders. The additional 4 inches in length of cap and sill forms a projection beyond the posts necessary on account of the decreased bearing space caused by the half-round logs and their variation in size. This type of set is not so strong as that made by squared timber, but is economical and in many cases is quite strong enough.

(2) The large set is 6 feet 4 inches in the clear from spreader to spreader and 3 feet in the clear between posts. Posts are 6 feet 6 inches long; caps and sills 3 feet 6 inches. In exceptionally hard, unfissured rock formations it is sometimes possible to place sets at 5-foot intervals, center to center, but this so reduces the factor of safety in resisting shell shock that it is generally inadvisable and should never be done without expert advice.

In exceptionally heavy ground it may sometimes be necessary to use heavier sets than the standards above noted. Under such circumstances the services of skilled engineers will be necessary, and special timbers will be separately ordered and cut as needed.

Sprags.—When gallery sets are spaced at intervals on inclines of more than one-fourth, which will frequently be the case in firm rock formations, sprags or distance pieces are placed between successive sets so as to catch up the posts and caps and prevent the sets from being overturned. These are 9 by 3 inch plank, 2 feet 3 inches in length. On these rare occasions when sets are placed at 5-foot centers, sprags are 4 feet 3 inches in length.

Sprags are to take up the strain on the cap sills. They are not to be framed or jointed, but simply fastened by toe nails to adjacent post and cap. Sprags are not necessary in horizontal galleries except in sets at the bottom of an incline, where they are extremely important in order to take up the strain transmitted through the successive caps of the incline.

Lagging.—To hold the ground between the posts at the sides of the gallery and between the caps at the top, lagging is placed behind and above the sets. Side laggings may be overlapping and is then driven in the same manner as spiling, or may be put in position so that the ends of the boards meet behind the posts or over the caps. When the roof lagging is driven it is usually sharpened and is then termed "spiling." Side lagging is of 1½ inch plank

of from 4 to 9 inches or more in width, according to the sizes most readily available. For sets spaced at 3 feet center to center it is 3 feet long. When driven it is 3 feet 9 inches long to allow for overlap.

Spiling boards and roof lagging are of 2-inch plank 5, 6, 8, or 9 inches in width, according to lumber available. The larger widths are less desirable, as they are more difficult to drive. Spiling boards are 3 feet 9 inches long or 5 feet 9 inches long, according to the spacing of sets.

Stair stringers.—When sets are placed normal to the slope in cave shelter entrances on a slope of more than one-fourth, stairways must be made to facilitate exit. Stair stringers will be made of 2 by 9 inch plank of commercial and readily transported lengths. Cleats 2 by 3 by 9 inches are nailed on for steps. Cleats are always to be attached before stringers are set, since difficulty is experienced in placing them properly in the constricted space of the entrance.

Steps have a 9-inch tread and a 9-inch rise and are made of 2 by 9 inch plank cut in 2 feet 9 inch lengths. They are nailed to the cleats and act as additional spreaders, and so materially strengthen the entrances.

STANDARDIZED MATERIAL FOR CHAMBERS

Chambers.—Chambers are supported by chamber sets extending crosswise of the chamber. Sets consist of two posts capped by girders whose clear span must not exceed 8 feet. These sets are separated 3 feet center to center. The posts are best made from 6 by 6 inch sawed timber 6 feet 6 inches in length. Sills need not be used, but instead the posts are set 6 inches in the ground to prevent their slipping inward. In soft ground, such as clay, blocks of 2-inch plank, 8 by 12 inches, should be placed beneath them to prevent them from sinking into the ground. Where sawn timber is not available, which is frequently the case, round posts may be substituted. They are in frequent use by the British and furnish quite sufficient support if not too widely spaced. They should not be less than 6 inches in diameter at the smaller ends.

Caps should be made from **I** beams of rolled steel wherever possible, since these have greater elasticity than equivalent wooden girders capable of supporting the same static load and return more readily to their original form after shell shock. Wood subjected to the same shock will often splinter and break. **I** beams should be 5 by 3 inches and 11 to 12 $\frac{3}{4}$ pounds to the foot. They should have a length of 9 feet and are designed for a clear span of 8 feet. They should be placed so as to bear on the posts for a full 6 inches and should never be placed only part way across the tops.

When **I** beams are not available, caps may be made from 6 by 8 inch by 9 foot sawn timbers set on edge or from two 9 by 3 inch by 9 foot planks nailed together and set on edge.

When **I** beams are used a cast-iron shoe is placed between the **I** beam and the post. This has a flange against which the beam rests on the upper and outer edge and another on the inner and lower edge which extends downward and engages the inner side of the post. This prevents the post from slipping inward and keeps the girder from biting into the post and splitting it and at the same time turning over.

When shoes can not be obtained, an 8 by 1 inch soft pine block is placed between the post and girder with a 5-inch strip of $\frac{1}{4}$ inch sheet steel beneath the wooden block. The ends of this sheet steel are bent at right angles into an **E** shape, the outer one upward and the inner one downward so as to exercise the same function as the cast-iron shoe. Clips shrunk on hot are sometimes employed for the same purpose, and are widely used by the Germans. Angle irons bolted to the **I** beams are also sometimes used, but the labor of placing either of these is in general prohibitive.

In addition to the lateral posts, a second row of intermediate posts is set lengthwise of the chambers on the side where the galleries enter; these posts are 3 feet center to center from the posts at the side. These lend additional supports to the caps and serve to support the foot boards of the bunks. Except in very heavy ground they need only be placed at 6-foot intervals beneath every alternate girder. In hard rock formations they may be omitted. They should not be placed in 9 by 9 foot chambers.

Two extra end posts are set at either end of the chamber to support the lagging of the end faces. These are set only 4 inches in the ground and are notched at the top so as to leave a 2-inch lip and afford an angle to receive the **I** beam.

The successive chamber sets are tied together by sprags into a compact whole. The sprags at the sides are made of 9 by 3 inch by 3 foot planks, notched so as to engage both the web of the girder and the post, and are merely driven tight in and not nailed. Similar sprags are placed between the posts at the ends of the chamber immediately beneath the girder, but in this case they are nailed into place by toe nails. The omission of these side and end sprags, even in square 9 by 9 foot rooms such as are designed for platoon leaders, in soft or even moderately firm ground soon results in the sets moving slightly until the entire chamber timbering is awry. They are very important and should in no case be omitted.

Additional light 2 by 4 inch by 3 foot sprags are driven in tight between the webs of the I beams of successive sets. They are not put in place until the chamber is finished, as they interfere with the placing of the roof lagging or spiling.

The roofs of chambers are lagged in hard rock in the same manner as galleries. In bad ground they are spiled. Lagging is of 2 by 5 inch to 9 inch planks 3 feet 9 inches in length. Roof lagging in chambers should always be overlapping. The walls of a chamber between the posts of successive sets and at the ends are sometimes left bare in very good ground, but there is always danger of small pieces falling in ground that is blocky or in chalk. The latter is apt to weather after excavation and spall off. For this reason it is customary to lag all chambers tightly, and it vastly enhances comfort and sanitation to do so. If boards are used for the purpose, it is done with $1\frac{1}{2}$ by 6 inch to 8 inch planks. If the lagging be driven, the length is 3 feet 9 inches; if set, 3 feet. Expanded metal and corrugated iron are often used.

Army Sanitary School No. 43.

WAR SURGERY

By Surg. Gen. Cuthbert Wallace, December 17, 19, and 22, 1917

General Wallace introduced his subject by introducing himself as a sheep in wolf's clothing, because, as he says, "I am not a military man. He nevertheless stated that he believed firmly in the necessity for the strictest military discipline in the Medical Department to the end that good medicine and good surgery can be done, and that it can not be done without good administration, which is the skeleton upon which all professional success is hung. He sounded a very important note, however, when he stated that for the consulting surgeon he believed it necessary that results should be obtained by the personality of the man and an appeal to the reason of those he wished to direct rather than that his intervention should be by force of rank.

Men are taken directly to the C. C. S. as soon as they are hurt, irrespective of the time it may happen, if this is possible. The work at all stations in front of the casualty clearing station should be limited to purely emergency surgery. The system of evacuation of wounded in the British Army was officially changed in May, 1917. Previous to that time all the wounded were collected in one spot, and a motor convoy collected once a day in a body between 11 a. m. and 2 p. m. to remove them. Besides leaving men at the front long periods when they ought to be at the rear, the accumulation of this motor ambulance train at the front drew fire, with its natural results, and badly congested an already overloaded road. Nowadays two ambulances are kept at the A. D. S. and men are sent in as soon as hurt, and if there are many, the worst wounded are sent in first.

When a R. A. P. is in a fixed position it should be made as complete and as comfortable as possible for the work which it is to do. It is of highest importance to make a correct diagnosis and to employ the correct official nomenclature for wounds, and this means that it is necessary to have good surgeons at the front, and in order to get them you have to make them yourself if you want them uniformly good. It should be a principle that after having done everything that is necessary for a wounded man at the front, he must be let alone until he gets to the rear. Dressings should not be changed so often, not only because there is a loss of time and risk of infection, but because dressings are expensive and they are none too easy to get. So never remove them unless there is some special reason for doing so. Be gentle when you handle wounded men. Don't slam them around or pull off their

dressings roughly. General Wallace approves very highly, and prefers, the French system of having packages of sterilized dressings in the three sizes. In the English Army sterilized dressings for these stations at the front are sent up from the M. D. S. or C. C. S. In this army the Helby box is used, and although not as pretty and made out of tea and biscuit tins, it is useful as the sparkling nickel Schimmelbusch box. This box is made by telescoping a tea tin into a biscuit tin and perforating the two over two faces. In the sterilizer the steam enters the box and before it is taken out the outer box is given a quarter turn and replaced, thus preventing the entrance of dust. This box can be sterilized in the Thresh apparatus and is lined with gauze, which also covers the dressings packed in it. The gauze is cut up into 6-inch squares so that it can be lifted out by forceps in layers. Wet dressings are the best, in that they do not cake when put on the patient. You can send them in the marmites reserved for this purpose. These are generally white-enameled casseroles. To sterilize, you fill them up with dressings, pour on water, and boil; then you pour off the water and add an antiseptic.

At the front do not try to do anything more than remove gross impurities; the mud and dirt is cleaned away; the visible foreign bodies are removed if possible; and all handling, even to the point of cleansing the skin, should be done with forceps, the forceps grasping the cotton or gauze used for this purpose. This is because surgeons have to work rapidly in aid stations and in the A. D. S. and C. C. S. and are unable to sterilize their hands after each intervention. At every R. A. P. it is well to keep these forceps in a wide-mouthed bottle containing an antiseptic. It is well, also, to have a transfusion apparatus kept sterilized in a covered pot. When a man is evacuated always send your notes on the case and your opinion. Iodine and picric acid used on the skin can not be confided in as antiseptic. They can be used by anyone who has a taste for pretty colors. One-half per cent of picric acid in alcohol is the best way to use that drug. Do not do any meddling surgery at the front, and stop the tendency to do wildcat surgery anywhere.

In the Army some have a tendency to strafe the men in front of them. That is why it is necessary for the men in the rear to know something about the front. We should be able to visualize the difficult conditions under which a surgeon works at our front. We should remember that while good criticism is useful if it is not captious, we should not condemn the men in front unless the work is unquestionably bad. In the R. A. P. and A. D. S. make use of the triangular bandages as much as possible. They are rapidly applied, they make the best dressings we have for head and large wounds, and can be used satisfactorily in any part of the body.

It shows poor judgment for anyone to allow a patient to die in a motor ambulance. It rarely happens, but when it does the man responsible hears of it later. If a man can not make the journey safely, keep him at the forward station until he can. There are some cases of shock which should not be moved, and these include certain chest and abdominal wounds; but remember that operative dugouts are failures.

Here is another reason for a good regimental surgeon. No man should leave a C. C. S. or a M. D. S. with a tourniquet on, and if he is sent from the R. A. P. or A. D. S. with a tourniquet it should be placed in position but not tightened, so that the attendants in the ambulance can tighten it if necessary en route. As a matter of fact, the tourniquet should only be used as a last resort. Before appealing to it we should try digital pressure and good bandaging. But the application of a tourniquet, without tightening, is especially necessary before traveling in the dark. If you have to bandage a limb to arrest hemorrhage, it is better to place a splint on the off side and bandage up against it. Most trench orderlies and stretcher bearers have a great fear of a little blood, and think that a man is bleeding to death when it is merely the natural hemorrhage which ceases of its own accord.

General Wallace calls special attention to the vicious combination of powders and pastes used on fresh wounds, and an especially devilish combination is b. i. p., which is bismuth, iodine, and paraffin. It is dangerous because it not only gums up the wound but is absorbed, causing ulcerations of the mouth and also of the intestinal tract. The creosote paste he denominates the W. C. paste and says it blocks the wound up and does no good.

War surgery is life-saving surgery. Don't think you are going to be a fancy operator. What you need to be is a good scavenger at least.

By all means do not use antiseptics in war surgery if you can help it.

FRACTURES

Thomas splints must be of the largest size so that you can put them on over the clothing. When a Thomas splint is not available you can use a Liston, which is a long, wooden splint extending below the heel. They can be fixed with a triangular bandage. The Liston splint is also used where there is a wound of the buttock and a Thomas can not be put on. A fracture below the knee does not require a Thomas splint; here you may use a Nevelle's splint, but you must add some side pieces to it and the thigh end must be well fixed.

In fractures of the arm above the lower third of the humerus, put a pad on the axilla and put up in a Velpeau position or bandage the arm to the chest and support by a sling. These men should be transported in a sitting position, which is the most comfortable for them. Of course, in these fractures a Thomas splint can be used for the arm, a clove hitch being placed on the wrist, but it is not very satisfactory and pretty painful. One of the fine splints for the arm and forearm is the Gooch, which is a laminated splint on cloth. Fractures of the forearm should be put up in supination and with interior angular and short-sided splint. Additional support may be given by the wide ladder splint.

THE GENERAL TREATMENT OF WOUNDS OF THE SOFT PARTS

At the beginning of the war it was noticed at the casualty clearing stations that the *Bacillus aerogenes* of Welch and the streptococcus were our worst enemies. The Carrel treatment began in the English Army in May, 1916. Débridement was practiced first, and after that the Carrel irrigation, but now we are back to first principles—aseptic surgery, as reflected by the primary suture. Antiseptic surgery has failed. This primary suture was begun in 1917. The primary or primary retarded suture has now become the accepted method of treatment.

General Wallace said that in "peace times" 70 per cent of the cases passing through a casualty clearing station are operated upon, but in strife times 25 per cent is about all that can be put on the table. The rest may be evacuated to the rear. At such times as these practically all that can be done is a débridement and excision of dead or dying tissues, and detach fragments of bone, clothing, and foreign bodies.

OPERATIVE SURGERY

Don't go into this war thinking you are going to do brilliant operations, because that's the least of the work. By far the greatest number of all cases in a C. C. S. fall under the category of wounds of the soft parts and fractures.

WOUNDS OF THE HEAD

If you receive a man that has a wound of the head, try not to touch him for 24 hours if you can help it. A slow pulse does not necessarily mean a compressed brain that is being seriously compromised. It is probably due to concussion or edema and will clear up of itself shortly. As a matter of fact such cases should be sent to a special hospital back of the C. C. S., which is always best; such cases travel well before operation, and mighty badly afterward. In treating brain injuries turn down an osteoplastic flap and expose the dura so that you have an edge of at least half an inch of healthy membrane. Open the dura well and remove the dirt, spicules, clots, etc., under a gentle salt solution, and close, draining the angle of the flap if you feel like it. But it is best to close without drainage, performing a primary suture, because you can always open it again and drain it if necessary. Any embedded projectiles that are near the surface may be removed, but those that are deep should be left alone, after a short but intelligent search.

In closing up defects in the skull, bevel it so that you can slide over bone and cartilage to fill up.

The mortality of such head wounds as reach the hospital alive is 50 per cent, and a slow pulse should be considered a good sign. The most fatal cases are those that penetrate the ventricles, and wounds of the base are very serious. Wounds of the cerebellum are rare, but serious. A case with a pulse of 120 is not worth operating on. The syndrome of injury to the longitudinal sinuses is spasticity of the arms and legs. Do not operate on this latent

class of cases until the clot forms well in the sinuses. Epilepsy following head wounds is rare. Serious compression of the brain is better revealed by the general symptoms rather than by the pulse. Stertorous breathing and flaccid muscles are better diagnostic points. Brain cases will require at least two months rest if they live, and for this reason alone an operation should not be done at the C. C. S. Another reason is that after operation the noises of war disturb them very much. It should be taken as an axiom that fine brain surgery can not be done on the battle field. Don't talk about your end results until six months have passed. The decompression of the brain in skull injuries is not done as much as before. It is very interesting to contemplate that while the mortality from head wounds is 50 per cent, there are few cases of insanity or epilepsy following those serious wounds.

WOUNDS OF THE CHEST

One of the mistakes in this war was to delay aspiration of the hemothorax. Such aspiration is required, but it should not be done within 48 hours, and there should be enough blood in the pleura to bring the level high in front, extending to the angle of the scapula behind. The fear is that the blood will reaccumulate, but it don't. In any infusion into the chest—in fact in most chest injuries—the temperature rises sharply, rather highly, and descends slowly throughout five days. This does not mean infection ordinarily, but if the pleura is aspirated the temperature falls. Occasion should be taken under all of these circumstances to have cultures made for bacteriological examination. If the temperature doesn't fall promptly when there is a hemothorax, it generally means infection. The course to pursue there is to aspirate and get a bacteriological report. If the bacteriological report is negative, and the clinical signs remain, operate anyway. Wash out all infected clots. Do a toilette of the pleura and sew it up. In fact, except in streptococcus cases where the mortality is high, 33 per cent of these get well. If you have to reopen a chest that you have operated on for infection the second time, leave a drainage tube in. One of the curious clinical phenomena of anaerobic infection of the pleura is the facility with which such cases are confused with shock and hemorrhage. What happens is that such cases usually develop on a train, the moving incidental to the transport having caused the anaerobic infections to flare up, and diagnoses for secondary hemorrhage are made. Anaerobic infections of the lung are by no means uncommon and they cause severe pneumothorax. If you open pneumothorax cases at the site of the wound, do a complete operation, removing foreign bodies and close up by primary suture, because if you merely put in a gauze plug they may do well for a time, but later on they die of sepsis. In general, wounds of the thorax are very grave, but if a big vessel has not been opened at the time of the wound, causing death, the hemorrhage is not severe—often a little blood spit up is about all that you notice. Nearly all chest wounds are transportable with the exception of those with pneumothorax, and really should be evacuated, unless there is some special contraindication. Mistakes made in chest operations still come from delay in aspiration and plain bad operating. One of the objects of aspiration is decompression of the lung. Sometimes purulent processes are loculated and when you puncture the pleura for a specimen for the laboratory you may not hit the pus, and in this case you may have to be guided by your clinical sense rather than the laboratory. Another mistake made in this war was that of open or “sucking” wounds. They were kept open. In this case you should excise the rib, clean it up and close the wound. When these cases come in the R. A. P. or A. D. S. they must be transported. With every breath the man is alarmed by the peculiar noise and there is apt to be some pneumothorax with it. The proper procedure is to either pull the skin over it with a few sutures or plug it with gauze. This causes great betterment and the man can soon be transported to the C. C. S.

Whenever you do a thoracotomy and pull out the lung to operate on it—which should be done by resecting the fifth rib—pack gauze around it to keep the air from making the lung collapse by entering the pleura. Men with wounds of the apex usually die, drowned in their own blood.

For wounds of the lung requiring operation, try to operate within the first 48 hours if possible. In large wounds of the chest it is best to have the patient rest for about six hours before operation after reaching the hospital. A massive collapse of the other lung is generally fatal and is a contraindication for operation.

ABDOMINAL WOUNDS

In the Boer War operations in this class of wounds were failures, and this had a great deal to do with discrediting the opening of abdomens at the front; but they were failures because of the enormous amount of dust in that country, which covered and dirtied everything; on account of the shock from cold, because it was a very cold country; the delay in getting the wounded; and the lack of water. The operating theater was so far back that frequently the wounded did not reach it until 48 to 60 hours after having been wounded. In 1914 abdominal wounds were kept at the front as nontransportable, but we began to operate in the British Army in the field in June, 1915.

Rapid evacuations and post-mortems prove that neither shock nor peritonitis was responsible for the high death rate in the early part of the war, but hemorrhage. Bullet wounds are not as dangerous as shell wounds as far as their ability to tear things up in the abdomen is concerned, and it is true that a bullet can go through the abdomen without opening a hollow viscus. We must always look out for an abdominal wound when a man comes in wounded in the buttock, and such wounds are very fatal when they reach the abdomen from that source. The operation mortality of abdominal wounds is 51 per cent, and the raking wounds from side to side are most fatal. The worst are those that occupy a space to the right and above a line drawn from the lowest part of the ribs in front to the anterior superior spine and the ilium, and their fatality is generally due to hemorrhage. The most dangerous wounds of all are those that hit the midline of the abdomen. Two-thirds of the wounds enter from the front and one-third from the back. Wounds entering from the thorax and penetrating wounds of the liver are very dangerous. The general mortality in abdominal wounds is 80 per cent. A high pulse in abdominal cases is very unfavorable. Most of the wounds entering the abdomen from other parts than the front of the belly are from bomb and surprise attacks. The mesentery seems to be the last organ in the abdomen to be injured. The general practice in simple bullet wounds and small bomb and shell fragments is to let them alone. The incision to make in abdominal cases is a paramedian one, 8 inches long. The mortality from wounds of the abdomen entering the back is higher than those entering the front. The mortality of stomach wounds is about 50 per cent. Wounds of the fundus are extremely difficult to get at, and it is best to do a thoracotomy first and deal with such a lesion from above downward, incising the diaphragm to get good exposure. In wounds of the stomach the bleeding from the walls is not usually very great. In the fundus there are usually slits shaped like exclamation points—a long slit and then a point. In the greater curvature you may get a notched or V-shaped wound. Wounds near the pylorus may cut the stomach in two. Some of these stomach wounds recover well, but don't ever give food by the mouth. Use the rectum; it is better.

SMALL INTESTINE

As this organ is in folds, multiple wounds are the rule. The mortality is 65 per cent. Twenty wounds of the small intestine have been successfully sewed up. When you open an intestine, if the holes are small sew them up as you find them, and go on hunting; but if they are large clamp them off, cover them with gauze, and go on hunting somewhere else. Do not be too hasty or desirous to resect, and in single small holes do a purse-string suture.

LARGE INTESTINE

It is generally the transverse colon that gets it. But as the large intestine does not hang in folds, multiple wounds are not so common. They are, however, at the hepatic and sigmoid flexures. The descending colon is sometimes cut in half, and as a rule it is empty at the time. The mortality of such colon wounds as reach base hospitals is 46 per cent; in the early part of the war, before the operative period, it was 80 per cent. The colon wounds reach the base more frequently than any other kind. If you have to intervene with the colon make a loin incision, which should be transverse. Colon wounds should be drained.

RECTUM

Posterior wounds of the rectum are often rapidly fatal, but when there is a chance and you can operate on them the best thing is a posterior colostomy. Notwithstanding this,

many rectal wounds do fairly well if left alone, especially the posterior cases which extend from the buttock. The Trendelenberg position during operation and the Kelly-Fowler treatment are still used.

COMPLICATED WOUNDS

When the stomach, small intestine, and large intestine are wounded, the mortality is almost 100 per cent. The reasons for this are due not only to the multiplicity of organs involved but also to the length of time necessary to operate and the increased amount of hemorrhage. A combination of bladder and intestinal wounds is almost always fatal.

While at times the liver does suffer a certain amount of explosive effect, very frequently the wounds are only tunneled. In general, don't try to suture because it is very difficult to make the sutures live, but pack. Wounds of the front of the bladder are not usually so dangerous, because they can be sewed to the abdomen and usually heal nicely. With this exception, bladder cases rarely recover.

The great feature in all wounds of solid organs is the amount of hemorrhage. You must never remove a spleen or a kidney if it is possible to avoid it, and the reason for removing one should be an injury to the hylum. The tunnel wounds of the liver usually do well unless the projectile is large and the damage great. If a large fragment of projectile is embedded in the liver remove it, but if it is small leave it alone and pack the wound. Extra-peritoneal wounds are bad, worse than wounds to the thigh, because they are usually accompanied by fractures of the pelvis.

GENERAL REMARKS ON ABDOMINAL SURGERY

You usually get your abdominal cases in from 8 to 10 hours after they are wounded. The most favorable time to operate is up to 6 hours. The limit of time in which a suture can be applied to an intestine successfully is from 36 to 48 hours after the injury. If it is a question of choice between patients, leave an abdominal case with a pulse of 120 to operate on one with a lower pulse. It is always better to let a man rest a little while at least before an abdominal operation, even when there is hemorrhage. Morphine is bad for most wounded men. Abdominal cases do quite badly with it. You should never use it except to relieve pain and anxiety, and it should either be given hypodermically or under the tongue, the buccal method, which permits it to be absorbed as rapidly as by the hypodermic. The dose should be from one-third to one-quarter of a grain; one-half is too much. This dose should be expressed on the diagnosis tag, with the time and the mode of its administration. The general principles to be followed in abdominal wounds are:

1. Always operate as a matter of course, just as you would lift the bed cloths to see what is the matter with the patient, and when you do open the abdomen explore well.
2. You should push your suturing of small intestine in preference to resection.
3. In the presence of colon wounds you should open from the loin.

Drainage of the abdominal cavity is used where drainage of the intestines is doubtful, but generally this is not good practice. Drainage is always necessary in colon wounds.

Abdomino-thoracic wounds are rather frequent and they give a very high mortality. The abdominal wounds should always be attended to first, and the diaphragm had better be sutured—(1) to get prompt return of function of the organ and (2) to prevent hernia. It is interesting to note that while abdominal wounds are generally promptly fatal, the fatality in thoracic wounds occurs in from three days to a week after injury.

Superficial drains of the abdomen should not remain in for more than 24 hours. Deep drains are proper for colon wounds. Transverse colostomy in the loin is the best operation. Artificial anus may be necessary.

AMPUTATIONS

There are three considerations in amputations, in order of importance: (1) The life of the man, (2) the length of the limb, and (3) provision for a good stump.

1. *Leg*.—Provisional operation can be undertaken at the front between 4 and 6 inches below the head of the tibia. In case of shattered legs, keep away from the thigh; that is, do not go above the knee in the C. C. S.; rather do a chaff or a circular operation. This is known as the guillotine operation. If you have to amputate through the thigh keep as low as you

can because the upper third is very fatal. In flap operations the anterior flap is by far the best method, but circular amputations are best. In general, one should not pay too much attention to getting a good stump at the first operation; that can best be gotten at the base later on. The Syme's operation is the best, but it must heal by first intention or it will be a failure. If you have a spluttered thigh, don't operate through the damaged skin, but above it. Try to get a good end-bearing stump. Don't try any disarticulation of the hip joint because they all die. Do not perform lateral flap operations. When it becomes a question as to going through the knee joint, it is better to preserve the joint and go through the head of the tibia, or when you disarticulate leave the whole surface open. Indeed, in all your flap operations they should be left wide open in your primary operations at the front, where you should content yourself with ligating the large vessels and packing the cavity. Always splint an amputated leg or thigh to keep it quiet.

In operations of the upper extremity we must remember that we must save all of the limb possible; keep away from the joints. For a good articular surface for an artificial arm you should have at least half an inch of the humerus. Here, also, circular operations are the best. Always save as much as you can, especially of the thumb and little finger at least. Let the wrist and elbow joint alone and go a little above them or below them rather than to amputate at the joint. In a circular operation, which is the variety that should be done, leave everything open, and all the skin possible. In amputating at the shoulder joint leave the head of the humerus.

There are two kinds of gas gangrene. First, that which affects certain groups of muscles and ascends along these groups, leaving the other muscles in the vicinity healthy; and, second, massive gangrene.

In the first case the affected muscles should be excised, and in the second case amputation should be done at the line of demarcation, which is found by making a lateral incision until live muscle is encountered.

Amputations for damage to nutrient vessels. There is no line of demarcation in this sort of injury and we must not wait for that line, but do not hurry too much; wait at least until the parts affected by the blocking show up in a general way on the skin.

In general, for all wounds of the soft parts that can not be excised you use Carrel's method. The reason for his great success was that he employed a continuous irrigation of the great crater wound. As a matter of fact a 5 per cent salt solution is a strong antiseptic. One should never remove fragments in a compound comminuted fracture unless those fragments are absolutely loose.

In gas gangrene there are etiological factors which are important:

1. Terrain.
2. Artillery wounds or hand grenades.
3. Seat of the wound.
4. Fractures with deep penetration.
5. Presence of foreign bodies, clothing, dirt, etc.
6. Fractures of large bones and joints.
7. Vascular lesions, ligatures, and prolonged use of tourniquet.
8. Multiple wounds.
9. Hematoma.
10. Traumatic shock.
11. Presence of other germs, such as streptococcus.

The preventive treatment is:

1. Rapid evacuation; wide débridement; removal of spicules, foreign bodies, etc.
2. In localized form, with or without infiltration, curative treatment consists in completely exposing to the air the utmost depths of the wound; excision of all gangrenous or suspected tissues.

3. Amputations in cases of massive gangrene. In case of extraction of projectiles by secondary operation, we must remember that surgical intervention can invoke a recurrence of a latent infection.

VASCULAR SURGERY

Arterial suture requires the patience of Job and the guile of a serpent. As a matter of fact, the opportunity to do this vascular surgery does not come often, anyhow.

When there is a wound in the vicinity of a large vessel and there is much bleeding, clamp off the vessel and leave the clamp in place until the man gets to the C. C. S., with a note on the card to the effect that a hemostat is on. There should also be a tourniquet placed upon the man's extremity to be tightened in case bleeding comes on en route; and these cases must be watched very carefully by a reliable person. Oftentimes, on the receipt of such a man at the C. C. S., after making sure that the clamp is in place, it is better to wait a while before operating.

General Wallace once saw a man that had a small piece of shell fragment lodged inside the heart. The man lived eight hours after his wound.

The field for plastic surgery is unlimited and should be aided in every way by the concerted action of surgeons at the front and base. If we send in the limbs or crushed parts free from infection and in good physical condition, then we have every reason to expect that plastic surgery will give good results.

In the large intestine, when you get a grouping of holes you may be forced to resect but in single small holes do the purse-string suture.

Army Sanitary School No. 60.

THE CHIEF SURGEON OF AN INFANTRY DIVISION (D. I.)—FUNCTIONS, RÔLE, AND METHOD
OF A DIVISION SURGEON (M. D.)

INTRODUCTION

In response to the verbal request of Col. Bailey K. Ashford, M. C., United States Army, the chief surgeon, first class, Theoris, expounds herein the results of his war experience in regard to the functions, rôle, and method of procedure of the Army M. D. (division surgeon).

We will take for consideration the case of a D. I. (Infantry division) under the direct supervision of army headquarters without any intervening corps headquarters.

CHAPTER I

Functions of the M. D. (division surgeon) in his relations with: (a) The commander; (b) the chief and subordinate technical branches.

a. The M. D. (division surgeon) and the commander

The relations of the M. D. (division surgeon) with the division commander and the corps commanders:

I. *The M. D. (division surgeon) and the division commander.*—The M. D. gives the general technical advice and makes recommendations; he receives from the general information and orders.

(1) Technical advice: Reserve for the general technical advice related to policies. Submit all details to the chief of staff, to the first office (personnel and matériel), to the third office (operations and movements).

Matters pertaining to policies must be explained verbally to the general himself; messages delivered through intermediate agents, however great confidence one may have in the agent, lose the tone of persuasion and sometimes the accuracy of direct communication. Confirm these matters in writing. Take advantage of every opportunity to make these statements. It is thus that the M. D. (division surgeon) accomplishes what might be called a psychological preparation of the command, which is as necessary to the execution of the division sanitary service as is the Artillery preparation to the execution of an attack.

Matters of policy refer to the object, the means, and the needs of the sanitary service of the Infantry division.

(a) Object of the division sanitary service: Far from being a separate organization having different aims, the division sanitary service is, on the contrary, a vital part of the organization called a division. The object of one part does not differ from the object of the whole to obtain a maximum of efficiency with a minimum of loss.

(b) Its means: The efficacy of measures tending to preserve the strength of numbers of effectives determines the means placed at the disposal of the sanitary service.

(c) Its needs: Its needs must be considered by the commander for the same reasons and with as much importance as the needs of other branches of the service are taken into consideration. The military importance of the recovery of the sick and wounded, especially in long wars, does not permit the classification of these needs as trivial or of no importance. Experience has proved that a good organization always succeeds in distributing work and matériel so as to drive forward all the components of the organization at the same time.

(2) Recommendations: Technical advice should never be given without sufficient grounds; instead it should be based on definite facts, and practical aims always kept in view. Conclusions must be explicit and peremptory. The conclusions take the form of recommendations. Thus every report of the division surgeon includes (1) a statement setting forth all technical considerations leading up to (2) recommendations, in which the conclusions are expressed with a view to their being translated into orders, the context needing no modification by the commander. The statements may be developed in detail; recommendations should always be brief and clear. (See Exhibit No. 1 as model.)

(3) Information: Obtain from the commander all useful information, in order to secure coordination of the sanitary and tactical plans.

(4) Orders: The division surgeon receives from the commander spontaneous and solicited orders. Spontaneous orders are given without previous technical advice; they are subject to alterations and eventually to corrections when they involve technical aspects. Avoid this obstacle by persuading the commander that it is more useful in the long run to consult the technical authority first.

II. *The division surgeon and the corps commanders.*—(1) Get the information on the spot. The division surgeon must confer with the corps commander, which causes a mutual exchange of warnings and appreciations leading to a better understanding of the common work.

(2) Periodical conversations are more valuable than any kind of written demands for the overcoming of difficulties and the amending of defects.

(3) Direct observation in the company of other observers having different points of view goes to make the best understanding of the facts. Discussion at or near the place about the different interpretations offered suggests conclusions which, because they touch realities, do harmonize the discrepancies which present themselves.

b. Relations of the M. D. (division surgeon) with the chief and subordinate technical branches

I. *The division surgeon and the technical chief.*—Technically the division surgeon is dependent upon the Surgeon General. He obtains from the latter technical instruction; he directs to him regulation reports, and requests from him personnel and matériel for the sanitary service.

II. *The division surgeon and the subordinate technical branches.*—The division surgeon directs those under him to comply with the technical orders received from the Surgeon General. He obtains from them periodical and occasional regulation reports^a besides the requests for personnel and matériel. He classifies the various chiefs under his orders with regard to their promotion and honors.

The division surgeon exercises his authority in an indirect manner over the corps surgeons, who are under immediate orders of their corps commanders; and in a direct manner over the chiefs of the division formations: G. B. D. (divisional litter bearer section), S. S. automobile and ambulance (field hospitals and ambulance companies). To the former he sends his technical orders through the corps commandants; to the latter, directly. He ascertains personally the execution of these orders in the corps and in the formations.

CHAPTER II. RÔLE OF THE DIVISION SURGEON

We must consider here the part played by the M. D. (division surgeon) at the front as well as in the rear. By front-line service we mean the sanitary service extending from the first-line trenches back to the rest camps and field hospitals; by service of the rear we mean the sanitary service at the rest camps and hospitals.

^a Occasional reports must always include a statement and recommendations.

A. Service at the front

The scope of this service comprises: (1) The wounded, (2) hygiene, (3) combating gas.

I. *The wounded.*—Two points to be considered: (a) Treatment, (b) transportation. The division surgeon will take pains to have the officers and men under his command understand that transportation is a part of the treatment and just as the dressing of the wounded itself. The safety of the wounded depends largely on transportation.

(a) **Treatment:** The time and matériel required in war dressings are directly proportional to the seriousness of the damage done and the number of the "multi-wounded." Strong emphasis must be laid upon the importance of first dressings; upon the need of spacious, comfortable, and well-protected dressing stations. The antitetanic serum must be injected at the dressing stations.

The rôle of the division surgeon is of capital importance in deciding upon the site, establishing and building battalion and regimental dressing stations according to a previously worked-out scheme. If need be, he supplies the corps commanders with men and matériel not included in the regimental allowances. As the division surgeon keeps in touch with the Engineer Corps and the first office, these supplies are easy to forward. These are the best measures to bring the corps commanders to a favorable attitude. It is advisable not to undertake anything that concerns them without having their consent. An undertaking in which this principle is not adhered to might well be deemed a failure in advance.

(b) **Transportation:** (1) Regimental; (2) G. B. D. (divisional litter bearer group); (3) S. S. auto.

(1) **Regimental transportation:** It covers the ground from the spot where the man is wounded to the regimental dressing station. The division surgeon should if possible establish different "navettes" for this stage. By "navette" we mean in this case the area covered in the two-and-from movement of litter bearer details. Each "navette" uses its special means of transportation.

First. "Navette": From the point where the wounded man falls to the P. S. (battalion dressing station), first line. The use of the litter is impossible, due to the character of the terrain; shell holes, narrow winding trenches, etc. (Transportation by hand, canvas, or hammock.)

Second. "Navette": From the first-line battalion dressing station to the relay or second-line battalion dressing station. (Litter carried by hand.)

Third. "Navette": From the second-line battalion dressing station to the regimental dressing station. (Litters carried on small carts.^b) (See Exhibit No. 3.)

(2) **G. B. D. transportation (divisional litter-bearer group):** From the regimental dressing station to the central dressing station of the G. B. D., the regimental dressing stations communicate with the central dressing stations of the G. B. D. by means of communicating trenches of galleries maintained by the G. B. D.

Evacuation trenches: Special evacuating trenches for the sanitary service should be secured to be used exclusively for that purpose in quiet times as well as under fire. The method of securing and maintaining these special passages for the medical service consists in: First, requesting the transfer of only those communicating trenches considered improper or useless for military relief purposes; second, to place them and keep them in perfect condition, employing Medical Department workmen (G. B. D.); third, to put up visible posts and signs serving both as property titles and to indicate the presence and operation of the divisional sanitary service. Evacuation trenches must lead to the central dressing station of the G. B. D.

The central dressing station, G. B. D., should be built on the same plan as the regimental dressing station but on a larger scale. Its capacity for an Infantry division should be at least 30 beds and room for 50 patients sitting. The dugouts must be easily accessible to litters, both entrance and exit. Always be careful to build annex dugouts for the Medical Department men.^c Dressing stations should not be used as quarters for the men. The

^b The carts have the same width as the litters, rubber wheels, and ball bearings.

^c This is hard to carry out; Medical Department men are prone to occupy all available empty quarters, used solely in case of attack.

central dressing station of the divisional litter bearers must be a resting as well as emergency treatment place.

Comfort or resting place: Kitchen, cooking of heavy or liquid diets; considerable importance is attached to the feeding of transient wounded.

Treatment: Antitetanic injections, in case they have not been administered before at the battalion or regimental dressing stations; emergency readjustment of dressings; treatment on the spot of nontransportable wounded.

In order to take better care of the category of wounded just mentioned, the creation of an advance surgical post adjoining the central dressing station is very commendable.

Chief surgeon of the G. B. D.: In a critical situation the G. B. D. chief surgeon becomes automatically chief surgeon of the battle; in this capacity he receives orders from the division surgeon and gives orders directly to all regimental surgeons. This is the only way to distribute reinforcements, to answer requests for help, and to coordinate the different parts of the evacuation service from the first lines to the central dressing station of the G. B. D.

The central dressing station of the G. B. D. must be accessible to the automobile ambulances. In cases of urgent necessity the divisional litter bearers (G. B. D.) must be reinforced by the G. B. D. of the rear line division of Infantry. If need be the employment of prisoners of war to help the bearers is advisable.

(3) Transportation by Medical Department ambulances: Installation of a good telephone system to facilitate calls for ambulances at the rate they are needed is necessary. Calls for ambulances must be directed to the division surgeon. They should always be made according to a set and permanent form. (See Exhibit No. 4.) Care must be taken to keep departing and transient wounded always warm. The wounded must be taken directly to the "ambulance" or hospital where surgical work is to be performed. It is desirable that the medical unit to which the wounded are to be driven should be designated by the central dressing station of the divisional litter bearers (G. B. D.), according to the distribution tags made out at the battalion dressing station through which all wounded pass and are examined.

Every wounded man must go through the central dressing station, where lists of names are drawn up. (See Exhibit No. 5.) These lists bear the wounded man's name, the time he was wounded, time of arrival at the G. B. D. They enable the division surgeon to calculate the average time, to draw its graphic curve, and therefrom to reduce the average time by systematic and successive corrections of delays.^d

In the case of an attack and ensuing congestion of transportation means and lines, it is a good plan to establish an automobile relay between the central dressing station (G. B. D.) and the ambulances. The relay station should consist of tents with a capacity for no less than two to three hundred seated men. Walking wounded will be directed to this point. The seated patients will be reached and assisted by special transportation details until they arrive at the medical units designated beforehand. This is the best way to prevent confusion and preserve discipline.^e

The division ambulances are apt to be at times greatly overworked, with resulting confusion in the effort to transport numbers of slightly wounded, which must be rushed through as quickly as possible in order to accomplish their return to the trenches and preserve the maximum number of effectives. It is, therefore, advantageous to transport them in trucks, and they can then be properly distributed in any desired numbers.

The lieutenant in command of the auto S. S. (automobile ambulances) remains with the auto relay during the attack; he is relieved by the second in command, and keeps in constant telephonic communication with the G. B. D. (divisional litter-bearer group), the ambulances, and the division surgeon. He functions as a regulator. The auto S. S. of the Infantry division in action must be reinforced by the auto S. S. of the rear-line Infantry division and by the T. P. It is imperative to conserve time in transportation and space

^d The main factors of delay are: Time employed in "Navette" No. 1, depending upon the character of the terrain; number of transfers; loss of time while ambulances wait before being dismissed.

^e A simple and quite effective method of preserving order among the slightly wounded during an attack is to compel every man to sit down and to prohibit loud talking.

in the ambulances. Also Medical Department cars and ambulances should not run during the periods when rations are being brought up. In so doing they are exposed to enemy artillery fire and suffer endless delays. To wait until the line is open again saves time and trouble. This moment coincides almost always with that when the wounded begin to arrive at the central dressing station (G. B. D.).

The division surgeon keeps his eye on the movement of the different parts of the evacuation machinery; i. e., regimental dressing station, central dressing station (G. B. D.), auto relay, arrival at medical units. His place is not at the general's post, but wherever his presence is needed to better the condition of the wounded.

II. *Hygiene*.—Preach by setting the example. Medical Department evacuating trenches should be models of sanitation, construction, care of shelters, latrines, etc. Disinfection service should be carried on by details of division and regimental litter bearers, four men to each "subquarter." Cleanliness of shelters. Chemical analysis of water made by the chief pharmacist of the toxicological laboratory; bacteriological analysis made by Army laboratory.

III. *Combatting gas*.—Individual protection: Mask inspection; experience in the gas chamber; marching practice with the mask. The division surgeon and personnel of the Medical Department serve as experts in everything concerning this subject. The toxicological laboratory of the G. B. D. (division litter bearers) is charged by the division surgeon with the distribution of apparatus for individual protection.

Collective protection: Fitting up the entrance and exit of the dressing stations with a system of two articulated panels hermetically adjusted to the joists of the large galleries, leaving between this double door a space equal to one and one-half the litter length. (See Exhibit No. 6.) The "Vermorel" and the hyposulphite reservoir must be placed in a small wall closet in this room. Similar apparatus may be obtained for the company dugouts. (Against attacks of blistering gas see Exhibit No. 7.)

Treatment of gassed cases: Regimental surgeons should not hesitate to resort to bleeding in extreme cases of suffocation by gas. These cases must be given the right of way in evacuation. Prompt washing and change of clothing for men suffering from blistering vapor attacks and evacuation of these men. The chief pharmacist, toxicological laboratory, is the technical agent of the division surgeon for everything concerning gas. The distribution of the collective defense matériel is in charge of the engineers.

B. Service of the rear

1. *The wounded*.—Ordinary ambulance service, concerning which the division surgeon has only general directions to give after having assured himself of the technical guarantees offered by the surgeons.

2. *Patients*.—Establishment of cantonment infirmaries for men not seriously sick and the crippled. Detail one of the division field hospitals to attend men more seriously sick and crippled but who may be returned to duty after 10 or 15 days. The division surgeon should frequently investigate the disposition made of the men he has evacuated. This field hospital constitutes in calm periods what might be called a filter, preventing the melting of the numerical strength. Select a very energetic commanding officer.

3. *Dental patients*.—The division surgeon should take particular care in looking after the installation of comfortable and efficient dental offices. Dentists render inestimable services, especially to officers who want to be treated at the front. Dental work is of such a character that it can only be performed in rest camps. Each rest camp should count upon one dental office with two operators.

4. *Hygiene*.—Camps and cantonments: Inspection of water, shower baths, latrines and quarters; use of efficient personal hygiene sections.

CHAPTER III. METHOD OF PROCEDURE OF THE DIVISION SURGEON

It is entirely a method of observation and execution. Success in execution never depends upon the number of detailed rules and regulations, but upon the personality and acuteness of the executive. The division surgeon should keep clearly before him the end in view and refrain from becoming involved in details. (See Exhibit No. 10.) Execution depends chiefly upon the man who executes and the division surgeon should be given full

power in choosing his men for their tasks. His is the task of psychological preparation of his men. Neither threats nor praise, but persuasion and enthusiasm, should stimulate the surgeon in his work. The method of the division surgeon is twofold, and the two aspects, though essentially different, are complementary to each other. The work is also twofold: Administration, on the one hand, and organization, on the other.

Administrative work.—It is essentially automatic work, to be entrusted to automatons, men capable of repeating well the same processes time and time again. The division surgeon should not touch administrative work with the excuse of improving the same, in spite of the importance attached to it in higher spheres. He will never become the equal of an automaton unless he is an automaton himself. (See Exhibit No. 8 concerning automatic work in the office of the division surgeon.) This does not mean that he should avoid intervention altogether. His intervention must be felt, for instance, when regulations clash with common sense; e. g., when the care of the wounded would seem to be sacrificed for the benefit of regulations. Regulations should be framed so as to permit any broad-minded man to justify measures taken by him in accord with common sense. Thereby the division surgeon can wisely help to correct the mechanical exaggerations of automatism.

Organization work.—Administration is the preestablished form to which is affixed the life of a given service, permitting to foresee, to purvey, and to control. This form provides great security to the development of foreseen, easy problems; it affords all sorts of contrivances to help solve unexpected and more difficult problems. Automatism is acceptable only when it makes possible the proper execution of acts repeating themselves identically and whose sole value comes from this very repetition of identities. There results for the division surgeon an economy of effort, allowing him more time for the solution of problems whose nature defies automatism. War calls forth entirely new unexpected questions to which ready made answers can not be given without risk of confusion and failure. Administration is a static form; intervention is a dynamic function, and its apparent form is called organization.

Organization is the coordination of means invented to resolve problems brought forth by reality as the incessant changes of war go on. Permanently adapted acts may be added as automatic functions, provided their adequate repetition proves to be expedient. They may be registered and regulated by the administration without, however, allowing them to interfere with invented measures, which are the privilege of the organizing genius in his endeavors to coordinate and adapt.

CONCLUSIONS

A biological example may help us to understand thoroughly the functions, rôle, and method of the division surgeon. The Medical Department presents, on the one side, periphery cells with activity of their own; such are the regimental surgeons and commanding officers of field hospitals and ambulance companies. They should possess the following qualities: Impressibility to facts, as one body attracts another; in short, they should be intensely familiar with the external world. It is not to be expected that everybody will show these qualities, but it should be the division surgeon's task to revive them when they threaten to perish. Surgeons can not be easily convinced; they take with great cautions all new suggestions. Innovations can not be forced upon them. In order to persuade them, rap at the door of their intellect, rap chiefly at the door of their heart. It will never be done in vain.

The periphery cells receive external excitation. Transmission, to that effect, must be rapid and direct. The suppression of all unnecessary intermediaries becomes imperative. The division surgeon, acting as central brain cells will revive thereby an undiminished excitation. Far from becoming detrimental to the periphery cells through a monopoly of all initiatives, this gray matter must be a kind of distributing agent of accumulated energies conducive to the maintenance of high individual will standards. Do not try to impose, but rather leave everyone to their own initiative, provided they tend to a common end. The organization of the division Medical Department service, wherein meet the functions, rôle, and method of procedure of the division surgeon, has everything to gain by the encouragement of a free original personality.

[SEAL]

(Signed) Dr. A. THOORIS,
74th Infantry Division, Medical Service,
Division Surgeon.

EXHIBIT No. 1

74th Division S. S. No. 6972.

REPORT BY CHIEF SURGEON, FIRST CLASS, THOORIS, ON MODIFICATIONS TO BE MADE IN THE EVACUATION OF THE MARGUERITE ZONE

DECEMBER 31, 1917.

The G. B. D. (divisional litter-bearer group) at the Moseow Brewery affords a very good shelter, spacious enough for 30 recumbent patients; owing, however, to the establishment at the sugar mill of a regimental dressing station, it was left outside the evacuating zone, and is therefore useless. A new study of the evacuation régime in this zone was made by the division surgeon and the chief surgeon of the divisional litter-bearer station (G. B. D.) after conferring with the colonel commanding the zone. There are reasons for abandoning the Moseow dressing station and attaching the wheeled-litter-relay, located at the junction of Moscow and Mitau communicating trenches, to the G. B. D. The fitting up of the common trench Mitau, ordered through note No. 4535, Q. G./74, dated December 29, 1917, just answers the new disposition recommended. It is understood that the evacuation of the Falaise quarter will be made directly through La Chapelle.

RECOMMENDATIONS

That the G. B. D. dressing station be transferred from Moseow to the wheeled litter relay, where Mitau meets Moseow trench.

Madelon Quarter.—That the evacuation be assured by battalion litter bearers from the point where wounded fall to the wheeled-litter relay.

The G. B. D. from this relay to La Chapelle.

Falaise Quarter.—Evacuation be taken care of by litter bearers belonging to the ehas-seurs company occupying the Marine Woods, extending from the point where wounded fall to La Chapelle.

Telephones be installed in La Chapelle.

Detailed orders will be issued by the division surgeon in regard to the G. B. D.

(Signed) A. THOORIS.

Recommendations approved.

The commanding general of the division.

(Signed)

DE LARDEMELLE.

74th Division S. S. No. 6818.

DECEMBER 22, 1917.

REPORT BY CHIEF SURGEON, FIRST CLASS, THOORIS, DIVISION SURGEON /74, ON THE SUBJECT
OF EVACUATION FROM THE FIRST LINES TO REGIMENTAL DRESSING STATIONS

EXISTING ORGANIZATION

a. Previous considerations.—(1) Technical: In order to obtain good results, transportation work must not exceed the physical strength of the men. Long stages, therefore, should be avoided and short ones encouraged.

(2) Tactics: Defense is organized by zones. It is advisable to adapt evacuation movement to defense dispositions and the men to quarter and zone work. Defense dispositions allow two quarters, one of the first line and one of the second line. Each of these quarters, occupied by one battalion, disposes of one dressing station attended by the battalion surgeon and part of his men. These men belong to the battalion. The roster of forces issued July 10, 1917, does not mention company. Litter bearers, infantry. Litter bearers are attached to the "battalion N. C. O. staff," 7 to each company. Stress should be laid on this fact: That litter bearers are substantially a battalion formation. This must be so to avoid the bad habit exhibited by some companies of "embezzling" all available litter bearers. This deprives the battalion surgeon of all his litter-bearer reserves, warps ipso facto the mechanism of evacuation, and furthermore charges the regimental medical service with duties it has no means of performing.

b. Transportation problems in a sector.—(1) Distribution of men: Litter bearers placed at the disposal of the surgeons of the various units are not sent without precise directions as to their employment.

(a) First-line quarter: The battalion disposes, in theory, of 25 litter bearers and 1 litter-bearer corporal, but he must count on 20 only on account of sickness, leaves, etc. He will attach to each Infantry company 4 litter bearers; that is, 12 to a battalion. Machine-gun companies, usually being divided into sections and these attached to different units, will avail themselves of the litter bearers of such units. Thus 8 litter bearers are left to the battalion dressing station under orders of the litter-bearer corporal.

(b) Second-line quarter: The reserve detail of 8 litter bearers can be reduced to 4, the other 4 being transferred to the zone chief surgeon as a zone reserve.

(c) Zone dressing station: The zone dressing station disposes of a litter-bearer reserve, 4 to each second-line battalion, under the command of a litter-bearer sergeant. If the dressing station attends two zones, it will have a reserve of 8 men.

(2) Transportation: Litter bearers must pick up and carry all wounded fallen in their zone, no matter what their arm or corps. Transportation is carried out by walking posts (navettes).

First post from the point where the wounded fall to the first-line quarter dressing station, in charge of company section.

Second post from first-line quarter dressing station to the zone dressing station, in charge of a battalion reserve section. If the distance is considerable, the zone chief surgeon creates an intermediate relay. In this case:

Third post from the relay to the zone dressing station, in charge of the zone dressing station reserve section. The second-line quarter dressing station can be used generally as relay station.

RECOMMENDATIONS

Experience gives us a few rules with regard to regimental evacuation in a sector.

1. *Post ("navette") method.*—A maximum of efficiency and speed should be demanded of regimental litter-bearer sections, though care should be taken to avoid excessive fatigue, the consequences of which the wounded man himself would be the first to suffer. The methodical operation of the post system accomplishes these ends. The post system consists in dividing the ground into sections, each section or post being covered back and forth by the same detail of men. Posts are limited by the dressing stations. First post from the first-

line trench to the battalion dressing station or first-line quarter. Second post from the battalion dressing station or first-line quarter to the regimental or zone dressing station. Third post under operation only when the distance between the first-line quarter dressing station and the zone dressing station is too long; a relay post is established. Sometimes the second-line quarter dressing station takes charge of it.

2. *Operation of posts.*—(1) Distribution of men in units and dressing stations: The regularity of posts brings forth a convenient distribution of regimental litter bearers. To this end the corps commanders will observe from now on the following instructions:

Each company in line shall have 4 litter bearers, except the machine-gun company, whose sections shall avail themselves of the services of the litter bearers of the companies to which they have been attached.

The first-quarter dressing station shall have 1 corporal and 8 litter bearers; the second-line quarter dressing station, 1 corporal and 4 litter bearers.

The zone dressing station shall have 1 sergeant and 4 litter bearers to each zone obtained from the battalion stationed in the second-line quarter.

(2) Men working on posts: First post, company litter-bearer section; second post, quarter dressing station reserve section; third post, zone dressing station reserve section.

(3) Coordination of posts: Only unity of direction can secure a coordination of posts. This direction is entrusted to the chief surgeon of the zone; he designates the details and regulates the automatic movement of the various posts. The squad sergeant executes the orders issued. The details of men under orders of the zone chief surgeon, without interfering with the distribution principles as prescribed by the post system, form a sort of platoon for sanitary maneuvers, held in readiness for service in its zone, or in the zones served by the zone dressing station, as the case may be. When because of an increase in the number of wounded, and despite the reciprocal aid between zones, the regimental sections fall short of their work, the chief surgeon of the zone requests a reinforcement from the division surgeon, through the division commander. In no case shall the services of the G. B. D. (divisional litter-bearer group) be utilized outside its own zone of action.

It is understood that the use of reinforcements, G. B. D. (corps litter bearers), or territorials, must be subject to the same adaptation to post duties. The same process should be repeated many times until absolute mastery is acquired. All litter bearers should have technical as well as psychological training for special quarter and zone duty. They should also be taught to lift and carry all wounded, irrespective of arm or corps. The division surgeon maintains wounded from the collapsing point to the hospitals.

EXHIBIT No. 4

(G. B. D. to M. D.)

From: Divisional litter bearers to division surgeon.

To: Requesting ambulances for recumbent patients and sitting patients.

N. B.—Requests giving the number of cars and not the number of wounded shall be refused. In time of danger requests for cars are usually overestimated, which results in some cars returning empty.

EXHIBIT No. 6

METHOD OF WORKING PANEL IN TIME OF DANGER

Shut both panels (doors); between them there shall stand constantly one litter bearer or other Medical Department man provided with a "Tissot" and with instructions to sprinkle a solution of hyposulphite in the intermediate space and over the panels.

Whenever a wounded man is to be taken in, open first panel, order the wounded and men in charge to step inside, and sprinkle again the space and the panels. Open second panel, order the detail into the dressing station, shut the second panel and operate again the "Vermorel" in the intermediate space.

EXHIBIT No. 7

74th Division staff. First Office No. 850/B.

Recent bombardments where gas shells have been used called for a rapid survey of the places shelled in order to ascertain the nature of the gas employed by the enemy and to take all necessary protective measures. Battalion sanitary squads are to be in charge of this work under the orders of unit pharmacists, who serve as gas experts.

Experts and sanitary squads will be distributed as follows:

Zone A: The regimental pharmacist and the sanitary detachment of the battalion occupying the bombarded quarter.

Zone B: The regimental pharmacist and the sanitary detachment of the battalion occupying the bombarded quarter.

Zone C: The pharmacist of the G. B. D. (divisional litter bearers) and the sanitary detachment of this formation.

Zone D: The pharmacist and the sanitary detachment of the B. C. P. (litter bearers of the central post) occupying the bombarded quarter.

The terrain occupied by batteries, when shelled with gas shells, will be surveyed by an expert pharmacist under conditions specified in note No. 850/B of 74th Division, dated December 27, 1917.

1. East of the road and north of the river: Pharmacists designated for zones A, B, and C.
2. West of the road and north of the river: One pharmacist of G. B. D. (divisional litter bearers).
3. South of the river:
 - (a) Geais Wood and Oasis Battery, the B. C. P. pharmacist of the eastern quarter.
 - (b) G. ——— Wood, pharmacist of the B. C. P. at rest.

Sanitary squads will be furnished by the batteries situated in places found to have been bombarded with gas shells.

Battery commanders will apply to the zone headquarters, to the G. B. D., or to the commander of the B. C. P. at rest, as the case may be.

EXHIBIT No. 8

OFFICE OF THE DIVISION SURGEON

I corporal.

1. Care and sorting of the mail.
2. Paper work and daily reports:
 - Situation report No. 2.
 - Situation report every 5 days.
 - Situation report every 10 days, etc.
3. Accounting:
 - Cash register.
 - Making out checks and transfer of deposit orders.
 - Quarterly accounts returns.
4. Classification of all documents, circulars, papers, and pamphlets.
5. Personnel report.

1 secretary.

Typewriting, maps, multigraph.

Telephones.

1 cyclist.

Recorder of mail (incoming and outgoing).

Liaison with the army and the division commander.

Checking up of the supplies and drugs requisitioned from the chief pharmacist of the laboratory of toxicology.

FILING OF DOCUMENTS AND CIRCULARS

All papers are classified and distributed in files with alphabetical references.

Experience has shown the convenience of distributing papers under the following main headings:

1. Personnel—
 - Officers.
 - Enlisted men.
 - Discipline.
 - Leaves of absence.
 - General subjects.
2. Subsistence—
 - Food.
 - Heating and lighting.
 - Clothing.
3. Pay and allowances.
4. Matériel—
 - Pharmacy and toxicology.
 - Gas masks and gas supplies.
 - Matériel for sanitary organizations.
5. Evacuations.
6. Treatment of sick and wounded—
 - Contagious diseases.
 - Venereal diseases.
 - Serums and vaccinations.
 - Poisoned men.
7. General hygiene and disinfection.
8. Reports from division surgeon.
9. Daily report on marches and operations.
10. Pay rolls.
11. Periodical orders.
12. Sector file (position and attack).

EXHIBIT No. 10

Without organization there is no good execution. Building up organization depends upon repeating the same things again and again, but it differs from plain routine work in the variation of means according to circumstances. Orders should specify the essential motive to be repeated, but they should leave a liberal margin for the choice of means for the execution of the details. In this way every man knows what he has to accomplish and at the same time he enjoys a certain liberty of action within the limits of his task. For example, orders should designate the starting and ending points of posts ("navettes"), but not the route to be followed, which varies according to the course of the battle; litter bearers will use their own judgment; the shortest road for them may be the straight line, the trench, the trail, or the road. They must be allowed to decide for themselves. The only restriction placed upon them is that they start from a set point and reach another within reasonable limits of time.

Organization is most necessary in the execution of orders while the battle is actually in progress and the inevitable disorder resulting. The argument sometimes presented by

the G. B. D., that it fails to keep the lists of names of transient wounded because of the rush of patients, should be rejected. The careful keeping of list of names in case of danger is an excellent contrivance to regulate the movement, to make the wounded understand that they can not escape being registered, and that any attempted deceit will come to light at one of the units in the rear. When a G. B. D. chief surgeon states that he is overwhelmed and becomes unable to behave in a crisis as he would in ordinary times, there is no clearer sign of his military incapacity. He should be transferred to a position more suited to his temperament. It is surprising to find how many unfit for a given sort of work will prove to be very efficient elsewhere. It is in appointments of this kind that the judgment of the division surgeon are put to the test.

Army Sanitary School No. 62.

WAR WOUND BACTERIOLOGY

SUMMARY OF A LECTURE BY M. LE MEDECIN-MAJOR TISSIER, OF THE PASTEUR INSTITUTE

Historical data.—Bacteriology of war wounds tracing back its origin to the beginning of actual war:

(a) Doyen and Yamanouchi, Weinberg, Sartory and Spillman, Reverchon and Vaucher, Levy-Fourcade and Bollach find *B. perfringens* in war wounds.

(b) Weinberg moreover finds *B. sporogenes* and *B. putrificus*. Sacquepee describes two distinct infectious processes: The one due to the common septic vibron, the other to a new bacteria, *B. bellonensis*. Weinberg and Seguin describe the oedematiens and three distinct infections: A gangrenous form due to *B. perfringens*, a putrid form to *B. sporogenes*, and a toxic form due to *B. oedematiens*.

(c) The work of Carrel on the sterilization of wounds assigns paramount importance to the number of microbes.

(d) Recent researches recall attention to the specific action of infectious organisms

A study of the microbes found in wounds in war.—Classification is derived from chemical properties.

(a) Simple ferments possessing only one dominating diastase which can act on albumen compounds. They may be divided into simple proteolytic and simple peptolytic ferments from their respective modes of action on the molecule.

(b) Compound ferments, two equally powerful diastases, the one acting on albumin compounds, the other on the hydrated carbon compounds. They are divided into compound proteolytic and compound peptolytic ferments.

Morphological features—

Aerobic:

(1) Compound ferments in war wounds—

M. candidus, nonliquefying.

M. flavus, liquefaciens.

staphylococcus.

B. cutis communis.

Diplococcus grisens, nonliquefaciens.

enterococcus.

streptococcus—

(a) true streptococcus; broth does not get turbid; hemolysis.

(b) Saliva streptococcus; broth turbid; no hemolysis.

(c) *Streptococcus tenuis*; very slender chains.

Pneumobacillus.

Proteus vulgaris.

Green fluorescing B.

(2) Simple ferments—

B. mesentericus and *B. Mucoides*.

B. pyocyaneus (4 varieties—yellow, blue, red, black).

Morphological features—Continued.

Anaerobis:

(1) Compound ferments—

*B. perfringens.**B. bifementans.**B. of Baval*, nonliquefaction—

(2) Simple ferments—

*B. putrificus.**Septic vibron.**B. of tetanus.*

Chemical properties.—These microbes are found crowded together and associated in putrefying matter. Study of common putrefaction.

(a) Period of action of anaerobic compound ferments: *Perfringens*, *bifementans*.

(b) Period of action of simple ferments: *Putrificus* and *Septic vibron*. Destruction of the albuminoid molecule.

The part played by aerobic microbes is secondary: In principle, they take oxygen from the tissues; in the end they decompose the amine compounds.

Microbe germs can exert a predominating influence only when local circumstances have become favorable.

Study of aerobic putrefaction. The *proteus* and the *pyocyaneus* taking the place of the great anaerobes—a case of aerobic putrefaction on the skin.

Biological properties.—Two kinds of “toxine”: An adhesive toxine with a small radius of action and an invading toxine, such as that in tetanus.

(1) Aerobic microbes are in general slightly pathogenic pyogenic microbes; streptococcus, the only one of importance in our case, seems to possess an adhesive toxine, a diffusive toxine, and a special hemolysin, *mesentericus* and *proteus*, possessing a hemolytic action due to their trypsin diastase. *Pyocyaneus* pathogenic: *Pyocyanase*.

(2) Anaerobes: They do not seem to possess any diffusive toxins, except that of tetanus. Living tissue is not a favorable medium for the growing of anaerobes; it must become a “terrain” prepared by, first, either aerobic microbes, or second, by a previous mortification of such a tissue.

In war wounds these two conditions are fulfilled. The rapidity of evolution depends on the nature of the superadded aerobic. The greater the tendency of the aerobe to spread in the general circulation, the sooner will the fatal anaerobic septicemia occur.

SUMMARY OF WAR WOUND BACTERIOLOGY, PART II

The primary infection of war wounds may be due to two kinds of causes: (1) Dust, mud, or dirt on clothing and skin; (2) feces and saliva. There exist carriers of putrid germs and also carriers of streptococci.

Two kinds of septic accidents in war wounds: (1) Putrid accidents; (2) purulent accidents.

Putrid accidents characterized by two chief features: Localized forms and diffusive, invading forms.

In localized forms, a variety of aerobes are found: *Candidus*, *griseus*, *enterococcus*, *mesentericus*, some anaerobic, *B. perfringens* always, *B. bifementans* occasionally, and *B. de Baval* as an exception in severe cases.

Afterwards the *Septic vibron* and *B. putrificus* are also found.

Every microbe has its own special cycle of evolution.

Anaerobic infection passes through a maximum on the third day, and disappears between the seventh and tenth days, but persists in badly cleaned wounds; generally it will terminate when swarms of phagocytes will have crept in.

A gaseous abscess indicates failure of the gangrenous and putrid process.

Arrival of secondary pathogens: Pyogenic.

Diffusive forms: Same anaerobic flora with same virulence as above; but aerobic flora is different.

In the slow diffusive form, besides the above mentioned species, staphylococcus or *pneumobacillus*, both pyogenies, are also found.

Stages of the invading process: "oil-stainlike" at first; then lymphangitis with staphylococcus, and finally lymphangitis with anaerobic microbes and hemolysis.

In the rapid forms, streptococcus is always found.

Out of 100 severe cases, I had as an average 39 putrid wounds (anaerobic); in 20 cases, associated with saprophytes only; in 10 cases, associated with staphylococcus; in 9 cases, with streptococcus.

Late putrid infections consist in partnerships of anaerobes and streptococci. Immunity exists up to a certain degree, and lessens danger.

Purulent accidents: Three categories: mucopurulent wounds, purulent wounds, febrile purulent wounds.

Mucopurulent wounds: Contain *enterococcus*, *candidus sarcine*, *mesentericus*; if left open, get infected with *proteus* and *pyocyaneus*.

Purulent wounds: Contain staphylococcus—progressive appearance of secondary pathogens; *Staphylococcus aureus*, *B. cutis communis*, *Proteus vulgaris*, *pyocyaneus*. Special action of the *pyocyaneus* finally predominates.

Febrile wounds: Contain streptococcus, special local reactions; liquid pus very abundant; paring of tissues; general reactions marked—fever, pale complexion, depression, loss of spirit.

Arrival of secondary pathogens; streptococcus does not disappear, is only concealed by overgrowth of the *pyocyaneus*. It can grow well in the blood, the bone tissues, and the articular tissues. Any articulation it has invaded may be considered as irretrievably lost; any bone it has touched will for months and years carry traces of streptococcus infection.

A wound in soft parts, with streptococcus, may occasion fever for 6 or 12 days only; a wound in bones, for 21 days; a wound in articulations, for several periods of 21 days.

So great is the affinity of streptococcus for bone tissue that I never met with any bone fistula, due to a war wound, where streptococcus would be absent.

Streptococcus is the most active, the most tenacious, the most dangerous aerobic species; its presence alone suffices to render surgical intervention of no avail. Secondary streptococcus infection should be avoided at all costs. Isolation for wounded who are germ carriers.

In war wounds, there occurs putrefaction: (1) Common anaerobic putrefaction in recent wounds; (2) aerobic putrefaction "en nappe" in old wounds.

Sudden and rapid poisoning in the former case; slow poisoning, cachexia, in the latter.

Summary: (1) Every wound has its special cycle of evolution depending on the microbial species which causes the infection. (2) Microbial infection is made easier by presence of mortified or bloodless tissue. (3) Any wound, if left opened, will be subject to new microbial invasion.

This shows the absolute necessity of rapid and complete surgical excision, and of suturing at earliest moment; except when streptococcus is present.

Any wound where streptococcus is absent, ought to be primarily closed, and will heal if excision was complete.

Results, Auto-chir 12: Before practice of excision 57 per cent of gaseous gangrene cases proved fatal. After excision, percentage has fallen to 22 per cent. Out of 21 very severe cases, sutured at first, then reopened on account of anaerobes and streptococcus, 3 only proved fatal. Out of 63 putrid wounds without streptococcus, 1 fatal case only (vascular lesion).

Out of 759 sutured cases, 722 cured, 37 voluntarily reopened on account of streptococcus.

Percentage of successes, 88 per cent (including 109 cases with fractures).

If wound was not sutured originally, apply secondary suture as soon as possible.

If saprophytes only in wound, cure certain.

If staphylococcus only in wound, wait from 6 to 10 days.

If streptococcus in wound, wait for 21 days at least before attempting intervention; cure dubious; failure, when it is a case of bone lesion or articular lesion.

WAR WOUND BACTERIOLOGY

By Medecin-Major Tissier

Let us pass rapidly over the phenomena attendant upon the wounds of war. It is a subject of great importance. A war wound is one where the tissues are broken up or carried away by a projectile. Complex phenomena of fermentation take place, upon which depend the future of the case. How can the surgeon foresee the result if he is not cognizant of this phenomena, if he not even able to predict the type of fermentation, upon which may depend not only the functional repair of the affected member but also the life of the patient. Let me warn you that the bacteriology of war wounds dates from this war. The immortal work of Pasteur has made us familiar with ordinary bacterial suppuration. We also know from him one of the particular organisms concerned in the production of gas gangrene. Recent work has shown another species, the *Bacillus perfringens*, even in malignant forms of edema, in various sorts of gangrene, and certain incidental fermentation. We also know from the researches of the Pasteur school the nature and evolution of the germs of putrefaction; but we did not know of the surgery of gas gangrene, diffuse phlegmon, or gas abscess. Suppuration was rare. We knew nothing of surgical intervention. There had to be terrible mistakes made at the beginning of the war to attract our attention to the bacteriology of war wounds. It must be admitted that the great wars of past times have given us no precise information. Neither the Manchurian nor the Balkan wars serve us as a light upon this subject. You all know the information we had at the beginning of this war. First, sterilization of the skin by tincture of iodine; second, packing the wound; third, function. The rôle of our field hospitals was to pack or dress wounds. We all remember the disasters that followed. Those who lived through the Battle of the Marne and the Yser have preserved an awful memory of this time.

Among those who stayed behind in their laboratories, some workers interested themselves in the task of studying and, if possible, of avoiding the dangerous complications which carried off so many wounded. In November, 1914, Doyen and Yamanouchi, and then Weinberg, made a report to the society of biology that in gas gangrene they found *Bacillus perfringens* and various pyogenic cocci-staphylococci, streptococci, etc. Fleming, Sartory, and Spillman, Reverchon and Vaucher, later Levy-Fourcade and Bollach, confirmed the specificity of *Bacillus perfringens*. However, they all brought out the fact that they found this organism more or less mixed with cocci and called attention to the devitalizing of tissues as a factor in the genesis of gas gangrene. The surgeons who closely studied the clinical phenomena were concerned with the multiple forms of these. They found gas forms, gangrenous forms, and massive forms. Raval described seven distinct forms. Bacteriologists tried to find the cause of these distinct evolutions. Weinberg reported *Bacillus sporogenes*, *Bacillus putrificus* and *Septic vibrio* in certain rare forms. Sacquepee described the variety of *perfringens* which he thought was the specific bacillus of malignant edema. Costa and Iroisier also described a new germ, *Bacillus lyticus*. They thought that ordinary gas gangrene was due to an association of pneumococcus and *Bacillus perfringens*. There gradually arose some doubt as to the specificity of *Bacillus perfringens*. It was found in almost all war wounds. Noll, Fisbinger, and Renemontac found a *Bacillus perfringens* in 80 per cent of their cases and the septic vibrio in only 20 per cent. The aerobic organisms played a lesser rôle. They were found in only 50 per cent of the wounds. In opposition to the studies of Edna Steinhart who discovered a toxin of *perfringens* which Hermath Taylor denied, stating that no endo-toxin or exotoxin existed, Sacquepee believed that the ordinary form of gas gangrene was due to the septic vibrio of the massive form, the white edema due to a new species of *Bacillus bellonensis*. Weinberg and Seguin also found different new germs, *Bacillus oedematiens*, in these same forms. Quite recently these two authors tried to find a different organism for each of the two clinical varieties. They divide gangrene into three classes: (1) The gangrene variety due to *Bacillus perfringens*; (2) the putrid variety due to *Bacillus sporogenes*; and (3) toxic varieties due to *Bacillus oedematiens*.

They recognize, however, the existence of mixed varieties. Then came talk of a vaccine of serum therapy. Weinberg and Seguin propose a polyvalent serum for the first hours of infection as a sort of preventive, as well as a serum directed against the dominating species—

therefore, a creative serum. Sacquepee, Marbat, and other authors made researches in the same direction. The surgeons did not seem to take much interest in these studies. They mostly went over to Carrel's method. They laid the wounds open widely depending upon progressive disinfection, the antiseptics, and the Dakin's solution. The chemical bistoury was made to complement the scalpel of the surgeon. The surgeons seemed to be busy in constructing germ cures; that is to say, that the number of microbes only was of importance. The quality of the invading germ was left more and more in obscurity. But a series of events fortunately brought the state of the quality of the germs to its true place and directed surgery into a new path.

We will now take up the microorganisms found in war wounds. They are aerobic and anaerobic. We will class each one of these two varieties in accordance with their chemical properties, which are, basically, the least changeable. We will, therefore, class them in accordance with their fermentative action into, first, those producing simple ferments; second, those producing mixed ferments. Simple ferments seem to possess but one diastase, acting upon albuminoid matter, depending upon whether the intact molecule of albumin is or is not already peptonized. These are designated under the name of simple proteolytic or simple peptolytic ferments. Mixed ferments seem to have equal diastases: One acts upon the albuminoid molecule, the other upon the carbohydrates. The latter produces acid bodies which at certain stages paralyze all diastase action. That is the acidity of arrest for each species. We will subdivide these ferments in accordance with this action upon intact or peptonized forms into, first, mixed proteolytic; second, mixed peptolytic.

Among the aerobes isolated from the wounds caused by war we find many combined ferments. These are first of all of a common variety, the microbes of the air.

Micrococcus candidus.—This has colonies of a characteristic concentric form, white in color, not capable of liquefying gelatine. We can distinguish two varieties: (1) Those which do not convert lactose, but convert all the other sugars; and (2) those which convert all sugars without exception. Their acidity of arrest is the same, namely, 1.47 per thousand, in terms of sulphuric acid. *Micrococcus flavus liquefaciens* has yellow colonies and liquefies gelatine.

One finds among the microbes of the skin or mucous membrane *Staphylococcus albus*, and very rarely *Staphylococcus aureus*, whose acidity of arrest varies between 1.47 and 1.96.

Bacillus cutis communis gives rise to small irregular colonies not discrete and shows the most varied kind of involution. This bacterium is known under many different names—pseudo-diphtheritic, eosine-baeterium, Bacillus of Seborrhea, Bacillus of Acne. It converts glucose, levulose, saccharose, but has no action upon lacto-glucose, maltose, or mannite. Furthermore, one finds three kinds of cocci, all of them forming small colonies. These are *Diplococcus griseus*, enterococcus, and streptococcus. The first is irregular in shape, even in short chains, and is capable of a slight effect upon glucose. The enterococcus, on the other hand, possesses powerful qualities. It converts all the sugars, giving an acidity of arrest of between 2 and 3. It always clouds bouillon and grows well on potato and gelatine.

The streptococcus deserves our more careful attention. There exist several varieties. The classification of streptococci has been the subject of numerous discussions during recent years. After admitting the existence of several varieties of this species, one is forced to return to the conception that there is a single one. You recall the celebrated discussions between those who admitted the existence of only one variety and those who believed in the existence of several. It is necessary to return to the ideas of Veillon, who 20 years ago described three varieties of streptococcus—*Streptococcus pyogenes*, *Streptococcus salivarius*, and *Streptococcus tenuis*. The means that we have actually had at our disposal, namely, the fermentation test and complement fixation, have only emphasized the difference between these varieties based on morphology. There is a true streptococcus in long chains which does not cloud acid bouillon. It does coagulate milk; it does not grow on potato and but poorly on gelatine; it gives an acid arrest on glucose bouillon of between 1.47 and 2 and hemolyzes blood.

Streptococcus salivarius appears in long chains, clouds bouillon, coagulates milk, grows on potato in certain cases, gives an acid arrest of between 2 and 3, and is not hemolytic.

Streptococcus tenuis is much less common and very little is known of it. Complement fixation emphasized the difference between the two species described, as well as did morphology and its clinical manifestations.

In addition to the aerobes possessing combined fermentative qualities found in wounds of war, we should mention three microbes occurring with varied frequency. All three ferments produce acids but very slowly and give a marked production of ammonia. Properly speaking they should be described as aminolytics. They exert a more marked action than those of peptone. They are *pneumobacillus*, *Bacillus proteus vulgaris*, and *Bacillus fluorescens*. These three species are not met with in the same frequency on all fronts. On the Flanders front in 1915 I did not meet with the *pneumobacillus*. I found several samples in 1916, but not often. On the other hand, on the Aisne, this bacterium appeared to me to be the most frequent especially in rainy weather. The Belgian bacteriologists told me that they have at times run across the *Bacillus coli communis*, but that has not been my experience. The aerobes that one finds in wounds of war are two classes—*Bacillus mesentericus* and *Bacillus pyocyaneus*. The first is very frequently encountered in recent wounds of the war; it grows easily in dead or contused tissue.

The most common variety that has come to our notice has been the *proteus*, which has a slow action upon glucose, maltose, and levulose. Le Gros in 1902 described among the gangrene-forming bacteria one very similar to this, if not the very same one, which he spoke of as *Septicus aerobius*.

Bacillus pyocyaneus is a well-known species. It has powerful fermentative qualities.

Now we come to a consideration of anaerobes. We have isolated the *Bacillus perfringens* as having fermentative properties. It is a large immobile bacillus, with square ends, and appears to be capsulated. It liquefies gelatine, destroying rapidly albuminoid material and sugars. It possesses three diastatic properties similar to that of the pancreas, all of which are very powerful. This very common bacteria was first seen and described by Welch, and more completely described by Veillon and his students, and finally studied from the surgical point of view by Tissier and Martelly. It gives rise to large oblong spores. In conjunction with this bacterium, of which one finds many varieties in the wounds of war, should be mentioned a similar bacterium, *Bacillus bifermentans*. It is immobile, destroys albuminoid materials, gives gas and traces of indol, but has no action on lactose. It was described by Tissier and Martelly. It produces small, round spores.

The *Bacillus putrificus*, isolated by Bienstock in 1899, was studied from a chemical standpoint by Sehaline and by Martelly in 1902. It is a well-known species. It has a round ball for a terminal spore. The *Bacillus Barat* is very mobile and is, in my opinion, a variant from the *Vibrio septique*, from which it does not differ either from a morphologic or surgical point of view. Weinberg and Seguin have noted a difference here, however. It is differentiated from *Bacillus putrificus*, because it possesses the appearance and greater part of its chemical characters in that it gives indol, and above all by its pathological action. Some authors also speak of similar anaerobic microbes isolated by Veillon and Zuber, found in different types of gangrene: *Bacillus ramosus*, *Bacillus fragilis*, *Bacillus Microc*, and *Bacillus parvulus*. These species are very difficult to separate, and of the chemical action of each very little is known.

But where did these species come from? It is an interesting thing that one always finds them grouped more or less together as associates, and more or less numerous following the intensity of the infection. Whatever the reason, one finds almost always the same microbes. Their common origin is animal matter (putrefactive) or detritus of food, and human or animal cadavers, mixed with the soil, the dust, and the mud. In order to better understand the action of these microbes on the wounds of our soldiers we will now seek to define the manner of their destroying a cadaver; that is to say, how they produce common putrefaction. Taking a fragment of muscle in a cadaver exposed to the open air, the chief element in the tissue is albuminous. The first microbes capable of attacking all of these materials ought to have mixed ferments; then when the hydrocarbons have disappeared, simple ferments will destroy the albuminoid matter. That is what happens. In the first phase of mixed ferments we see the aerobes appear, staphylococcus, *M. candidus*, *enterococcus*, streptococcus, *Diplococcus griseus*, *pneumobacillus*, and the *Bacillus coli communis*. They prepare the terrain; they deoxidize the mass. Then rapidly, at the end of some hours—12 to 24—the anaerobes appear—*Bacillus perfringens*, sometimes *Bacillus bifermentans*. Their action is lively, brutal, and rapid; the muscle loses its rose tint and becomes livid, swollen; between the muscles and muscular planes and throughout the length of the vascular sheaths small bubbles of gas

are produced, tearing apart the tissues. This production of gas gives a slight sulphurous odor. The microbial fermentation seems intense, muscular fibers are torn apart, and the fibrillae are separated one by one from their attachment to the sarcolemma on account of its liquefaction. The trypsin attacks the albuminoid substances and the serum-albumins, and the gelatines are liquefied first. The saccharolytic diastase destroys the glycogens and the lipase destroys the fats. At the end of some days another phase is produced—the phase of simple ferments. The important anaerobes (putrid) increase in numbers in their turn and now get into action. They are the *Bacillus putrificus*, the *Septic vibron*, and in its turn, the *Bacillus sporogenes*. At this time appears the real putrefaction. The tissues assume a darker hue, then become black. They become disassociated and make a frightful putrid mass. There are no more hydrocarbons and the diastatic action is now confined to the albuminoid materials. First the molecule is disassociated and albumoses, peptones, etc., are produced by these anaerobes. Second, the above-mentioned albumoses, etc., are now changed into amines. They may even commence destruction of the amines with throsin derived from phenol or tryptophane. Third, these residual substances, these incompletely destroyed amines are attacked by the microbes of the rear guard, great producers of ammonia, and are completely destroyed. These anaerobes are such as the *diplococcus magnus* or the aerobes, such as *Bacillus pyocyaneus*, *Bacillus proteus vulgaris*, *Bacillus griseus*, *Bacillus coli*, and *Bacillus* of pneumonia (Friedlander's).

As we shall see, each microbe preexists in the tissue, but it can not preponderate until the medium has become favored for it.

Such is common putrefaction. But if we open the tissue to the fresh air the anaerobes can not develop. They will be replaced by the aerobes—*Bacillus proteus vulgaris*, *Bacillus pyocyaneus*, *Bacillus mesentericus*. The action of the aerobes will be different. They will be less brusque, less strenuous, their action will be more insidious and a great deal slower. These actions will be more specialized. Each organism produces its acid action. The great proteolytic representatives will alone produce the destruction of the albuminal molecule. They will take it intact from organic tissue and change it into biurates or into amines or ammonias. We will also have the first phase of mixed ferments with that of candidus, staphylo- and streptococci, and a phase of simple ferments by *pyocyaneus*, *proteus vulgaris*, and *mesentericus*. There exists, however, one type of case in which putrefaction is frequent. It is in the skin of dirty, unkempt persons. The epidermal scales and secretions accumulate in the folds of the skin, where they ferment and putrefy. The same thing happens under the nails.

You will find here all the aerobic microbes of which we have already spoken some. They are the color of sweat of unclean persons. The blue and red sweats seem to be due to different varieties of *Bacillus pyocyaneus*. The *Bacillus cutis communis* belongs to the preceding group. It is a type which seems to have a special avidity for certain fat bodies secreted by the skin.

Now, gentlemen, we have studied the microbes of war wounds. We have seen from whence they come and what they are capable of doing without the body; and we will now see what they do within the living being. Let us study the pathogenic characteristics:

We know that microbes act in two ways; by toxins more or less fixed or adherent to the microbial body, and directly on the cells in the vicinity. But there are microbes that produce gangrene and those that diffuse their poisons to a distance, as those of tetanus. By inoculating animals with pure cultures of bacteria one is able to tell the nature of bacterial toxins.

Sarcinus, candidus, griseus, enterococcus.—*Sarcinus, candidus, griseus*, and *enterococcus* are not pathogenic. It is necessary with these to inoculate the animal with great quantities of the culture to occasion any trouble whatever; that is to say, saprophytes have only local action. All the other microbes are called pathogenic: *Staphylococcus*, *streptococcus*, *pyocyaneus*, *pneumo-bacillus*. When they reach the cells the phagocytes are poisoned, die, and form in the blood globules of pus. This action is visible and slow, as with *staphylococcus*, gold and yellow. *Pneumo-bacillus* acts in the same manner. The *streptococcus* has not only a local action but a general action; that is, it produces the diffusing toxin. Marnerec says that he has killed a rabbit with a thousandth of a cubic centimeter of culture. The other microbes have no toxic hemolysin. It is a microbe living very usually in the blood. It is a forceful

species on account of its action against neighboring tissues, its toxin action, and its hemolysin. The *mesentericus* and the *putreficus* destroy blood also by the action of tryptic diastase. *Bacillus pyocyaneus* is pathogenic and acts locally. It secretes also a curious diastase, *pyocyaneus*, which had the property of rapidly dissolving all cellular elements as microbes do in culture.

Living and bloody tissue is not a favorable medium for anaerobes. It is necessary that the soil be prepared first. The septic vibron kills easily, with the staphylococcus in 20 hours, with the streptococcus and the *mesentericus* in 6 hours. In considering the virulence, the *Vibron septique* becomes inoffensive when the aerobes are removed; you obtain the picture of gas gangrene described by Pasteur, sometimes a slow process, and phagocytosis is produced, and gas gangrene is abated, prevented by phagocytosis. Second, in tissue destroyed or digested by chemical action, *perfringens* or *vibrions* are killed incidentally. Third, by mixing in damaged tissue aerobes we produce exactly the condition of a war wound. This condition produced generally by the local action caused by the growth of anaerobes. The corpuscles are destroyed by hemolysin and the microbes produce a zone of dead tissue, the microbes will diffuse quickly while decomposing the killed cells by the tryptic ferment, and then, by a process of other actions of diastase, they make a veritable putrefied body. They extend like a spot of oil and stop at the articular plane. At last acute septicemia and death results.

The rapidity of the change depends on added aerobes, saprophytes. Staphylococcus and *perfringens* take one day; streptococcus and *perfringens* take one-half day. The aerobes have a great tendency to spread into the whole circulation and septicemia is then very quickly produced by the anaerobes, the last stage of the disease.

These, gentlemen, are conclusions of my personal researches. Do not forget, however, that other investigators have obtained the death of animals by injected cultures. I have seen guinea pigs die from subcutaneous cultures of *perfringens* in Gelose. Weinberg and Seguin say that they have killed guinea pigs with injections amounting to 1 or 2 cubic centimeters of liquid culture. I do not know the technique of the first experimenters, but I know that Sacquepee centrifuges the culture and injects the precipitate. He can then produce in this case a true chemical action in the living tissue that favors the growth of anaerobes. In finishing I want to call your attention to the series of experiments of Vaillard and Vincent on tetanus, cultures in which the diffusible toxin of Nicolaier's bacillus never developed. Young cultures in consequence of their youth do not produce a diffusible toxin. These bacilli follow the same development as the anaerobic Nicolaier.

It is necessary that the microbes have a favorable terrain to germinate in, in living, healthy tissue. Now remember well this last. It is a precious knowledge that will guide us when we attempt to cure our wounds of war. So in the destruction of dead tissue, as well as in an attack on living tissue, we see the microbes associated together. They aid one another in a fight where each gains his profit. As soon as one of them finds a suitable medium he increases and suffocates the others. In his turn he dies in the medium which he has destroyed.

In the next lesson we will study the growth of microbes in the wounds of war, the character that they impress on the wounds of war, and the surgical deductions that we will draw from this investigation.

In finishing, gentlemen, let me say that the greater part of the works that we have studied in this course of our researches—that is, the knowledge of anaerobes, the study of gas gangrene in distribution of bacterial flora action against microbes—these works are almost exclusively French, and it is with joy that I say they serve the most of cases.

SECOND CONFERENCE

In our first conference we have occupied ourselves solely with bacteriology, which was a subject which it was indispensable to consider in order to know better what will now follow. We have enumerated the different germs found in war wounds, at least in those parts of the front which were the theater of military action—Flanders and Champagne. We have studied the characteristics, chemical properties of these germs, and we know under what conditions they can be dangerous for the living organisms. We know their common origin; we have followed their evolution. This common origin is important in a study of putrefaction. This

putrid material is abundant all around human habitation, manure piles, débris of all kinds, etc. We had already noticed at the beginning of the war how differently wounds act when they are soiled and when they are contaminated. Those were exceedingly grave that had been polluted by the soil of stables or cattle sheds, which are receptacles of all kinds of filthy material. Later when trench warfare began these differences became greater. This first-line zone contains so many corpses and so many kinds of refuse that the wounds become, so to speak, uniformly infected. The weapons, the uniform, the skin were soiled dangerously by this earth. But putrid matter is not only found around us; it exists also in our interior and mucous membranes. Meat diet favors intestinal putrefaction, and it exists in animals and fowls. We find *enterococcus* and *Bacilli perfringens* in almost all individuals. *Staphylococcus*, *streptococcus*, *pyocyanius*, are exceptions. These are, to use the expression, pathologic germs, but each may be found in individuals presenting digestive trouble of slight character, and such people remain more or less germ carriers. We know how frequent these intestinal infections are amongst men who give little care to their elementary hygiene. Lax, notwithstanding all the advice and supervision they get, they are not very careful of their bodily hygiene. They are frequently soiled, and it is easy to understand that the second cause of infection is perhaps more common than the first. From a clinical viewpoint we can distinguish two kinds of wounds as putrid and purulent. The first to appear are putrid conditions; gangrene or gas appears. We hardly knew them in peace times. They were exceptional accidents occurring in cases of crushing. They have shown themselves from the beginning of the war extremely frequent and have caused numerous victims. Purulent conditions give a dirtier appearance. They are observed in hospitals in the lines of communication and the rear. We believe that putrid accidents can be divided into two categories: Localized forms and invading forms. The putrid process seems to localize around the wound. Tissues are pale, allowing blood like beef washings to escape, reddish brown in color, putrid in odor, and containing fine gas bubbles. The general condition is bad, the skin is pale, the pulse a little rapid, and the temperature reaches 30 to 38½. In the slightly progressive form the tissues appear washed out. The muscle takes the color of a dead leaf and between the muscular layers, in the fluid which looks like currant jelly, there is slight crepitation. The skin is pale, slightly yellow. It shows long streaks of brownish hue, giving a color that causes the name, trench lymphangitis. The skin is tense, sonorous. The general condition is bad, the pulse is small and rapid, temperature reaches 39, the patient is anxious, perturbed, and appears to suffer. In rapidly invading forms the muscle is likewise the hue of a dead leaf. When the wound is opened by incision the tissues have a washed-out appearance. The muscles are swollen; they bulge between the lips of the wound. The same edema, the same serous blood, and nauseating odor exists, but it seems to infiltrate the whole limb. The blood which is collected in a pipette does not coagulate any longer. The skin is tense and produces a special sound when it is scratched or when it is percussed. The streaks of lymphangitis are numerous and appear rapidly. In many forms the skin remains pale and we have to deal with the so-called malignant white edema, which is almost always fatal. The general condition is extremely bad. The pulse is thready, uncountable, the temperature reaches 39° or 40°. The patient is anxious. Death appears likely when surgical intervention is inadequate or delayed. Indeed, death may occur when the intervention is rapid and judicious. What is the flora in each of these cases? One may say that as a general rule the serous blood collected in the tissues are gorged with bacillary forms which culture reveals.

Germs of putrefaction.—In the localized putrid form we find in our Petri dishes or in ordinary agar tubes the following germs: *Sarcina*, *M. candidus*, *griseus*, *non-liquifaciens*, *enterococcus*, and *B. mesentericus*. All our tubes with deep inoculation show thousands and thousands of colonies of *B. perfringens*. Sometimes one also notices, but more rarely, *B. bifermentans* and *B. bavai*.

We see that this putrid process is not of long duration. On the third day the influence of phagocytes takes place. The putrid serous blood is replaced by a serous blood of a more reddish hue, more and more thick, more and more purulent in character. On the tenth day anaerobic germs disappear. But this is so only in case that our wounded man has been treated. If he has remained between the lines or has not been brought to the hospital in time, putrefaction will continue around foreign bodies, around fragments of clothing, in pockets

containing devitalized tissues, where we will find multiplication of our putrid organisms to which newcomers have joined themselves—*pyocyaneus*, etc. An abominable stench escapes from the wound, and on the fragments of putrid tissues we will find the development of fly maggots; fetid pus escapes from the wound. Gas abscess may form, but gas abscess is the end of a putrid process. It is an abortive form of gas gangrene process. The gravity of these wounds depends upon two factors:

First, the extension of the process up a muscle, or, better still, the extension through tissues which have lost their normal blood circulation. As we have seen in the course of our experience, anaerobic germs only develop while in tissues that are deprived of their normal oxygen; that is to say, a tissue deprived of its blood. Every obstacle to circulation increases largely the extension of the putrid process. The patient may die from the absorption of these putrid products, outside even of the absorption of toxins. The same effect can take place in wounds of hand grenades or by aerial torpedoes. Multiplicity of wounds produces an intensive result.

Second, or the other factor of gravity, is the intensity of the infection which can be appreciated by the great number of anaerobic germs. In light forms one only meets *B. perfringens*. In more serious cases one finds, besides, other mixed forms, such as *B. fermentans* and *B. Barati*, *B. putrificus* and *B. septicus*. All of these wounds contain *B. perfringens*. Every gas wound, every gas pus, contains *B. perfringens*. In not one case have I found in a wound from which escaped fine bubbles of gas only *B. mesentericus* and *enterococcus*. In these cases anaerobic germs develop in the crushed tissue when the multiplication is abundant; their zone extends slightly like a grease spot until phagocytes appear on the third day, but the pyogenic organisms associated with the anaerobic develops better in normal tissue; these extend further and prepare the way for the anaerobes. One can follow these two classified advances in the evolution of lymphangitis. First one has the course of the ordinary lymphangitis, giving to the skin a rosy hue. Then later the first is attended by a red or violet hue, spread in irregular curves. This is due to the anaerobes and the purpuric spots due to the hemolyses which it produces. If the surgeon intervenes he amputates in an apparently normal tissue and will stop the putrid process, but the lymphangitis will continue in the stump. This lymphangitis due to anaerobes is attended by a series of symptoms due to these germs. The tissues are tense, there is an abundant production of gas and destruction of the red blood cells. The process stops for a few hours at the level of joints where the same tense tissue seems an obstacle to its development. Naturally, the two factors of gravity which we have mentioned for the other form exist in this much graver form. They may terminate, as we said above, by the formation of a gas abscess, but their extension, more or less rapid, is always to be feared. In the rapidly invading form we find, also, the same anaerobic flora, varying likewise according to the intensity of the infection, but the real factor of rapid extension has not appeared to me to be due to one or another anaerobe but to the association of aerobes, in which we constantly found staphylococcus. Everything seems to bear the mark of this. The patient is depressed, his pulse is rapid, and his high temperature recalls what we have observed in grave staphylococcus infections.

It is easy to understand the gravity of the accidents which took place when one realizes that to the putrid and toxic action of the anaerobes is added the action of the streptococcus.

In the case of white edema, with a subcuticular discoloration of the skin, the destruction of red blood cells is very considerable and invariably death follows when the surgeon has not been able to excise and cut short anaerobic activity at its onset. One may operate and stop the putrid process, but one does not stop the streptococcal invasion and the patient continues to have fever and to run down in health in a manner characteristic of all streptococcal infections. These putrid indications, of which some are so grave, are relatively frequent in the hospitals on the front. Thus in Auto-chir No. 12 we were able to observe in June and July, on an average, in a hundred grave wounds 39 putrid infections due to anaerobes, with 10 cases of streptococcus and 9 cases of staphylococcus.

Aside from these initially putrid infections, we must say a word on the secondary ones. In the hospitals of the rear one can observe accidents simulating gas gangrene following surgical intervention—the removal of a foreign body or a piece of shell. I have been able to observe only one case in a hospital in Dunkerque. The bacterial flora was of that rapidly invading form, that is to say, association of *perfringens* and streptococcus.

Purulent conditions.—There are three categories: (1) Mucopurulent wounds; there is only a film of muco-pus covering the wound like a varnish. (2) Purulent wounds; the pus is more abundant, always thick, yellow in color, the edges of the wound are red and moist, there is a slight lymphangitis, and there is no fever. (3) Febrile purulent wounds; the pus is very abundant, and it has a tendency to extend, to dissect up surrounding tissues; borders of the wound present a livid aspect. In summer the patient is surrounded by flies which further contaminate the wound. It is to be noticed that in our putrid wounds when the anaerobes have disappeared they will take one of these three aspects.

Here, gentlemen, you can see three curves which are most characteristic. Let us now study the bacteriology. In muco-purulent wounds one can only find saprophytes. This flora is not very harmful. In the process of cicatrization very little pus is produced, but contamination by new species of organisms is insistent. This may occur from frequent dressings, the constant contamination from bedpans, sheets, hands of other patients and orderlies. In purulent wounds the flora is more complicated, and we find in more or less greater quantity staphylococcus.

The temperature begins to drop on the fifth day. In the fluids which soil the skin, in the squames of the macerated epithelium, we find the *pneumobacillus*, *B. cutis communis*, *proteus vulgaris*, and *pyocyaneus*. The wounds yield an odor of old urine when it is infected by *proteus*, a pungent odor when it is infected by *pyocyaneus*, and the gauze dressing is colored a golden or yellowish red with a greenish blue border according to the variety of the infecting bacillus. From the moment of their appearance in the wound these last two germs appear to occupy the stage. They appear to drive the others off. It is only after long weeks when the wound is almost completely scarred over that we note the disappearance of *proteus vulgaris* and *B. cutis communis*. Evidently every purulent wound has not such a rich flora. There are some which contain no *proteus*; there are some which contain no *pyocyaneus*. In some we find only staphylococcus, but they are rare. These secondary infections, notwithstanding what has been said, are almost the rule. In febrile wounds one always finds, alone or associated with the preceding, the true *Streptococcus pyogenes*. One may say that from the moment of its appearance in the wound this germ gives the wound and the patient a special character which does not mislead a trained observer. Local reaction, violent and rapid, with more or less extension of lymphangitis and infiltration of the surrounding tissue which stiffens the lips of the wound and gives it a livid appearance. General reaction is as violent as the local one. When you enter a ward containing streptococcus patients their appearance remains forever graven upon your memory. The evolution of this germ in the wound is also very characteristic. As you see, the descent of the curve is infinitely slow. The same secondary infections take place as in other infections—*pyocyaneus*, *proteus*, etc.

One finds it holds out to the last in the diverticula of the wound where it still abundantly grows. This germ is one that grows rapidly in blood owing to its hemolytic property. There are also two other tissues for which it has a special preference, joints and bones. Whenever a joint or a bone is in the neighborhood of the streptococcus, the slightest erosion, the slightest trauma is sufficient to open it a passage. Sometimes even one is puzzled to know if this infection can not take place without a preceding lesion. This invasion is always attended by a violent reaction, both local and general. Every joint that has been contaminated can be considered as lost; every bone that has been infected will keep for a long time—months, and even years—a trace of streptococcal infection. A wound of the soft parts contaminated by streptococcus will be attended by fever lasting 6 or 12 days; a wound of the bone will produce fever for 21 days, and an articular infection will produce an excessive series of fever lasting several periods of 21 days.

Army Sanitary School No. 64.

THE GENERAL ORGANIZATION OF THE MEDICAL SERVICES IN THIS WAR

By Col. B. K. Ashford, commandant

Gentlemen, you had an opportunity to visualize some of the problems and the manner of their solution at the British front, and have heard how these same problems are met by the French. Let us try, if we can, to consolidate our ideas, in view of what we have seen the exigencies of this war require. Three essentials in the medical services at the front stand out very vividly:

First. The collection of the wounded from the trenches, their conduction to the battalion aid post, and administration of first aid, and their forwarding to the ambulance head.

Second. The rapid, and as far as possible uninterrupted, conduction of these wounded to the first hospital on the battle field which can offer proper surgical conditions for treatment.

Third. The surgical treatment at a well-equipped hospital generally requiring definitive surgical intervention and retention until convalescence is established in time of relative inactivity, of surgical intervention on practically all seriously wounded—I would rather say in a large portion of the seriously wounded, and any such number of other selected cases as it may be possible to operate on, with generally immediate evacuation thereafter, during the strain of violent activity in which great streams of wounded pour in. This hospital corresponds to what we know as the "evacuation hospital" and should be on a spur of a railroad.

That is to say, the first problem is collection and first aid; the second, rapid and comfortable transportation to the rear; and the third, surgical intervention to avoid infection. The first two elements in previous wars were considered to be military necessities; the third, thanks to the new method of Lemaitre and the removal of devitalized tissue and foreign bodies and closure of the wounds, imposes upon all thinking men this third desideratum also as a military necessity, upon which depends whether the soldier is to rejoin his organization promptly and be fit to take part again in active operations or be sent to suppurate for an indefinite time in the interior and, perhaps, lose a part or all of his efficiency as a soldier.

FIRST. COLLECTION OF WOUNDED AND FIRST AID.

Our large battalions require two battalion surgeons—one free to accompany troops and be within call for special situations in the fire bay, and the other to remain on duty at his post in the aid station. At this station, the first place where the wounded man usually sees a surgeon, there should be a small case of instruments for emergency surgery, corresponding dressings, and such medicines as are necessary for the treatment of the ordinary medical conditions which may arise. Special features, however, should be noted. Dressings should be abundant and renewed at frequent intervals as per necessity from the field hospital; there should always be on hand Thomas splints, and every man should know how to put them on—knowledge to be acquired by drill—so that under the excitement of battle or in the darkness of the night the Medical Department soldier will be able to perform his duty mechanically. One of the most important of all the preparations for a wounded man at this station should be those providing for the prevention of shock, and the British system—three blankets on litter with stove underneath—is recommended as of universal feasibility. Lastly, this is the station par excellence for adequate gas protection and means of overcoming the immediate effects of gas.

We have seen how regimental surgeons seem to be keener on the gas situation than on any other thing that happens to the soldier and more than ordinary preparations should be made to have oxygen apparatus prepared; to provide for change of clothing, and for soap and alkali baths to get rid of the progressive effects of mustard gas.

Whatever may be the source of the stretcher bearers, 32 to a battalion is a bare necessity and provision should be made to run in 32 more in time of attack. Great care must be taken to get strong men and men of exceptional bravery, as there is no more exhausting work than stretcher bearing and no soldier should possess higher morale than the sanitary soldier. En route from the battalion aid station to the ambulance head, at some portion of the road, perhaps all of the way, both wheeled litters and narrow-gauge railroads are of utmost importance. Indeed, over these long stretches, especially where carrying by hand has to be done, relays of sanitary soldiers should be provided, the distance between them not being over a thousand yards. There is no wheeled litter better than the Miller-James of the English or the latest model of the French. Both are rubber-tired wheels and all steel. The Miller-James wheeled litter has the disadvantage of having pneumatic tires and the great advantage of being collapsible, allowing large numbers to be carried on a wagon.

The conduction from the battalion aid station should be uninterrupted, and it is very questionable whether the regimental aid station is needed or even justifiable; indeed, the ideal would be to have the regimental surgeon oversee the work of his three battalion stations

and attend to the evacuation of the wounded to the ambulance head, where he could see them get off in good condition and effect a liaison between the medical units of the regiment and those of the division at that head.

SECOND. EVACUATION TO THE REAR

The ambulance dressing station should be equipped to receive a sufficient number of patients and hold them for short periods in event of interruption to the line of communications. Indeed, near the battalion station there should be a forwarding station dugout manned by sanitary soldiers. At some points it appears evident that the function of the ambulance dressing station is chiefly summed up as follows: Protection during delay in forwarding and preparation for emergency treatment. Here antitetanic serum will often have to be administered, gassed cases treated, shock prevented or combatted, splints supplied, dressings readjusted, and men fed as well as given hot drinks. Two ambulances should be kept at all times at this station, where there should be at least two officers and such a number of men as may be necessary to handle the wounded coming in. There should be accommodations for at least 30 lying and 50 walking wounded. This is an ideal not often, unfortunately, possible to attain. There should be no undue waiting about to collect a load before starting when one considers that the chief object, once a man's shock is treated and he is prepared for the journey, is to get him into a surgical hospital where immediate operation may be done to avoid the consequences of infection. The ambulance used by the British, by common consent of all who hear me, is the best ambulance we have yet seen. Its motor is quiet and it is large enough to move about in, much larger than our own, which preserves all of the qualities of our original horse ambulance, but which has given us no more room to move about in. In fact, the British ambulance is a sort of a van and is well sprung. Above all, I wish the officers to bear always in mind the perfect condition of repair and the orderly cleanliness of these machines at all times. They all look as if they had just come from the shop, and some of the brightest and best looking of all, we were told, had been running three years. This means hard work on the part of the team assigned to running the ambulance. We have heard that there is no excuse for a dirty ambulance, and whenever the ambulance stops the man sets to work to clean it up immediately; it is the first thing he does in the morning and the last thing he does at night, no matter how late it may be. We have seen the horse ambulance as well. I don't believe in all my life I have seen transportation in such beautiful condition. The matter of transportation to the rear is a very important one, and one of the three links in the great chain that make for the salvage of wounded men.

Concerning the evacuation of wounded, the British hold that there are no nontransportable cases, on the ground that once a wounded man reaches the ambulance head he has already passed through the worst part of his trip to the rear. He can not be kept at the battalion dugout, and once at the ambulance head a half or three-quarters of an hour more in a comfortable ambulance will not injure his chance for recovery nearly so much as to retain him where he can not be properly treated in time to prevent infection or in time to perform operations which are manifestly impossible at the front. The English state that they have tried out special surgical hospitals near the front and save in rare instances, where they could be put in quarries and tunnels or caves, they have been failures. It was stated to us on no less authority than the chief surgeon of the First Army that surgeons can not properly operate on a patient under shell fire, nor can any considerable number of badly wounded men be provided with sufficient surgical matériel when fallen on the battle field. They, therefore, do not call a man nontransportable until he reaches the casualty clearing station, which corresponds to our evacuation hospital, which they have recently placed at a distance of not less than 12 km. from the line. They believe, as necessary transportation from the trench to the ambulance head has been done, that the only considerable thing that would prejudice his condition has already been done, and that that which remains is much better than to leave him at the front in a hospital which must always be manifestly inferior in equipment and infinitely more dangerous. The French still try, where possible, to provide some sort of surgical equipment in men and matériel for the wounded man while still under fire, and the answer for us is practically that in cases where humanity demands such an advance of a surgical hospital it should be in the shape of a motor, portable operating,

and radiological equipment, which should be sent to the front only under conditions of great stress. Anything which interrupts in the ordinary course of events the prompt transportation of a wounded man from the first-aid station to the first hospital where he can be treated under modern surgical conditions is in principle wrong. Moreover, the scattering of special hospitals, as has been attempted by many humanitarian physicians and surgeons, all over the battle field should bring to our minds that each one of these hospitals has to be equipped and manned and requires a separate and distinct line of evacuation and multiplication of ambulances. The watchword for us to-day should be to get our patients back, within eight hours at least, to the place where they may be finally operated upon and wherever possible retained until convalescence or until they can be safely moved, a rule which must be modified only in time of great activity, a time which does not occur more than 2 weeks out of 52 in the lives of most divisions.

We come, therefore, to the third essential, the evacuation hospital. Roughly speaking, this should have 2,000 beds per 25,000 troops. Operative cases, with primary suture, débridement, require that they be kept a week to 10 days at least. There should be special wards and special teams for fracture cases, chest cases, abdominal cases, and the ordinary wounds of soft parts. It is better to have any special hospitals which may be created in the rear of the evacuation hospital but within reach by motor from this hospital. Especially important are hospitals for fracture and brain cases.

The utilization of the field hospital of the American Army is best translated in trench warfare into a hospital for sick and gassed cases, and perhaps at times and under certain conditions war surgery can be done, with the exception of the slightly wounded, which it is better ordinarily to send to the evacuation hospital. These field hospitals can be nearer the front and should receive their patients direct from the ambulance head. Brain cases should also go direct to their hospital.

Before closing, only a few words on the subject of convalescent depots. The duty of the Medical Department in war is now clearly understood. The humanitarian calling of a medical man must always influence every act, in civil or in military life; and in the application of the medical services to the war, the part of the medical officers of the Army is that they constitute the salvage corps for men.

Patients who reach the stage of convalescence and are able to leave their beds, instead of being sent to some hospital farther into the interior, should be sent to a convalescent depot commanded by medical officers, and gradually reconstructed into fighting men by exercises and games. Use every possible means to induct the men out of the convalescent frame of mind into the enthusiastic military spirit. Bands of music are a help. The companionship of the courageous men, above all, preserves a military atmosphere. Line officers should not be in command of the military exercises; you should use noncommissioned officers under the supervision of two or three medical officers. The convalescent depot is one of the greatest contributions of the Medical Corps to the effective force of the Army.

Army Sanitary School No. 65

THE USE OF DAKIN'S SOLUTION, DICHLORAMINE-T, AND EUSOL IN THE TREATMENT OF SUPPURATING WOUNDS

Lieutenant Wyant, at Lieutenant Colonel Keller's hospital, January 11, 1918

In the treatment of wounds I wish to mention the use of the chlorine containing solutions as eusol, Dakin's solution, and "dichloramine-T."

The preparation of the dichloramine-T oil embraces three steps:

First. The solvent eucalyptol (U. S. P.) is chlorinated; 500 c. c. are treated with 15 gm. of potassium chlorate and 50 c. c. of concentrated hydrochloric acid for 12 hours or longer; then well washed with water and sodium carbonate solution. The water is drawn off and 15 gm. of dry sodium carbonate are added to the oil and the whole is allowed to stand for 24 hours. The oil is filtered off, dried with a little solid calcium chloride when it is ready for use.

Second. The paraffin oil is chlorinated. To 500 c. c. of concentrated paraffin oil, 15 gm. potassium chlorate and 50 c. c. of concentrated HCl are added and the mixture exposed to light, preferably sunlight, for several hours. It is then transferred to a separating funnel and washed successively with water, a solution of sodium carbonate, and again with water. The opalescent oil is drawn off, sodium calcium chloride added in small quantities, and about 5 gm. of animal charcoal. On subsequently filtering through paper, a yellowish oil ready for use is obtained.

The third step is the preparation of the oil solution of dichloramine-T for use in the spray; 0.2 gm. of the dichloramine-T is dissolved in 2 c. c. of the chlorinated eucalyptol without heating. When the solution is complete, 8 c. c. of the chlorinated paraffin oil are added. After mixing, the solution is ready for use. The solution contains 2 per cent dichloramine-T and is relatively unstable and should be discarded as soon as a distinct precipitate makes its appearance. An opalescence or moderate cloudiness is not evidence of material deterioration. It is a safe rule not to use the completed solution for more than three or four days after its preparation. It should be protected from strong light and is best kept in a cool place. Where large quantities are needed, a stock of 10 per cent solution of dichloramine-T in eucalyptol may be prepared and kept on hand in a cool dark place for dilution with the paraffin oil 1:4, as required. The eucalyptol solution will suffer little deterioration in a month.

It is best applied by an oil spray, an ordinary hard rubber or all-glass atomizer being the most practical method. Metal atomizers are not suitable since the metal is attacked by the chlorine. This oily solution presents the first great advantage—the dressings do not stick to the wound and the entire act of dressing is relatively painless. The gauze does not have to be separated from the granulations by soaking; the old dressing is simply lifted off and the wound sprayed; the force of the spray will dislodge the sloughs, and the wound is covered with a fresh dressing. It is evident that a very important saving of time results from this simplicity of dressing.

The solution contains enough available antiseptic so that one dressing every 24 hours is ample for large deep wounds, and one dressing every 48 or 72 hours is enough for the simple or more superficial wounds. The oily solution creeps into all the wound crevices and corners, and it can be readily introduced into sinuses by means of a cotton swab dipped in the solution. The preparation is not irritating to the skin of mucous membrane, except possibly to the rare individual who possesses an idiosyncrasy to the eucalyptus oil. The points in favor of dichloramine-T in solution in eucalyptol and paraffin oil in wound treatment are: The elimination of the Carrel tubes; the time taken for the periodic flushings as necessary in Carrel-Dakin application; the rapidity with which a surgeon can dress his cases; the appreciable saving of dressing material; the lessened amount of pain of wound dressing.

In the use of eusol the same technique is employed as with the Carrel-Dakin treatment. In the preparation of the solution we take 135 c. c. of the B. P. liquor calcis chlorinatæ; dilute with water 1 liter, add 10 gm. of boric acid and shake until dissolved. The solution remains clear and without further treatment is ready for use. If preferable, a saturated solution of boric acid may be stocked at room temperature. This contains 4 per cent of boric acid; therefore 250 c. c. give the amount required for 1 liter of solution of eusol. In making eusol this way, the 135 c. c. of liquor calcis chlorinatæ should be diluted to 750 c. c. and 250 c. c. of boric acid solution added. This prevents the formation of the precipitate which occurs if boric acid be added to undiluted liquor calcis chlorinatæ.

By this method eusol can be prepared at a moment's notice by diluting and mixing two stock solutions, both of which are stable.

The Carrel-Dakin treatment is the introduction into the wound of a hypochlorite solution in sufficient amounts and strength to retard the growth of bacterial flora and produce progressive sterilization in the wound if possible.

The solution used is Dakin's, consisting of:

Chloride of lime.....	200
Dried carbonate of soda.....	100
Bicarbonate of soda.....	80

and water enough to make 10 liters of solution. The 200 gm. of chloride of lime are placed in a bottle with 5 liters of water and shaken well at several intervals, then allowed to stand overnight. The carbonate and bicarbonate of soda are dissolved in 5 liters of water in another container and then the solution of the soda salts is turned into the bottle containing the solution of the chloride of lime. This is shaken vigorously and then allowed to stand for a few minutes in order to allow the carbonate of lime to settle to the bottom. The clear fluid is then siphoned off and filtered through filter paper to obtain a perfectly clear solution, which is now ready for surgical use and contains about one-half of 1 per cent of sodium hypochlorite with small quantities of neutral salts of soda. No heat is used in the preparation or in the use of the solution. It must be freshly made and kept from the light in well-corked bottles.

It is a neutral solution and markedly isotonic to blood serum. Marvelous results are obtained with this solution upon infected wounds, especially if used before the suppuration is well established, and even then it shortens the suppurative period, rendering the wound almost germ free in a comparatively short period.

In changing the dressing, careful attention to details and antiseptic precaution is necessary, and for this reason we observe our technique as carefully as in an abdominal operation. Two pairs of dressing forceps are used to handle the tubes and dressings. Rubber tubes of size No. 7 tubing, and about 10 inches long, are used to carry the solution into the wound. The distal end of the tube is closed with a ligature with numerous lateral small openings perforating the tube for about one-half the length. The part of the tube with the perforations in it is buried in the wound and held in place with a small piece of gauze dampened with the solution. The proximal ends of the tubes coming from the wound are held by the assistant who connects them up to a glass distributor, which in turn is attached to a larger tube, which brings the solution from a bottle hung at a convenient height to allow instillation into the wound. The number of tubes employed as well as their size is determined by the size and extent of the wound, as well as the amount of infection. The number and intervals of the irrigations being regulated by a stopcock on the main tube. It is necessary for the solution to come in contact with every corner of the wound, so just enough fresh solution is allowed to gravitate to the wound every two hours to flush the tissues and keep the dressings moist. Several layers of gauze moistened with the solution are placed on the outside of the wound as a dressing, and a large pad placed over the whole to absorb any superfluous solution which may have come from the wound.

In large superficial areas, as many tubes as deemed necessary are placed on the surface of the wound, being held in place by gauze saturated with the solution. The proximal end of the tube is fastened to the skin with adhesive at a safe distance from the wound.

In case of wounds involving the pleural cavity, a drainage tube is inserted with the Carrel's tubes to permit a return flow of the fluid and discharge. In case of excessive coughing due to the irritation caused by the fluid, the irrigations are temporarily discontinued.

We continue the use of the solution until the discharge is of a mucoid nature and a smear shows one organism in from 3 to 5 fields. After we discontinue the irrigations, we dress the wound every day with a dressing saturated with the solution.

The solution may have an irritating effect on the skin of some patients, but this can be avoided by applying sterile vaseline around the wound when changing the dressing.

Army Sanitary School No. 66.

GENERAL PATHOLOGICAL ANATOMY AND PHYSIOLOGY OF WOUNDS—SPONTANEOUS EVOLUTION: HEALING PROCESS

By M. le Medecin-Major Policard

SUMMARY: A STUDY OF SPONTANEOUS EVOLUTION OF A SIMPLE CUTANEO-MUSCULAR WOUND DUE TO ANY MISSILE

I. The first stages of wound evolution

a. Various elementary forms of pathological changes due to physical causes; mechanical resistance of tissues; mechanical elasticity; distant hemorrhages.

b. General conditions in a recent wound; lesions affecting epidermis, derm, hypodermis, and muscle.

c. The wound during the first hours; latent period; mortification; phenomena in those tissues where circulation is absent; arrival of leucocytes; limiting zone between dead and living tissues.

d. First microbial growth. (Refer to lecture on bacteriology of wounds.)

II. Cleansing of wound

a. Physiological mechanism in the spontaneous cleansing of a wound; proteolysis of dead tissues.

b. Proteolytic agents; essential part played by leucocytic ferments; secondary importance of autolytic endoferments.

c. Result of proteolysis; toxicity of proteolytic products, their elimination. Such products are the culture medium for wound microbes.

d. Limitation of proteolysis due to periphery of wound; separation between dead and living tissues.

e. The importance of the cleansing period, which is that most liable to gangrene. Surgeons, as much as possible, ought to avoid spontaneous proteolysis by the surgical removal of mortified tissues. Such tissues are a culture medium for microbes.

III. Filling in and closing of wounds

a. An essential point is that muscles and tendons do not regenerate. Necessity of filling in the wound cavity with a special connective tissue; i. e., granulation tissue.

b. Internal structure of granulation tissue; surface layer of embryonic character, with numerous cells; deep layer undergoing fibrous transformation; rectilinear masses of capillaries giving individuality to each granulation.

c. Deep sclerosis. In the deep muscular planes of a wound an internal sclerotic process is developing more or less actively. Origin and practical importance of such sclerosis.

d. Epidermis covering the wound surface; histological changes; relation between epidermis and underlying granulations.

e. Pathology of the granulation tissue; edema; leucocytic invasion; vascular alterations.

IV. The scar

a. Structure; epidermis; fibrous masses; vessels; sclerotic zone under scar.

b. Scar physiology; connective tissue shrinking; imperfect circulation in scar, and consequences.

V. Practical deductions derived from the above data

a. Dangers during the proteolytic stage; physiological basis for surgical cleansing of wound; mortified tissues govern growth of microbes; part played by this culture medium; toxic symptoms in the wounded during war time.

b. Infected foreign bodies remaining in wounds; latent infection in cicatrices.

c. Granulation tissue, origin of sclerotic masses. Its production is, as much as possible, to be avoided (primary or primo-secondary sutures); otherwise, surgical intervention has to be resorted to. Physiological rebuilding of anatomical layers in suturing wounds.

GENERAL PATHOLOGICAL ANATOMY AND PHYSIOLOGY OF WOUNDS.—THEIR SPONTANEOUS EVOLUTION: HEALING PROCESS

In this lecture, M. Policard confines himself strictly to the histological anatomy and physiologic processes of wounds of war. He stated that we must consider, first, the ballistic state in the formation of wounds. First, the direct effect of the ball, and then the indirect. A great deal depends upon an accurate knowledge of the histology of the skin. The skin is an elastic organ and is put on the stretch by the missile, and while on the stretch the missile slips through, generally leaving a hole smaller than its diameter. On reaching the subcutaneous tissue, however, its effect is more extensive, the hole being larger than the projectile, and pieces are liable to be blown tangentially and vessels in the path of the bullet are torn, which bleed and cause hematoma. It then slips through a hole in the aponeurosis the size of its diameter, shredding the edges. Underneath the edges of this aponeurosis, pieces

of clothing are apt to be deposited. On reaching the muscle, which is filled with fluid, cells at a great distance from the path of the bullet are killed by molecular shock, a true explosive effect. Many of the vessels are torn and there is a great deal of bleeding. There is thus a large chamber of attrition where pieces of skin, foreign bodies, and dead tissues are inextricably mixed. The tissue in which the projectile comes to rest has lost less by molecular shock in this locality than in that surrounding the tract through which the projectile has passed, as by this time its force has been spent. One should not lose sight of the fact, also, that the skin itself may be found deep in the wound, it is blown in ahead of the projectile. In the muscle beneath the torn aponeurosis there is wide destruction, and this chamber of attrition, filled with dead and devitalized tissue, foreign bodies, etc., is the seat of the digestive processes which are nature's method of cleaning the wound.

After the twelfth hour three distinct phenomena are noted and they come together: (1) Multiplication of microbes; (2) collection of leucocytes; (3) transformation of these leucocytes into globules of pus.

It is well known that the albuminoids, even the most complex, are constituted by the union of muscles of aminic acids, which should be considered as the foundation stones of the albuminoids. These amines have a chemical constitution which is rather simple. They are crystallizable, dialysable, and not toxic. They group themselves into infinitely varied types of what are known as polypeptides, and as later they lose their crystallizable and dialysable characters they become colloids. The peptoses and peptones, with all of their varieties, still little known, are the ultimate intermediaries between the polypeptides and the albuminoids, but contrary to the aminic acids they are very toxic.

Let it be understood that before tissue is digested it has to be coagulated. In fact, this happens always in digestion. Proteolysis is the phenomenon of digestion of this coagulated substance, which breaks up the albuminoid molecules and produces some aminic acid, but much more peptone and proteose, which in their turn are broken up more and more until they become less and less toxic. Fibrous and elastic tissues are resistant to this proteolytic action.

This proteolysis is due to diastases. Some of them directly destroy the albumin molecule, breaking it up into aminic acids, but some only carry the process as far as the peptones, from which they are attacked by other ferments which are peptolytic. These proteolytic diastases are more active the nearer the temperature gets to 40° and the process can be almost stopped by placing ice over the member. Above 60° and 70° these diastases are destroyed. We may explain thus many clinical results in the employment of hot air and heliotherapy. Water is indispensable to the progress of fermentative action. In a dry wound you do not get proteolysis. It is produced especially in mediums free from oxygen, and the reaction of the medium should be within certain limits. Antiseptics have no action on this phenomenon.

The sources of the proteolytic diastases in the wounds of war are various: First, the tissues furnish them themselves. This is known as autolysis, but it has a very feeble rôle in the evolution of the wounds of war when one compares it with that of the leucocytes or microbes and, besides, it is a slow process. Second, the only great agent in proteolysis in wounds is the neutrophilic polymorphonuclear leucocyte. This leucocyte produces some extremely active proteoses which seem to work best in an acid medium, although some prefer one which is alkaline. They are not specific, but are very energetic. The maximum amount of proteoses is produced by the rupture of normal leucocytes. Third, the plasma of the blood and the lymph has some proteolytic qualities but these proteases are weak. Fourth, the microbes in wounds are important agents of proteolysis, especially the anaerobes, but the real agent in the cleaning of the wound comes from the polymorphonuclear leucocytes.

This proteolysis sets free acids which on being absorbed contribute to shock. But proteolysis, useful at the beginning, is extremely harmful when reparation of the tissues begins. At this time the infecting organisms are aerobic and these have little or no proteolytic action. On the contrary, that of the leucocytes is powerful, a harmful influence that nullifies their phagocytic action. Poliard has demonstrated that the vitality of granulations is in inverse proportion to the number of leucocytes they possess. These leucocytes are the cause of necrosis of granulations. There is a direct relation between the amount of pus and the volume of granulations which when the first is increased are edematous, full of leucocytes and in process of destruction. These phenomena of necrosis are all the more intense when the

leucocytes are dead. The deduction to be drawn from this is that we should preserve the life of the leucocytes to get their phagocytic effect and prevent their death which results in an outpouring of destructive proteases. For this reason antiseptics are to be shunned as they kill leucocytes and isotonic bland solutions should be employed to wash wounds.

As a matter of fact, the wounded are far more intoxicated than infected. We are just coming to realize the importance of the toxicity of proto-albumoses in producing a proteose intoxication. These phenomena are at their maximum in gangrenous processes, when to all this is added the incomplete proteolysis caused by anaerobic organisms.

It looks even as if the excellent effect of Dakin's solution was due in great part to the oxidizing of the proteoses by the hyperchlorites rather than simply to a bacteriocidal action.

All these phenomena of proteolysis are counterbalanced by the antiferments, on a basis of lipoids, especially of the nonsaturated series of fatty acids, and their cleates. In the blood, normally, these fatty bodies prevent proteolysis. But if they are suppressed the proteolytic ferments are unmasked and come into play, with digestion of proteins and proteose intoxication. In this fashion the phenomena of anaphylaxis, the "crises" of acute diseases like pneumonia and the terminal scenes in starvation, have their explanation. These antiferments are of great importance in also explaining the resistance of sound tissue to proteolysis. It is easy to demonstrate the fatty character of gangrene tissue which makes proteolysis more difficult and which favors the production of peptones and toxic proteoses. There comes a time, suddenly and without the influence of any therapeutic agent, that this fatty degeneration is inhibited and these fatty tissues are transformed into liquid pus; the phenomena of proteolysis reappears and the fatty barrier is digested and liquefied.

The anaerobic bacteria accommodate themselves to their new surroundings and thrive on the dead tissue as soon as the aerobes have used up the oxygen. All of this digesting mass is a fine medium for anaerobes and it is necessary to operate in order to avoid this condition, to do what nature does, separate the live from the dead tissue. The natural way is for the leucocytes to collect at the head of circulation of the blood, near the devitalized tissue. At this point, therefore, are found the cells that secrete a substance which is proteolytic. This natural method of cleaning the wound is a dangerous part of the process for the patient, for it is here that gas gangrene begins. The surgeon should cut out everything destined to die.

Muscle does not regenerate. This inner area occupied by dead tissue must be filled, and there are two elements only that take part in that process—connective tissue cells and epithelium.

The connective tissue cells which are embryonic in the outer layer of the conical wound are developed into connective tissue fibers as one goes deeper. Into this mass little branches coming off at right angles from underlying vessels are pushed out and form loops covered with embryonic connective tissue, forming the so-called budding layer or granulation layer. The ultimate destiny of these embryonic cells and the enormous number of small vessels that feed them is that the cells become connective tissue cells with fibrils, and the majority of the right-angled vessels tend to disappear. As this takes place there is a shrinkage. At the level of the skin the destroyed derm is not replaced, but the epithelial edges of the wound run over this sclerotic tissue.

The vessels of granulation have almost no anastomoses. As soon as the skin covers over the wound all the vascular connective tissue growth ceases and process of sclerosis begins and invades all the granulation tissue up to the epidermis before there is a decided regression of the vessels, in which the majority disappear. The former presence of these vessels is only indicated by the bundles of connective tissue, whose cells, in embryonic form, once covered over the vessel and which persist now in the fibrous tract seen perpendicular to the wound. These bundles are the thicker the longer the granulation is continued. Finally, the connective tissue grows no more and a third phenomenon begins, the retraction of the fibrous tissue. The result is that the shrinking of the bundles, which are tangential, brings the lips of the former edges of the wound together and puckers it, and the shrinking of the perpendicular fibers tends to depress the scar. The worst of it is that not only does the increase in the connective tissue take place in the site of the destruction caused by the wound, but that activity extends inward and invades the muscle, which produces an interstitial sclerotic myositis. In the end this connective tissue may even ossify in the muscle.

Now, it is not only necessary to cut away the dead tissue, to take away the food which anaerobic and other germs need to feed them, in order to prevent the phenomena of infection, but it is necessary to prevent that fibrous mass forming between the lips of the wound by uniting skin to skin, muscle to muscle, etc. Granulation tissue should be avoided and its effects in binding down muscle in pressing on arteries and nerves may be avoided. Besides, the granulation tissue is poorly nourished as a rule and is liable to break down and be a weak spot, not to speak of a latent infection in the scar where some microbes may be entangled in the process of healing.

Army Sanitary School No. 67.

TETANUS INFECTION

By Medecin-Major Lecene

SUMMARY

Since the war we have learned new facts concerning tetanus, chiefly from the clinical point of view. Before the war we did know that:

1. Tetanus is, like diphtheria, essentially an intoxication.
2. The tetanus anaerobic bacilli are abundant in the manured soil.
3. The tetanus bacilli grow only at the site of inoculation and produce there a soluble toxin.
4. The tetanus bacilli are highly favored in their culture in the broken and uneven wound by association with pyogenic bacteria and by the presence of a soiled foreign body (implantation infection).
5. The tetanus toxin travels from the point of inoculation up the nerves to the central nervous system, although it is also diffused to some extent by the blood and lymphatics.
6. When the toxin is fixed like a dye, on certain groups of nerve cells (the motor nuclei of the spinal cord, and medulla, and perhaps, too, the motor cortex of the brain) the symptoms appear.
7. A certain latent period elapses before the symptoms appear, and the longer this incubation period lasts the less serious is the disease.
8. The acute cases, beginning around the fifth or sixth day after the inception of the wound, are almost sure to end fatally.
9. The effect of the tetanus toxin is to produce extreme rigidity of the musculature of the limbs, always preceded in the acute cases by clenching of the jaw (trismus) and stiffness of the neck, followed by contractions of the muscles of the back.
10. Reflex or spontaneous convulsive attacks of great violence occur in the severe cases.
11. When the muscles of respiration (and perhaps, too, the bulbar cardiac centers) are involved, death ensues.
12. In the acute cases, the mortality of tetanus is very high, about 80 per cent.
13. In some cases the incubation is prolonged (two or three weeks) and the course of tetanus infection is subacute and much milder (about 30 per cent mortality).
14. In some rare cases the tetanus remains localized to the head (cephalic tetanus) with trismus and facial paralysis (difficult to explain).

The numerous cases of tetanus observed during the first months of the war showed us that three new clinical forms of tetanus should be described:

1. *The delayed form of tetanus* in which the symptoms of tetanus appear only after a long time (two or three months after the injury). This delayed tetanus can be mortal, but it is not so severe as the acute form (about 40 per cent).

2. *Local tetanus*.—This form was very well known experimentally but almost unknown or illy described in man. The pathogenies of this local tetanus is very easy to explain: The toxin is fixed only in the motor cells of the spinal cord corresponding to the motor nerves of the wounded region (upper or lower limb, or, much more rarely, the abdominal wall). In this local tetanus it is very frequent to observe the absence of trismus. Local tetanus can be observed in the period immediately following the wound, like acute tetanus. It remains localized. Its severity is certainly less than that of the acute generalized form, but it is, however, often fatal (about 40 per cent).

But the most curious form of local tetanus is the delayed form. It can occur one or two months after the wound. The prognosis of this local delayed tetanus is not bad, but it can be enduring and produce muscular and tendinous retractions. The diagnosis of the delayed and local forms of tetanus is not difficult if you are well aware of the existence and relative frequency of those clinical forms.

The treatment of tetanus must be chiefly preventive.—The prophylactic treatment is grounded on two bases, equally important and consequently inseparable: (a) The local, surgical treatment of the wound; (b) the immediate injection of tetanus antitoxin (10 c. c. soon as possible after the injury and again in 10 days if wound remains soiled and suppurating)

With the combined and systematic use of these two proceedings the frequency of tetanus infection is now very low. When the symptoms appear, the tetanus antitoxin can no more counteract the fixed toxins, but can be yet useful to neutralize the toxin which can be again produced in the wound. The subcutaneous or intravenous injections of antitoxin in these cases are preferable to the very difficult and not more effective intrarachidian injection.

We possess numerous and certainly useful drugs against the declared tetanus infection; they are chiefly useful in the milder forms of the disease. Among the drugs we can mention: (1) Ingestion per os or enema of chloral, 8 to 10 gm. per day during 18 or 20 days; (2) subcutaneous injections of $\frac{1}{2}$ per cent of carbolic acid per day during 10 or 15 days; (3) intravenous injections of 20 c. c. of a 5 per cent solution of persulphate of soda per day during 8 or 10 days.

TETANUS INFECTION AND THE SEROTHERAPY OF TETANUS

Since the beginning of this war we have learned considerably more about tetanus, but the knowledge we have acquired is chiefly clinical, the bacteriological and serological knowledge being already complete. Before the war began we knew that tetanus was like diphtheria in that it produces a diffusible poison. To achieve tetanus infection the bacillus needs to be introduced under the skin, but its activities are favored by the presence of aerobes which use up the oxygen in the locality. In fact, this combination with aerobes should be looked at in the same light as that known to be favorable to other anaerobes.

The tetanus bacillus was discovered in 1884. Infections take place much more commonly when men operate over soil that has been lived upon for many hundreds of years. In the South African War the English found very little tetanus because it was rare in the virgin soil where they operated. The incidence of tetanus to-day among the French is about one-tenth of 1 per cent, because all wounded men receive the antitoxin promptly after injury as a prophylactic measure. At the beginning of this war its incidence was many times greater because of lack of this serum. The tetanus bacillus does not cause a septicemia but an intoxication. The nerve cells of the central nervous system are the only ones which have receptors for this toxin. They are chiefly those of the motor group in the cord, but the bulbo-spinal nuclei are especially susceptible; it is probably also bound to the cells of the motor area of the brain also. In fact, some think that general convulsions in tetanus depend upon involvement of cells of the cortex. Tetanus toxin is carried in the axis cylinder of the nerve directly upward from the point where it is produced to the nerve cell, but it is also carried in the circulation directly to that nerve cell.

The antitoxin of tetanus acts only as a prophylactic, and it should not be considered a means of cure of a developed case inasmuch as the poison is already bound to the nerve cells and can not be dislodged. Its only application as a therapeutic measure is in those cases where tetanus bacilli still exist at the point of their introduction and still produce their toxins. Injection of antitetanic serum will counteract a certain percentage of these toxins which are circulating in the blood and prevent additional damage to nerve centers. It should not be injected intraspinally or into the ventricles of the brain, as once recommended. The American serum has twice the strength of the French manufactured at the Pasteur Institute, but with a greater tendency to produce anaphylaxis. As a matter of fact, however, in this war anaphylaxis plays no important part and should be disregarded unless there is time to inject small quantities before the massive dose to test the susceptibility of the patient. This time is usually not obtainable inasmuch as the wounded should receive it always as soon as possible in the first-aid station or at the ambulance head; certainly at the field hospitals or the evacuation hospital on arrival. All patients having received this serum should have a "T"

marked on their foreheads with indelible pencil or some dye. Men with multiple wounds require a greater dose than those with simple wounds, and they should receive it every 7 to 10 days for four doses. All patients secondarily operated upon should receive tetanus antitoxin, as well as those who have been burned or who have advanced forms of trench foot. Injury to old wounds or damage to sites of fractures caused by gunshot wounds, whether accidental or surgically produced by secondary operation, is liable to light up tetanus again due to the liberation of latent forms in the interstices of the scar.

The clinical signs of tetanus are not so frequent now; injection of antitoxin has created a relative immunity in those cases in which tetanus develops, as a rule, and we find the most aberrant clinical forms, forms once rare, very difficult to diagnose and requiring an acute clinical sense which we must develop as rapidly as possible.

Acute tetanus in a nonimmune subject will be found to be a febrile disease. It has an incubation of five or six days and is very fatal, with a mortality of at least 95 per cent; it can be afebrile. The fever is probably due to the involvement of the thermic center. The longer the incubation of tetanus the less dangerous it is, however. The incubation period of tetanus may be lengthened by artificial immunity to 700 days, during which time the bacteria may lie latent in the tissues and are only awakened to activity by an injury which may be very slight. This incubation period is a perfectly silent one. Wounds of the face produce a violent form of tetanus and are very dangerous, with a mortality of not less than 80 per cent. In this latter case (cephalic tetanus) there is early trismus, and rigidity of the muscles of the neck due to early and intense involvement of the bulbo-medullary centers. The point of origin of the toxin is usually in a wound of the head and causes also paralysis of the facial and cranial nerves. In tetanus, dysphagia is a most important and early sign and much more reliable than trismus. The so-called hydrophobic form is a misnomer. It is due not to a fear of water but to an inability to swallow. Death occurs in acute cases in 10 days as a rule. It should not be forgotten that while tetanus patients are usually conscious, there may be maniacal delirium in very acute forms. The action of the toxin is that of a diastase. The cephalic form, with trismus, is a peculiarly fatal one. There is a suspension of reflex reciprocity of governing nerve centers for muscles. He explains the term "reflex reciprocity" in the following manner: The stimulus which travels to the center and which should produce a normal reflex calling forth action of certain muscles in an orderly manner is vitiated. Ordinarily in such normal action there is an excitation of the proper center and an inhibition of opposite centers controlling contrarily acting muscles. The result is, normally, that one set of muscles is relaxed to allow another set to act, but in tetanus this reflex reciprocity is destroyed by an abrogation of this inhibition and the stimulus acts upon the opposite centers as they do upon the center they should normally act upon alone. The consequence is a spasm of all muscles at the level of the cord or brain affected, a familiar example of which is the "lockjaw." Dysphagia is also explained in the same manner.

The result of this action upon nerve centers produces hypertonicity of muscles, causing intense pain and punctuated by clonic spasms, which are due probably to irritation of the cortical centers of the brain. The action of the contrary muscles also enhances this pain. Death from asphyxia is slow and not sudden. Death said to be from failure of the heart does not come from a direct action on the heart muscle but the heart literally runs away. Sweating is free in tetanus and the temperature is usually in the ordinary case, around 99; the pulse is below 100 until toward the end. Lecene does not believe in chronic tetanus. In subacute tetanus there is no fever and the symptoms are attenuated. The picture is only one of degree. In these cases the incubation runs from 8 to 30 days, the course is milder, and the mortality is around 40 per cent. We must always remember that the characteristic symptom of tetanus of whatever sort is muscular hypertonicity accompanied by great pain.

The retention of foreign bodies containing in themselves, or in their vicinity, locked up in scar tissue, the spores of tetanus may be the cause of a fulminating tetanus after some late operative procedure which disturbs that part.

Local tetanus is most difficult of diagnosis and is confined, as a rule, to segments of the central nervous system. This is the form which has called out a remarkably acute clinical sense among surgeons of this war. It is similar to a form of tetanus produced experimentally in animals by the local injection of small doses of toxin, not sufficient to kill, into muscle in animals, resulting in a spasm of this muscle only. If a larger dose is used the curious fact

is observed that the muscle of the corresponding side is affected; and if a still larger one is used other muscles on both sides are involved. In other words, it is a question of dose, and this phenomena happens in man and accounts for some of the queer aberrant forms referred to as being so difficult of diagnosis. In fact, local tetanus can be said to be similar to the experimental form, but at any time infection may flare up in man and entrain the generalized form. It is not a very uncommon condition, but such forms are very apt to come on two or three months after the injury. The mortality is about 40 per cent. Among the queer forms seen in this war we must mention what was known in old surgeries as "traumatic surgical spasm." This is the local tetanus we are describing. The treatment is preventive. For instance, to illustrate a case of localized delayed tetanus: This man had two of the three shrapnel bullets in his left thigh removed. For two weeks he had great pain, the slightest movement of the foot would bring a spasm of certain muscles of the thigh. In localized tetanus, even after a man is apparently cured, very weak electric currents give an excessive muscular reaction in the muscles previously involved. The treatment of tetanus is 8 to 10 gm. of chloral by the mouth or rectum per day, and in case the focus has not been rid of the bacilli entirely he recommends subcutaneous or intravenous injections of antitoxin rather than intraspinal, because the object is to get the antitoxin into the circulation, which it will enter but slowly from the spinal canal.

There are two forms of tetanus seen commonly in this war: First, local tetanus, confined to the nuclei of the motor nerve of the part affected only. There is never any trismus or general rigidity or convulsions. At times bulbar phenomena appear, but these are really acute localized conditions. This is the form called by the old authors, in their ignorance, "traumatic surgical spasm." Second, retarded localized conditions after a secondary operation is done for the removal of foreign body.

It is not necessary to isolate cases of tetanus because the proven cases of infection from man to man are very rare. One should institute early physiotherapy to avoid contractures. Above all, please remember that there is no real danger to be apprehended from anaphylaxis.

Army Sanitary School No. 68.

RIFLE SPLINT

By Captain Cowell

I. *Preparations*.—Five narrow, folded triangular bandages; two broad, folded triangular bandages. Remove the bolt of the magazine.

II. *Placing of splint*.—Butt up, magazine pointing in the opposite direction from the operator. Lay a bandage across the butt, two-thirds hanging down on the right if for the right leg; take a turn around the butt with the long fold.

Tie a butt loop.

Place the rifle, with its magazine up and muzzle projecting below the sole of the foot. Take another triangular bandage, cross it behind the ankle, bring the long end between the rifle and the malleolus, first passing over the rifle, then encircle the muzzle at the point of the sight.

Then cross the short ends, pass over the dorsum, under the instep, and tie over the dorsum.

Next, pass a bandage under the buttock and crotch, and pass the outer strip through the butt loop, from below upward; upper slip from below downward.

Pull taut and tie.

This pulls the body and upper fragment one way and the thigh and lower fragment the other, producing extension and counterextension.

Then put a bandage around the head of the tibia. Now apply the Goch splints, as in the Thomas drill; place a bandage around the ankle, then one around the waist to bind the butt to the hip; then tie the legs together.

Army Sanitary School No. 70.

SURGICAL VARIETIES AND TREATMENT OF GAS GANGRENE

By M. lé Medecin-Major Piollet

SUMMARY

Gas gangrene is an infection caused by anaerobic germs, its initial localization being in the muscle, where it produces rapid mortification of the injured tissue, causing gases and having a tendency to spread, largely producing grave and often fatal poisoning.

The present war has shown its frequency.

Bacteriology.—Anaerobic bacilli: *Vibrio septicus* of Pasteur, *B. sporogoncs*, *B. bellemensis* of Saquepée, *B. oedematiens* of Weinberg, *B. perfringens* (*aerogenes capsulatus* of Welch (of Veillon)). These bacilli are alone or associated with streptococci and aerobes. Real gas gangrene is a general infection. Localized gangrenous infections must be studied separately.

Clinical varieties.—Ordinary variety: Diffuse gas gangrene. Starts locally by production of gas in the wound. General condition is quickly impaired. Evolution is fatal in from 24 to 35 hours.

Very acute variety: Malignant edema (traumatic erysipelas). Starts a day or two after the wounds and before incision. White swelling of the limb, no gas. Poisoning general and overwhelming. Death occurs in a few hours. Grayish green edema (bronze colored erysipelas). Starts a few days after the wound. Grayish green swelling with small bubbles of gas under the skin and blisters. Poisoning general and rapid. Death occurs in from 12 to 24 hours.

Subacute variety: Gas phlegmon. Infection of the wound which takes a brown dry aspect, producing gas all round. It spreads progressively but slowly and is curable by immediate surgical treatment.

In opposition to these varieties must be placed the localized gangrenous infections without a tendency to spread: Gas abscess; gas mortification.

Varities and their chief localization: Gas gangrene is a disease of the muscle. Occurs most frequently in the lower extremities (78 per cent), in particular the buttock, the thigh, the calf of the leg.

These infections are not, strictly speaking, specific.

One germ corresponds to each clinical form of varying gravity, according to the nature of the aerobic germ associated with them. Their association with saprophytic germs causes a mild form with staphylococcus a severe form, and with streptococcus a form of excessive gravity.

The *perfringens* (bacillus of Welch) alone produces a mild form.

Treatment.—Treatment by serotherapy: Has not yet given definite results. The following sera are prepared: Antivibrio septicus, antibellonensis, antioedematiens, antiperfringens, serum of Bull.

(NOTE BY COMMANDANT.—See remarks on Bull's serum.)

Surgical treatment: Prevention very important. Immediate incision and excision of mortified muscle, extraction of metal, objects, and clothing.

Treatment curative: Can not be successful unless applied immediately, before the poisoning of the subject.

Very acute variety: No treatment can cure it. Even amputation is useless.

Acute and subacute variety: Large incision of the skin and the aponeurosis. Very large excision of the injured muscles.

Medical treatment: Local—useless or harmful (injections of hydrogen peroxide or of oxygen). General—warmth; intravenous injections of alkaline solutions; general treatment of the infected parts.

Conclusion.—Infection is of such extreme gravity that it must be diagnosed at the beginning under pain of certain death to the wound.

SURGICAL VARIETIES AND TREATMENT OF GAS GANGRENE

By M. le Medecin-Major Piolet

In 1914 all wounds were badly infected and gas gangrene was common and very fatal.

The cause of putrid infection is the anaerobic variety of microorganisms, but these are much more potent when combined with aerobes.

The affected part is swollen and is generally brown in color; it gives rise to crepitation in handling and is sonorous by percussion (nail fillip or "chicotage"), one of the earliest signs.

A radiograph will also disclose gas areas in time to give a very precocious diagnosis. The skin is often marked by dusky lines. On incision there is not much bleeding; in fact, it is characteristic that the muscle is bloodless due to the shutting off of circulation by the pressure of gas developed under muscular planes. This in itself devitalizes the tissue and causes the spread of infection. The tremendous pressure to which the muscles are subjected is evidenced by the herniating of this muscle on incision. Both the ischemia and the preliminary action of pathogenic aerobes (staphylococcus and streptococcus) kill the muscles and deprive the tissue of oxygen, giving a favorable medium for the anaerobic bacteria. Another peculiarity of invaded muscle is that it has lost its normal color and power of contracting to a stimulus. Moreover, fine gas bubbles escape from amongst the fibers. The tissue is greenish or gray. There is no line of demarkation in gas gangrene, as in certain muscles, single or in groups, the invasion runs high, while other muscles at the same level but not in the same sheath are quite untouched. It always tends to spread longitudinally and this spread is typically rapid. As ischemia invites invasion, the lecturer emphasizes the necessity for preventing any constriction of vessels.

CLINICALLY

Diffuse gas gangrene is extremely fatal. The facies are leaden and the picture of that of shock. There is a septic intoxication, which may be enhanced by a true concomitant streptococcal septicemia. The pulse is rapid; there is dyspnea and a subicteric tint. There are no subjective symptoms; often a condition of euthanasia. Loss of consciousness is not characteristic. The extremities are cold and death occurs in 24 to 48 hours. If amputation is performed in time the patient may, however, recover. Notwithstanding its serious nature, gas gangrene may be self-limited.

Gas gangrene may not develop for from two to five days, but these late infections are not necessarily benign. The infection is heralded by the wound becoming dry. This is an important sign; it finally develops an odor, there is swelling of the part, and "bronzed erysipelas," the name given the peculiar discoloration of the skin, comes on. These retarded cases give a dry wound with a mousy odor, there is swelling and consequent constriction from the bandage, and thus a subacute or chronic form is initiated.

MALIGNANT EDEMA

In some cases there is no crepitation and the muscle, although greenish brown, contains no visible gas. This form is very serious and the patient may die in 12 hours. There is a white swelling of the limb which extends high up. The condition is that of an overwhelming massive intoxication.

BRONZED ERYSIPELAS

This is a variety marked by the color of the skin as per its name. There is a tendency to ecchymoses and blisters around the edge of the wound. Here also gas may not be in evidence and death occurs in from 12 to 24 hours.

Both malignant edema and bronzed erysipelas are very rapidly fatal forms.

Professor Piolet states that the principle of treatment is to follow up all affected muscles to the point where normal muscle appears. He states that there are now comparatively few surgeons who insist that the injection of oxygen under the skin will arrest gas gangrene and that it is an old and broken-down theory.

The subacute varieties, which are in general slower, are still quite rapid in producing their evil effects. In fact, all forms are found from local gangrenous wounds to general gas gangrene.

GAS PHLEGMON

This develops in from 24 to 36 hours. The wound has a disagreeable, ratlike odor and gas accompanies the serum which escapes. There is a slight temperature and a cavity in the green or brown muscles. If incision is prompt and sufficiently extensive up to normal muscle the progress of this form can be arrested, but it should be remembered that such incision should include the edematous parts beyond the actual gangrene. Many times a large muscle may be only affected in a portion of its mass and yet give a tense covering fascia as if it were all attacked. In such a case, if the limitation of the process can be made out, it is enough to remove only the damaged part.

Gas abscess and localized gangrenous dissolution of tissue are not really cases of gas gangrene, although they are caused by anaerobes. The treatment is free incision and Carrel-Dakin.

In his experience one-fifth of his cases were of the malignant edema type, one-fifth bronzed erysipelas, and three-fifths of localized forms. Seventy-eight per cent of such cases were of the lower extremities, the buttock, thigh, and calf of the leg, in order named. It was usually associated with fractures.

M. Piolet spoke strongly against the indiscriminate use of tourniquets.

He said that while one can not find a clinical type of gas gangrene for each type of anaerobes producing the disease, his impression was that the *Vibrio septique* was most common in serious cases and the *perfringens* in the localized forms. The most deadly cases are those in which the streptococcus is associated.

Too much emphasis can not be laid on the necessity for immediate intervention when gangrene is limited to a segment.

Dissect out all the muscles affected. Where amputation is decided upon, go as high as possible and do not close the stump.

Gas gangrene does not ordinarily affect the tissues of the head.

Army Sanitary School No. 73.

VISIT TO AMBULANCE 3/66

May 12, 1918

At 12 o'clock the parties of both groups who visited the trenches in the morning met at this field ambulance for medical cases, in a beautiful little town, which was very ancient and in a very historic portion of France. It was in a château on a height, the entire hill belonging to the château and being parked. Here we took dinner with the officers and were shown over the place later. The hospital proper is in barracks, neat and very restful, from the beautiful views and fine walks in every direction. It was chiefly used for sick and skin cases, but it did not present any special features save that it was remarkably well administered. Gassed cases were brought to the gas quarter by a separate entrance. They sprayed lightly gassed clothing with an alkaline solution, beat it, and hung it out for about two days. Heavily impregnated clothing is sent to the sterilizer. All of the division gas cases come through here. We were told that liquid paraffin is an excellent thing to use for mustard gas in the eyes, and, also, we were given the following prescription for a powder for skin burns, due to the same cause:

Talcum.....	200
Sodium bicarbonate.....	100
Zinc oxide.....	100

The ambulance was a divisional one and had a capacity of 300.

In anticipation of complications which must frequently arise in the nose and throat, a laryngologist was on duty there, and he used 10 per cent gomenol in oil as a spray for the throat and nose in addition to putting several drops in oil inside the cavity in cases of mustard-gas poisoning.

We noticed in visiting their general ward for sick that they had a small epidemic of what looked like influenza going on.

In addition to the sick and gassed there were separate wards for skin cases with separate douches.

THE SALIENT POINTS IN LECTURE BY MAJOR COLLIN, AT HIS FIELD AMBULANCE, MAY 12

It is necessary for front-line surgeons to know the roads and trenches well, and part of the instruction of the enlisted men of the detachment should be insistent upon this point. The work of the litter bearers is a severe test of endurance. At Douamont we had 1,500 yards to carry and each litter squad covered it six times in 24 hours, which means 21 km. at 3 hours 40 minutes per trip, under fire and over a most difficult road. Of 25 litter bearers available on paper, 20 only can be counted upon because 5 will be sick or on leave. Of these 20 men, 12, or 4 per company, must be destined for the battalion, which consists of 3 companies; 2 teams, or 8 men, should be left the medical officer at his battalion station. You should keep these men yourself, and don't let the regimental surgeon have them, nor the commanding officer. When you are in unorganized sectors do not tell off the men to companies but keep the men near you so that you can dispatch them as they are needed in critical moments. In that way you always have them in hand.

The litter bearers of the G. B. D. should carry from the regimental aid station back. If a regimental medical officer needs help to get men back from his battalion aid station, he should get it from the G. B. C. (*groupe brancardiers du corps*). It should be a policy of the corps surgeon to keep these organizations well up to the front in an attack so that they can get to the regimental aid station to reinforce them in time to be of use. He mentioned a situation where he once sent for G. B. C. men at ———, but he didn't get them until 24 hours afterwards, when the real crisis was over. The place of a regimental medical officer during combat is at his station. This is no time for him to assume heroic attitudes or satisfy his personal romanticism, as the men will be thus left without a doctor at the place they are told to go and find one. The regimental medical officer's duties are not only medical and surgical but paramedical and parasurgical. He means by this that the regimental medical officer can start a man right medically and surgically so that when he gets farther back he will automatically receive the best and the most scientific attention. He also means that his paramedical duties are to study the psychology of the men, anticipate their wants and their needs, and provide for those things which, although not strictly medical, prevent disease and a breaking down of morale. The regimental medical officers should see that men are always as comfortable as possible, and this should be his first thought. If we provide for them light, warmth, and food we have gone a long way in this direction. The surgery that he does can be summed up in the words: Clean up and stop hemorrhage. Treat shock, and evacuate as soon as possible. He says that antitetanic serum should always be given at the battalion aid station and that it is rare that it can not be done if it is made the business of the surgeon to do it. He likes porch curtaining for splints for small bones like those of the forearm and leg. His treatment of shock is rather primitive, because he seems to depend a great deal on stimulation by camphorated oil in large doses. He says the best place to treat shock is at the R. A. P. He lays, however, a great deal of stress on the heating of patients. He is not convinced that advanced surgical posts are feasible. If they are used at all they ought to be put at the side of the ambulance head, but, as he says here, the worst is then over and the short distance back to a decent hospital is easily covered without much more damage to the patient. The answer to the whole thing is that when a regimental aid station, or even a battalion one, is far from the ambulance head or very far from the H. O. E., or both, the proper thing to do is to prepare it properly for the maximum of surgical work. He believes in good surgical equipment at regimental aid posts because they are often cut off by barrages, and you must have some place to do surgery.

A gas attack means a sudden overwhelming of the battalion aid station if order and discipline are not maintained. What happens is that everybody falls in at once in great confusion and in a great deal of excitement. If the cases are mustard-gas cases, after proper change of clothing, etc., they are easily evacuated, often sitting or even walking, if only lightly gassed. But it is absolutely forbidden to evacuate a chlorine gassed man save in the recumbent position. They are a very serious problem when there are very many of them, as there usually are. If there are only a few you can treat them yourself, because first aid here

is most important. You have to be ready to do a tracheotomy at this place. He lays great stress on the thoroughness of gas discipline and gas prevention which has an educational effect on the rest of the command. If your gas preparation is good, they imitate you.

The disposition of the G. B. D.—The best way is to have advance posts in echelon. They are usually commanded by an auxiliary medical officer or a pharmacist. They send out squads who are in immediate contact with regimental aid stations. In the latter case it is well to make your G. B. D. men mess with your R. A. P. and sleep with them if possible. It makes them think they are all a part of the station and it prevents arguments as to who is to carry the patient back. At every thousand yards there should be a relay of one noncommissioned officer and 4 to 6 men. One of these G. B. D. posts should be at the ambulance head. These dressing stations should be of large capacity, because men are held up there very frequently awaiting transportation on account of condition of roads, shelling by day, blocking, barrage, etc. Great preparations should be made to feed men and give them hot drinks and a place for them to lie down. There should be preparation for emergency treatment and dressing room to replace bloody dressings, etc., but no dressing should be interfered with at this station unless some definite reason for changing it or adjusting it appears. You may use poussettes or bruettes (wheeled litters) in transferring patients from this station to the field ambulance, and you may even use them between the regimental aid station and this station, especially on paths at night. The narrow-gauge railroad, 40 cm. wide, can be utilized either forward or in the rear.

The triage at the field ambulance.—We must have faith in the regimental surgeon and be guided by his diagnosis in making triage. The triage ought to be liberally interpreted in a crisis, such as battle, and the regimental medical officer ought to be able to direct where the patient is to go and send him there by the shortest route. At the field ambulance hemorrhage can be stopped, shock can be treated, and grave cases can be operated upon.

The personnel of the medical department for a regiment having three battalions.—Each battalion comprises a technical personnel and a mobile personnel:

Technical personnel—

- 1 medical officer.
- 1 auxiliary medical officer.
- 1 corporal (dresser).
- 3 enlisted men (dressers).

Mobile personnel—

- 1 corporal (litter bearer).
- 1 cyclist.
- 25 litter bearers.

Total for a regiment:

Technical personnel—

- 6 medical officers.
- 3 corporals (dressers).
- 9 enlisted men (dressers).

Mobile personnel—

- 3 corporals (litter bearers).
- 3 cyclists.
- 75 litter bearers.

Regimental medical staff—

- 1 major.
- 1 pharmacist (officer).
- 1 sergeant (litter bearer).
- 1 corporal (clerk).
- 1 cyclist.

Disposition of personnel of a regiment in an organized sector prepared for combat.—The battalion of the first line:

Technical personnel—

- 1 medical officer.
- 1 auxiliary medical officer.
- 1 corporal (dresser).

Mobile personnel—

- 1 corporal (litter bearer).
- 1 cyclist.
- 8 litter bearers.

The rest are distributed to the companies.

Battalion, second line: Same, except that he has 4 litter bearers in place of 8.

Regimental aid station:

Technical personnel—

- 1 major (chief of the service).
- 1 pharmacist (officer).
- 1 corporal (clerk).

Mobile personnel—

- 1 sergeant (litter bearer).
- 1 cyclist.
- 4 litter bearers.

He refers to the elephant iron of the dugout as “abri metro” and states that it should always be below ground if possible and have a bursting layer above it. He refers to the cap for trench frame as the “chapeau” and to the upright as the “montant.”

Groupe de Brancardiers Divisionnaires.—Medical personnel:

- 1 major (chief of the service).
- 1 medical officer, assistant.
- 1 pharmacist, officer, chief of the laboratory of toxicology.
- 1 assistant medical officer, auxiliary.
- 4 auxiliary pharmacists.
- 6 petty officers.
- 12 corporals.
- 106 litter bearers, of which one is a cyclist.

The battalion aid station ought to be big enough for 16 lying and 30 sitting, with food, medicine, and other matériel, prepared to take care of patients for 30 hours without resupply.

The regimental station ought to be larger and must be ready to take care of patients for 48 hours. The regimental station should have room for 90, 30 of them recumbent. The Hospital Corps men should be taught to dig dugouts. When you go to organize a sector, organize from the rear battalion aid station or regimental aid station forward, because if you begin in front you may be working for the boches.

Army Sanitary School No. 74.

GENERAL CONSIDERATIONS OF THE WOUNDS OF WAR

By M. le Medecin-Major LECENE

SUMMARY

(Translation)

The wounds produced by missiles (bullets, shrapnel, shell splinters, bomb fragments) are in the most cases primarily infected and, besides, the best conditions are realized in these wounds for the culture of bacteria.

The causes of severity of infection in cases of shell and gunshot wounds are mainly two:

First. The presence in the tissues of foreign bodies, viz, the missiles and, above all, pieces of clothing or equipment; these latter fragments are always grossly soiled by the anaerobic bacteria of the earth.

Second. The crushing, tearing, and shattering of the tissues (especially of muscles, involving rupture of their blood vessels) prepares a perfect culture medium for contaminating bacteria; hence, the frequency of septic complications in the nontreated gunshot wounds (tetanus, gaseous phlegmons, cellulitis, etc.). Therefore, the best treatment of gunshot wounds is to hinder, to prevent the development of the infectious process in the wound.

During the first 24 hours which follow the injury, experience has demonstrated that it is possible to prevent infections:

1. By dissecting anatomically the track of the missile.
2. By removing the severely bruised and torn part of the tissues.
3. By removing the missile and the pieces of clothing and equipment introduced with the missile.
4. By accomplishing a careful hemostasis.
5. By accurately suturing the clean surgical wound so created (with a safety drainage of one or two days).

When applicable, this method of treatment of gunshot wounds is undoubtedly the most certain of giving the best results.

But when, for various reasons, the wound can not be treated within a sufficiently short time after the injury, it must be treated as a septic wound; that is to say, freely incised; cleaned; freed of the missile, foreign bodies, and dead tissues; and left open, or, at the very least, well drained. It is often possible in cases so treated to make a secondary suture of the wound.

Generally, if the dead and devitalized tissue, foreign bodies, etc., are removed within 24 hours, infection is prevented. When wounds can not be handled with a view to primary suture, or the primary delayed suture, the wound can be treated as a septic one by the Carrel-Dakin method. As a matter of fact, infection can be prevented or attenuated by removal of this dead and devitalized tissue up to 72 hours, but there is no certainty of a good result with such delay. A gentle stream of water to wash out the ground up material and foreign bodies is useful in cleaning the wound. Lecene considered that 80 per cent of wounds are due to shrapnel, shell, and grenade fragments, and 15 per cent to rifle bullets. He emphasizes particularly the difference between shrapnel, which produces the old lesions of bullets in the Civil War, inflicted by projectiles of low velocity, bruising and lacerating the tissue immediately surrounding the tract, and the sharp, cutting edges of the irregular pieces of shell blown in at high velocity, which cause molecular death at a distance from the tract and cut as well as lacerate and bruise, frequently nipping pieces out of arteries and veins and half sectioning nerves. In the case of vessels, the hemorrhage may be controlled temporarily by a little clot, which gradually gives way, forming a traumatic aneurism. However, if this little clot breaks down soon enough a secondary hemorrhage occurs. Partial section of nerves in this war is very common. In the Balkan war evacuation from the front was slow, and there was no teamwork between surgeons at the front and the rear. The result was that the wounded that got to the rear alive were usually those wounded by bullets and the wounds had sealed aseptically; hence the conclusion that bullet wounds were not serious; but in reality what happened was that it was merely a survival of the fittest, as many of those who were wounded by ricochet bullets, shrapnel, and high explosives either did not arrive at all or were considered to be shrapnel wounds only when they did. As a matter of fact, in the Balkan war nothing special was said of artillery wounds.

Rifle bullets at short ranges, 300 to 500 meters, cause an explosive effect. The explosion of a shell may be near enough to produce shock, which may be fatal without producing a wound. Most of the fragments of a shell removed from a patient are small ones. The reason for that is that the large pieces kill the man outright. At 50 yards pieces of shell act like rifle bullets at short ranges; that is, with explosive effect. The hand grenade is feared more than the shell because in addition to the injury which it produces there is the shock, as most of those grenades explode near the soldier. Lecene has seen as many as 200 wounds produced by the explosion of a hand grenade.

One of the great differences between military and civil surgery is that in military surgery we get large numbers of wounded at once, under conditions where it is difficult to have enough surgeons and enough material.

All of these high-velocity projectiles, bullets and pieces of shell, hitting at short distances, destroy the bone by perforating two-thirds of the distance and blowing out the last third, the fragments of bone acting as secondary projectiles. Thus it can be seen that the surgery of war has changed just as have the instruments of destruction made to produce wounds. The speaker did not believe that the wounded should be held at a field hospital

or ambulance head for operation or sorting, but that they should be sent directly to the nearest surgical hospital for proper treatment; nor does he believe in antiseptics if aseptic surgery can be done, because antiseptics devitalize tissue.

There are a certain number of wounds which do not lend themselves to primary suture, or even the excision of all devitalized tissue, as such an operation would take too long and produce too much shock, and might sacrifice an unjustifiable amount of such tissue. In such cases the Carrel-Dakin solution should be used after removal of foreign bodies and as much dead tissue as possible. The first-aid package is of use only in preventing additional infection (especially to reduce the danger of implanting streptococcus from infected fingers). The slightest wounds occurring in the trenches may mean infection and should be cared for even if they are nothing but scratches. An interesting phenomenon is the deep infection of wounds by the *Bacillus cutis communis*, which is caused by the blowing in of a section of skin in front of the projectile. Some slight amount of injury to the tissues may occur from burning by hot projectiles.

Ricochet bullets or bullets purposely reversed by the enemy before firing in passing through the soft parts have the effect of destroying in their path only the amount sufficient to let them through, but the edges are burned and there is molecular shock of the flesh surrounding the tract. When a ball strikes an object before hitting the body it explodes and causes what we call a "hernia" of the lead, causing it to look like a mushroom. This has a very destructive effect. It is known as a "dum-dum" bullet when produced artificially. The same effect can be produced by turning a bullet backward before firing (reversed bullet). The characteristic fracture produced by such a bullet is the butterfly fracture with long fissures that may run to the joint.

He mentions that in cold weather a great deal of heavy clothing is carried in if the projectile is irregular, but that a rifle ball will slip through it without carrying in much, if any. Shell wounds can be compared to a certain extent with the kind of wounds that we see in railway accidents. They are very large and very dangerous, chiefly on account of their irregular cutting edges as above described. Incomplete fractures are very common in this war. The burst of a hand grenade generally wounds up to about 40 yards.

Army Sanitary School No. 75.

THE FLAVINE ANTISEPTIC IN THE TREATMENT OF INFECTED WOUNDS

Paper read by Lieutenant Valdes, Lieutenant Colonel Keller's Hospital, January 11, 1918

Undoubtedly, the introduction in therapeutics of the Carrel-Dakin treatment produced in 1915 a revolution in modern surgery, decreasing to a considerable extent the percentage of mortality among wounded soldiers. Due to the marvelous results obtained with the Carrel-Dakin method, other antiseptics were brought under investigation, for use in the treatment of infected wounds, and one of these is the product known as "flavine."

In January, 1917, Browning, Gulbrandsen, Kennaway, and Thornton, in England, made a careful and detailed study of the bactericidal properties of acridine dyes, and several compounds belonging to this group were brought under observation with a view to determining their suitability for therapeutic use in infected wounds. Among the substances investigated was the compound "flavine," now called "acriflavine," prepared by Benda for Ehrlich, and originally named "trypaflavine," on account of its therapeutic action in trypanosome infections. There are two varieties of the flavine compound: "Acriflavine," which is diamino-methyl-acridinium chloride, and "proflavine," which is diamino acridine sulphate or chloride, and "proflavine," which is diamino acridine sulphate or chloride. Proflavine is a preliminary product in the manufacture of acriflavine and therefore cheaper. According to laboratory investigations, these substances should yield practically equal results in the treatment of infected wounds, and, therefore, they are always referred to as flavine. Observations, however, have indicated a point of difference between these two compounds which is of clinical interest, viz, that proflavine exerts a degree of hemostatic action. In view of the attention which has recently been directed to the employment of "flavine" compounds

in the treatment of infected wounds, Lieut. Col. W. L. Keller encouraged me to make a concise description of these antiseptics in order that those of you who intend to employ them clinically may have more fully at disposal the indications for their use.

It was found that while in the case of all the diamino-acridine compounds tested the antiseptic effect was enhanced by the presence of serum, especially for *B. coli*, diamino-methylacridinium chloride (acriflavine) and diamino-acridine sulphate (proflavine) exerted the least degree of inhibitory effect on phagocytosis. Browning, Gulbransen, and Thornton extended their investigations by studying the effect of prolonged contact of a solution of antiseptic in serum on the phagocytic power of leucocytes, when subsequently staphylococci were added. The mixtures of one volume each of "leucocyte cream," serum, and antiseptic solution were incubated in capillary tubes at 37° C. for two hours. The control contained saline instead of antiseptic. At the end of this time, one volume of staphylococcus suspension was added, and after thorough mixing the whole was again incubated for 20 minutes in order to permit the phagocytosis to occur. It was then examined under the microscope and it was found that a 1:10,000 solution of the flavine antiseptics, after two hours' contact with the leucocytes at 37° C., had little effect on the phagocytic power, whereas this concentration of mercuric chloride reduced the phagocytic count to below 50 per cent of the control. In doing these investigations, they bore in mind that, so far as bactericidal action is concerned, 1:10,000 represents the limiting concentration of mercuric chloride, any further dilution of which with serum abolishes antiseptic action; on the other hand, such highly bactericidal concentrations of the flavine antiseptics after prolonged contact, leave the leucocytes still capable of phagocytic action.

PROPERTIES DESIRABLE IN A THERAPEUTIC ANTISEPTIC

The most advantageous properties of an antiseptic depend almost entirely on the particular purpose for which it is used. Thus, the sterilization of material outside the human body, as in disinfecting garments, instruments, etc., is a matter entirely different from the sterilization of a wound; in the former practically the sole necessity is to destroy the organisms, but in the latter the properties of the antiseptic must be so adjusted as to insure efficient action on the bacteria, but producing the minimum of tissue destruction, and without interfering with those protective and proliferative functions upon which healing depends. Thus, it is far preferable to succeed in inhibiting organisms in a wound, at the same time avoiding damage to tissues, or diminution in their resistance, than to aim at obtaining bacterial sterility by means of reagents which produce necrosis and throw out of action protective mechanisms such as phagocytosis.

Therapeutic application.—The sterilizing action of flavine compounds has been compared to that of mercuric chloride and phenol. It was found that it progresses gradually, thus after two hours' contact in the presence of serum mercuric chloride is equal to acriflavine in its lethal effect on staphylococcus and *B. coli*. But by this time the effective action of the mercury salt on the bacteria has come to an end, and a concentration which has then failed to kill the organisms exerts subsequently little or no inhibitory effect on the proliferation of the survivors. On the other hand, concentrations of the flavines which at this period have merely inhibited multiplication, later on prove bactericidal, so that finally the flavine compound is ten to twenty times more lethal than corrosive sublimate.

It has been shown clinically that when the flavine compounds are used for therapeutic purposes in the treatment or prevention of septic infection in wounds, the tissues are not harmed by the concentration of the antiseptic, and the admixture with the serous secretions of the wound enhances the sterilizing effect instead of bringing it to an end. The fact that the maximum antiseptic effect of flavine is obtained in a serous medium is of extreme importance and should be kept in mind to avoid too frequent flushing of the wounds. Unsatisfactory results have been obtained following the two-hourly irrigations as in the Carrel treatment.

The application of flavine is as follows: The "open" wound with assured free drainage is swabbed out once or twice a day with swabs soaked in flavine (1:1,000), care being taken to reach into all the crevices of the wound, and also to remove sloughs. The wound is then lightly packed with gauze saturated in the antiseptic, and the whole covered with dry gauze.

Once the infection has been practically overcome, weaker solutions may be subsequently employed, for instance, 1:5,000, with advantage, or else the application of flavine may be intermitted for a day every few days, dry dressing being substituted in the intervals. Should it be desired to adopt the method of introducing flavine compounds into wounds by means of tubes, as in the Carrel-Dakin treatment, instead of packing with gauze soaked in the solution, it should be remembered that only small amounts of fluid should be introduced, the frequency of the irrigations not exceeding 3 or 4 in 24 hours. However, in the cases we employed flavine here we observed that it gives the best results in local dressings.

About 24 hours after the flavine dressing is applied, the surface of the wound is of a bright yellow color, especially where fascial or tendinous structures are exposed. Pus, if present, soon diminishes in quantity. This remains the characteristic condition of the wound for from two to three weeks. Then the yellow surface, mainly due to the deposition of a tough layer of plastic lymph, gradually disappears, being replaced by small granulations of a pale pinkish color. In some cases, this change takes place much more rapidly, giving good small dark red granulations. In the course of the third week, generally the epithelium starts growing.

THERAPEUTIC VALUE OF FLAVINE COMPOUNDS COMPARED TO THE CARREL-DAKIN TREATMENT

Not long ago Captains Bashford, Hartley, and Morrisson, of the R. A. M. C., made a careful study of 50 cases treated by flavine, comparing their result with that obtained from other 50 cases treated by the Carrel-Dakin method. They used both the aeriflavine and proflavine, and the results were substantially the same. The primary object of their work being to confirm the good results claimed by the earliest workers with flavine, they made it a point to adhere as closely as possible to the lines of treatment laid down by them. The wounds as a whole were not of great gravity, a fact which they had in consideration in estimating the value of the treatment. Almost all had been treated previously at the front by the Carrel-Dakin method within 24 hours of being wounded, and, in the majority of cases, very efficiently. The patients reached their wards at periods varying from one to six days from the date of reception of the wound, and the flavine treatment was then substituted for that of Carrel-Dakin. For comparison, a similar table of results obtained by the Carrel-Dakin treatment was made, dealing with as nearly parallel a series of 50 patients as possible. The only material difference was that the Carrel-Dakin series was made up of much more seriously wounded men. It included all the severe cases regarded as unsuitable for the flavine series on account of the experimental nature of that treatment.

They kept a close watch on the flora of the wound surface in order to practice a secondary suture at the earliest possible moment. It is a curious thing to mention that in the wounds treated by the Carrel-Dakin method, the streptococci were usually the last organisms to disappear from the infected wound surface. In the cases treated by flavine, however, the commonest type of organism to outlive others in the wound surface was a Gram-negative bacillus.

They made several charts showing graphically the comparative rapidity with which wounds treated by the Carrel-Dakin method and flavine, respectively, became ready for secondary closure by suture. It was demonstrated that from the tenth day on till the eighteenth, the number of flavine cases bacteriologically clean varies from one-third to one-half of the number of cases similarly clean under the Carrel-Dakin treatment. The temperature reached normal distinctly earlier, as a rule, in the flavine group, but the percentage of failures to reach the normal line while under treatment with flavine was rather greater. Under the influence of flavine, only 38 per cent of the cases attained the standard required for suture. This is in marked contrast to the 68 per cent under treatment in the Carrel-Dakin series. The authors sustain the superiority of the latter, considering the number of wounds sutured (54 per cent as opposed to 34 per cent) and the percentage of patients evacuated to England healed (56 per cent, as opposed to 22 per cent); that is more than two and one-half times as many.

Flavine, however, is an important antiseptic in the treatment of abdominal wounds, as it has been demonstrated that besides being highly bactericidal, it is absolutely innocuous if injected inside the peritoneum. In fact, some English surgeons highly recommend it in the treatment of intestinal wounds.

We have had the opportunity of observing that in wounds which have been kept for a long time under the Carrel-Dakin treatment and in which the continuation of the Dakin's solution shows no further improvement, the immediate change of antiseptic and the employment of flavine soon produces nice red granulations and a rapid healing.

Army Sanitary School No. 76.

VISIT TO AMBULANCE No. ———, MAY 12

This is a field hospital for nontransportable and is one of the two field ambulances under Major Okinezye, consulting surgeon of the Army, who has devoted himself in this war chiefly to abdominal surgery. He has been operating as near the front as possible on non-transportable cases, and he is one of the chief exponents of the theory that an advance surgical hospital should be pushed well forward to operate on serious visceral injuries which would be harmed by further transportation. His hospital used to be 3 km. behind the lines, but he was shelled unmercifully and had to fall back to a distance of 12 km. from the lines. At present he gets his patients six hours after they are hit.

The ambulance is immobilized in a small barrack hospital, which was Lemaitre's and where he did his first work on the primitive suture. Lemaitre described to me personally how, when he exhibited his first 30 cases to the inspector general of the Medical Department that gentlemen, after listening silently and observing the results, told him that it was marking a new era in military surgery, but inasmuch as there were strict orders against sewing up any wound at that time in the French Army, he should proceed in a manner to avoid unjust criticism. He did, not however, order him to stop. Lemaitre says that this little hospital was far easier to work out a good line of cases than a big hospital would have been. He had a group of very loyal assistants and a fine administrative officer. They lived there like a community of monks until the results of this remarkable work had to be made public. The hospital is so small compared with the big H. O. E.'s that we have seen that it looks like a little toy village. Everything is miniature, everything is complete, and everything absolutely clean. It has recently been spoiled by the fact that they have built around it cantonments for troops and a big supply dump. Moreover, it is near the town, only a few meters, which, because it is pretty and neat and quaint, will probably receive attention from the boches. In anticipation of this, the huts are all well protected by revetted, splinter-proof breastworks, and there is an underground splinter-proof dugout in case of bombardment, which would not, however, protect against direct hits. The personnel for this hospital is as follows: 5 medical officers, 1 radiologist, 1 pharmacist, 1 administrative officer, 42 men, and 15 drivers.

Three sectors supply this hospital with patients. Recently the two army corps field ambulances are used—one for surgery and one for medicine.

There was no feature of bathing, operating, radiology, laboratory, etc., that was left untouched. The plan of the hospital in general is that it is built around a rectangle, the wards and operating rooms leading off at right angles to a covered cement porch running all round the wall, so that everything is compact and right in the hollow of the hand, as it were. In the center of the court a Bessonneau tent had been erected for the reception of the patients, and the floor of this tent was sanded. There was a reception room for disrobing and taking of histories, and beyond this a bath, also a heating room with the usual litter trestles and hoods, tables for washing up the patient, combating shock, giving transfusion, etc. In this room the hood differed somewhat from that we had previously seen. There was a battery of electric lights below the litter and one above the patient, within the hood, so that he lay between lights, underneath and above. In this room the operating surgeon saw his cases and made his selections. At the end of the rectangle were the operating rooms, offices, pathologist and bacteriologist, radiologist, sterilizing room, etc. Electric light was furnished by the group complementaire. There were two operating rooms and the hospital accommodated 400 patients. The slightly wounded in this hospital were used for donors for the transfusion of blood. During periods of inactivity there are two operating groups at this hospital and they alternate for duty—one on one day and the other on the next. Near the operating room there is a shock room separate from the rest, which is a hot room. The sterilizing room

lies between the operating rooms and divides both. We saw a few cases here. A wound of the axilla in which the axillary artery had been successfully tied and the median nerve repaired by primary suture. Unfortunately, it was not observed at the time, owing to the hurry and bad condition of the patient, that the musculospiral and the ulna nerve were also cut. The result is that at this late date, after the operation, the median nerve suture has been entirely successful and has almost recovered its function, but there is a paralysis of the muscles served by the other two nerves with what looks to be a hopeless contracture. The lesson to be drawn is that the primary suture of nerves is eminently successful, but that more careful work should be done to examine, at the time of operation, the condition of these nerves.

Case 2.—Fracture of the tibia.

Case 3.—An eviscerating shell wound of the abdomen with primary suture. This man was in desperate condition when operated upon and owing to the necessary incompleteness of the operation has still a jejunal fistula. The surgeon says he will close this fistula under cocaine very soon.

In reality ——— is a small evacuation hospital of the first echelon and a very good example of the type. The place was exquisitely clean, attractive, cheery. Major Okinezye took us in to the Bessonneau tent, which was empty, where he provided chairs and a table and gave us a talk on what he considered the proper treatment of the nontransportable should be. He said the idea of the advance surgical hospital was an excellent one, and he intimated that this hospital should be a field ambulance. He defined the nontransportable as those patients who could not be further moved without endangering their lives or seriously aggravating their condition, and mentioned the following classes of cases which might properly fall into the category of patients for such formation:

First. Those suffering from or in danger of hemorrhage, requiring ligature or transfusion, or both. None of these cases should ever leave a field hospital with a tourniquet on. This should be an axiom.

Second. All chest and abdominal injuries. The most important are the chest because they will surely die, especially when they are open, unless primarily treated. Their sufferings are great and they are generally in terror of death. Not less serious are the wounds of the abdomen, but the suffering is not great at first, and in many cases they do not appear to be in very bad condition. These should be operated on immediately for obvious reasons. Brain cases should be sent on, as they bear transportation well.

Third. Compound fractures of the thigh. They should always be rested here and at least have their splints examined and adjusted, if necessary. As a matter of fact they very frequently require shock treatment, but if they are in very bad shape with much damage to soft parts and to vessels they had best be kept.

Fourth. All cases of shock should be rested here until their condition improves at least.

From the above limitations as to patients to be held at this hospital it will be seen that only the very bad or the moribund cases are stopped, so you must have no roseate hopes for fine statistics. You ought to be mighty happy if you get 70 per cent of recoveries; that is to say, if 70 per cent of your patients live. It is believed that under such conditions the surgeon should be brought to the man and not the man to the surgeon. Besides, intransportable cases are nonevacuable anyhow, and they will need to be stopped at the evacuation hospital. Unfortunately, in times of activity these hospitals can not be depended on, as their accommodations are always small, and for other reasons most surgeons must be held at the main operating center. It is very difficult to turn a regimental hospital into an advance surgical station, as the demands upon them are very great. A good example of this is that in periods of activity they frequently haven't even time for men to give the antitetanic serum. Under such conditions a new advance surgical hospital would relieve the regimental aid station of a large amount of work and responsibility, as the most you can get done at a regimental aid station is to check hemorrhage and amputate a dangling limb. He adverted, however, to the fact that the scheme of advance surgical hospitals on a systematic scale would probably fall down in a push. His idea of an advance surgical hospital is that there should be three in each army corps and one for a division, and all must be underground. They had best be 40 feet long and the usual 2 m. wide, with three entrances, and on one side of a main corridor (which should be used for the waiting patients and their preparation), six alcoves. One for an X-ray room, one for an operating room, and the rest for wards. The whole thing can

hold 15 or 20 patients. Each of these hospitals should possess its own electric lighting apparatus, generated on the spot. The average distance from the line should be 5 to 7 km. There should be three per army corps and one for a division.

Army Sanitary School No. 77.

LOCALIZATION OF FOREIGN BODIES IN WAR TIMES—METHODS COMMONLY USED IN THE SANITARY STATIONS AT THE FRONT

Summary of a lecture by Dr. Th. Nogier professeur agrégé de physique medicale, à la faculté de Lyon

The X-ray tube.—Details of its structure. Its important parts, the focus or emitting source. X rays are produced within one hemisphere of the tube only.

The normal ray.—Among all the X rays in the tube, one is of quite special importance, and is called the normal ray; i. e., the ray perpendicular to the fluorescent screen. The position is determined by means of a normal ray finder, in French a "centreur." The normal ray passing through the axis of the "centreur" also passes through the center of a diaphragm or stop in front of the tube. If such a diaphragm is very narrowly opened, only a very thin pencil (i. e., practically the normal ray itself) will come through and will be easily traced out on the fluorescent screen.

Methods of localization such as are used in sanitary stations at the front may be referred to as radioscopic, magnetic, or electric processes.

A. RADIOSCOPIC PROCESSES

We consider, in succession, simple methods, complex methods, and anatomical methods.

(1) *Simple methods.*—Turning limb or body of wounded, which leads up to two following principles: (a) If image of projectile travels in same sense as that in which the limb does, the projectile is to be found between screen and axis of revolution of limb. (b) If image of projectile travels in opposite sense, the projectile is to be found between focus and axis of revolution of limb.

Impressed motion of projectile: The touch-handle or "palpeur" of Nogier allows easy finding of parts where such motion is most intense, and consequently easy determination of shortest distance between projectile and skin of wounded.

Use of two parallel rays: Two rays, both normal and parallel, the one passing through projectile, the other grazing tangentially surface of skin, render the exact measurement of distance between skin and projectile quite easy.

(2) *Complete methods.*—We shall study successively those which may be used in light cases, and those which must be resorted to for severe cases.

(a) Double axis method suitable for application in light cases: Use of two perpendicular axes or rays passing through projectile. How marks may be printed on skin at points of emergence or entrance of the normal ray (lead ball, metallic ring). Use of Nogier's "pince radioscopique" for simultaneous finding and printing on skin of above-mentioned points. Debierne's graph, showing true position of projectile within limb of wounded.

(b) Double axis and double image method suitable for application in severe cases: The "knife" process. Principle: The image of two metallic bodies that are equally distant from screen undergo equal displacements for given displacement of the X-ray tube. Use of Hirtz-Gallot's screen. Principle: Replace the real projectile by a virtual projectile whose image will undergo some displacement as that of real projectile, for one and same displacement of tube. Double image by displacing tube. The distance between screen and projectile is given by:

$$X = H \frac{l}{L + l}$$

where H is distance between focus (anticathode) and screen, L displacement of tube, l distance between two images on screen. Graphical construction of Haret and Jaugeas. Use of ready reckoners (Baremes).

(3) *Anatomical methods.* (a) Front view and side view. (b) Use of "troneonnages"; the numerical dates arrived at in above process are referred to as "coupe anatomique." (c) Noticing movements of projectile. Such movements, v. g. muscular contraction, breathing in and out, systole, etc., may give indications as to seat of projectile.

B. MAGNETIC OR ELECTRICAL PROCESSES

(1) *Compass.*—Its needle deviated by magnetic projectiles.

(2) *Bergonie's electro-vibreux.*—The magnetic projectile is made to vibrate within tissue under influence of electric magnet which is excited by alternating current. One may feel with hand parts where such vibration is maximal.

(3) *Hughes four-induction balance.*—Four small inductive coils in perfect equilibrium with regard to magnetic conditions. Presence of metallic foreign body destroys such equilibrium, and causes sound to be heard in telephonic receiver. (Apparatus: La Baume Pluvinel's "doigtier audioscopique.")

Army Sanitary School No. 79.

INJURIES AND WOUNDS OF THE EYE

By Major Magitot

The frequency of wounds of the eye can be estimated at 5 per cent of the total number of wounds.

For the facility of description it is expedient to consider three groups: (a) Laceration of the eyeball—the eye is destroyed; (b) wounds of the posterior hemisphere; (c) wounds of the anterior hemisphere.

(a) *Laceration of the eyeball.*—Only fragments of the organ remain. Line of conduct may be summarized thus: Wash with serum 12 per 1,000; remove the fragments, preserving the conjunctival flaps; restore the eyelids. Evacuate the patient as soon as possible to an ophthalmic center.

(b) *Wounds of the posterior hemisphere.*—The fragments of the shell reaches the deep segment of the eyeball by passing through the temporal region or along one of the walls of the orbit. Clinical symptoms are: More or less marked exophthalmia, chemosis, hemorrhage in the anterior chamber; loss of vision; dilated, motionless pupil. Line of conduct: Wash with saline and suture the eyelids to protect the eyeball and prevent corneal ulcer. Evacuate if possible.

(c) *Wounds of the anterior hemisphere.*—These are the most important ones. The vulnerating agent may touch the cornea alone, or the ciliary region alone, or both simultaneously. The extent of the wound is likewise an important factor, for a small wound may close up in a few hours. One can consider three kinds of wounds of the anterior segment:

1. Wounds respecting the shape of the eyeball: The first question to solve is presence or absence of a foreign body in the eyeball. Place the patient in a dark room and examine him with a pocket electric lamp held laterally. Pay attention to the following signs: Discoloration of the pupil; pupil more dilated than on the other side; turbid aspect of the aqueous humor. Examine in the field of the pupil; cataract.

One must always look for the point of entrance of the foreign body and see if there is no corresponding wound in the iris (in the shape of a little black hole). Skiagram necessary. In doubt admit the presence of a foreign body, for toleration is exceptional. Wash the eye with 12 per 1,000 saline and send the patient to an ophthalmic center, for extraction with an electromagnet. Never use atrophine.

2. Wounds causing collapse of the anterior segment: More or less large lacerations with hernia of the iris or ciliary body. In these cases it is extremely important to begin by installation of a few drops of novocaine; then wash with 12 per 1,000 salt solution. The treatment of these cases consists in excision of the hernia and covering the wound with a conjunctival flap.

Enucleation is never an imperative operation, and it is better for the wounded to have it performed by a specialist. If the patient be untransportable, and it is deemed indispensable to enucleate, the essential thing is to preserve the conjunctiva, or the eye socket could not hold a glass eye. Once the eye is removed never insert a drain or gauze in the wound.

Sympathetic ophthalmia is very grave, but happily not frequent. In the whole course of the war French ophthalmologists have only seen 30 cases. It can be avoided by asepsis and sending the patients to an ophthalmic center promptly.

There is a twofold aim to be attained: (1) Preserve the remaining vision. (2) If vision is irretrievably lost, preserve a normal appearance so that the patient will not consider himself like a mutilated man and enable him in many cases to continue his former profession.

Laceration of the eyeball; remove fragments of the eye and bone splinters. Repair the eyelids. Drain the injured facial cavities.

Wounds of the posterior segment.—Signs: Loss of vision; chemosis; lowered tonus of the eyeball; blood in the anterior chamber; motionless pupil; sometimes exophthalmia.

Treatment: Expectant; if exophthalmia, suture eyelids; slightly compressive dressing covering both eyes.

Wounds of the anterior segment.—(a) The shape of the eyeball is preserved: Wash with saline solution; excision of the hernia of the iris; removal of foreign body with electromagnet; cover the wound with the conjunctiva; binocular dressing.

(b) The eyeball is collapsed: Wash with saline solution; amputate the anterior segment or its remnants.

(c) Infection: Signs—chemosis and pain; slight temperature. Remove the eyeball.

Army Sanitary School No. 81.

VISIT TO FRACTURE HOSPITAL AT ———

This was about 20 kms. from ———, northwest, and was 25 kms. from the firing line. It had accommodations for 400 patients, and was a beautiful old château. The hospital proper was chiefly of huts, on a height, overlooking a rolling country, well wooded, filled with flowers, and near a picturesque little town. It is one of the most attractive spots I have seen in this very beautiful country. The connecting covered passageways and all outside construction was of the rustic style. It was clean and neat, well furnished and supplied, and everybody seemed comfortable and happy there. It was much too far from the front line and the surgeons stated that nearly all of their cases were already infected when received.

We went first to the surgical group and saw the triage. This room was equipped with trestles upon which were placed hooded litters for five patients, to each one of which was led off a lateral rubber tube connected with a central supply pipe, 2 inches in diameter and 30 feet long, which furnished hot air for shocked patients. The entire five could be heated with two alcohol lamps from one central point. In addition there was a large stove in one corner of the room for hot drinks and a place for heating sandbags, bottles, etc. The triage is connected by covered ways with the hospital wards.

In the extensive park in which this hospital was accommodated, with its walks shaded by tall trees and lined by flowers, was an open-air amphitheater fitted with easy chairs, for those patients who were convalescing from old infections. The surgeons seemed to think that this sunning played an active part in their recuperation, which evidently took the place of the Carrel-Dakin solution, and which he did not believe in apparently—at least he did not use it to any extent. The following cases were shown:

Case 1.—Wounded November 27, 1917. Received 13 hours after injury. Primary resection of left elbow and left knee. The resection of left elbow was followed by primitive suture, and this joint was immobilized three weeks before movement was attempted. It was halfway between pronation and supination and half extended. He did not mention what result he had gotten from the knee. The elbow, of course, was ankylosed to a large extent.

Case 2.—Severe comminuted fracture of the humerus near the head. He removed the head of the bone and all the pieces for 3 inches. Has a flail joint as a result, but he will do a myoplasty later on to help to remedy conditions.

Case 3.—A compound, comminuted, subtrochanteric fracture of the femur in an aviator due to a phosphorus shell which caused phosphorus gangrene. Later on this man had secondary hemorrhage from the femoral artery near the profunda. He was transfused with blood and the artery was tied, but there was no gangrene of the lower extremity. This man was wounded on the 20th of March. He was primitively sutured, but dangerous infection

resulted and the flat sterilized dressing which was being used was rapidly substituted by Carrel-Dakin solution. Then the temperature fell rapidly.

Case 4.—Shell wound, middle third of left thigh, with fracture of the femur and considerable destruction of bone. He was wounded the 26th of September, 1917. Was plated three months after being wounded, although he had streptococcus at the time. The plate was removed after three months. Carrel solution was never used in this case, and in the operation many bone fragments were removed before plating.

Case 5.—Fracture of the patella. Civilian. States he expects to cure in a month, as it is a simple fracture.

Case 6.—Subepiphyseal bullet wound of left humerus. As it was punctiform, it was simply immobilized with a Delbet apparatus and an aseptic dressing put on it.

Case 7.—Compound fracture of the femur due to accident. This had streptococcus and *prefringens* infection, and primary plating. The result was not determined.

Case 8.—Primary resection of the knee and removal of splinters from the humerus.

Case 9.—Shell wound of right femur, September 26, 1917; 8 inches shortening. There was streptococcus infection and septicemia, but despite this the plate was put on and kept on two months. Immobilization was produced by freshening the tibia and setting the lower end of the tibia upon it. Drained for two months and plated in spite of the streptococcus. Leg was about 8 inches short and the man was still on his back. The union was not bony, but fibrous.

Case 10.—Phlegmon of the pelvis resulting from osteomyelitis of the ilium with secondary hemorrhage from internal iliac artery, necessitating 500 gm. of blood transfusion.

Case 11.—Shell wound of the upper humerus, right, March 18, 1918. Upper third of the humerus destroyed and the scapula badly splintered. The result is not determined.

Case 12.—Shell wound of the left arm, with fracture of the humerus and severing of the musculospiral nerve. Carrel-Dakin is used in this case. Also shell wound of the left knee—treated by resection.

Case 13.—Shell wound of the upper third of the left femur. Loose fragments removed.

In a lecture and demonstration of this hospital by Doctor Latarget he expressed his opinion that bone plating was not done enough. He says he doesn't resect joints unless half or more of the joint is destroyed, but nevertheless he showed one head of a humerus and one femur that was absolutely without any injury whatsoever which he had resected for a diaphysis beneath it. He showed us in connection with his bone plating a very handsome dental rotary burr and an apparatus for applying screws and plates. He also demonstrated a large number of X-ray plates to illustrate results obtained in bones and joints he had resected. In general he goes by all of Leriche's most extreme views, but he "out-Herods Herod." He states that they make their own splints in this hospital. The operating statistics he gives are roughly, as follows: Out of 553 fractures, 281 were of the upper extremities with 3 deaths; 136 of the lower extremity, with 20 deaths; 130 cases were multiple fractures, with 52 deaths.

These should not be sent very far to the rear of the battle field for operation, as they die of shock. Fifty-five of his complicated fractures showed injury to large vessels. Of these, 6 of the upper extremity and 8 of the lower were operated on on account of gangrene. He had 15 deaths from gas gangrene. Of 12 transfusions of blood in the shock room, 7 recovered.

In the evening on returning, the commandant asked Major Baer to speak of his treatment of joint wounds. In substance he stated:

REMARKS OF MAJOR BAER

Wounds of the knee joint require primary excision of devitalized tissue and removal of the foreign body. The joint should be washed out with ether, chloroform, or normal salt solution, but you should not use the Carrel-Dakin solution because it will produce ankylosis. Then the capsule should be sewn up and a primary delayed suture done for the muscles and skin as soon as the bacteriologist reports that it is safe. The knee should be moved within 6 to 12 hours and voluntarily by the patient—never passively, and the man should be gotten out on the knee in 10 days.

If the joint fills up with fluid so that it can not be moved, it should be aspirated. If a portion of the condyle is loose, it should be removed, but never resect a knee if one condyle is left.

Major Baer explained how the standard treatment in surgery was being recommended by the interallied congress. He states that any new subject or new treatment that is proposed is gone over by a committee, opened for discussion and acted upon, and that in general the above is what the interallied congress had decided was the proper thing to do in joint injuries. He states that for infected joints the treatment of Wilhelms was now creating much comment, as the results seemed very good. This treatment consists in crucial lateral incisions over the joint and one flushing out with Dakin's solution. Then a large, loose dressing is placed on it and the patient is encouraged to walk. This squeezes out the pus and increases the synovial fluid, which acts as a continuous bath from within outward, irrigating the joint. The results he quoted were very remarkable and seemingly better than any so far obtained by any other method.

Bone plating is not considered applicable to any save the following bones in war surgery.

Subtrochanteric fractures, supracondylar fractures running into the joint, and fractures of bones running into the elbow joint. While here admissible, it must be remembered that bone plates compress the periosteum which they overlies and cause necrosis of the same and are not well tolerated. Its importance, however, is not yet decided and bone plating is being again used a good deal in a tentative sort of way. It is hoped that it will give better results under improved technique and especially with the primitive suture to help it out. Bone grafting is not considered applicable in war surgery, as wherever it can be used it must be used a long time after the wound is healed—a year or more.

Army Sanitary School No. 82.

VISIT TO H. O. E. 32, MAY 8, 1918

This beautiful hospital is the best evacuation hospital that we have yet seen in any of the armies and one of the best administered. It was situated at the foot of an abrupt hill, from which it gets its water, which is said to be abundant and of good quality.

The hospital receives its patients from the right wing of the army, and the nearest point in the firing line is 15 km. away. Patients are received directly from the regimental aid stations, G. B. D. posts, advanced surgical hospitals, and field ambulances. Its capacity is 3,350 patients, but, like all of these hospitals, it can be expanded, in this case to 5,000. There are several distinctive features about this hospital which made it exceedingly agreeable to visit. In the first place there was no trash lying about, and everything was put in its place; second, the grounds were ornate and many flowers were seen; third, the huts and barracks were well painted and in good repair, and tents were well pitched and new; and, fourth, the discipline of the place was excellent and men were not lying about in slouchy uniforms. Any man able to be about rendered the customary salute.

The water is stored for distribution in a central group of tanks raised on a high platform. There were four of these tanks and they are used in pairs. The water is Javelized. They are filled by gravity from the mountain and pipes leading out from them supply the various buildings, also by gravity. This hospital has no shell-proof cellars or dug-outs, but the huts are revetted for about 3 feet against the scattering of bomb fragments. The roads are good, of macadam, and are well guttered. Supplies are delivered over the grounds by a narrow-gauge railroad. Patients are received by motor vehicles, and evacuated from the hospital by hospital trains. A double spur runs up to a long curved platform, which allows the patients to be loaded without difficulty into two trains at once. This, of course, is immediately beside the evacuation wards.

The hospital was burned and built up again about five months ago. It is near its twin hospital, and lies toward ———. The first portion of this hospital visited was the operating group. There are three receiving wards. The two on the end are used for the reception of patients requiring operation. They are deprived of their clothing and cleaned in two rooms, where there are two tables for that purpose, but in these rooms the wound itself is not touched. They are then placed in bed in wards. From there they pass on to the center barrack into the preoperating room. If, when they reach here, or even before it, they are in a state of shock they are sent into an adjoining room for shocked patients, where there are four beds with the feet raised. This room is very simple and is heated to 35° and kept that way all

the time. It is practically a hot-air bath, but in case patients still need more heat there are the electric-lighted hoods, described in other papers for rechauffement. The surgeon divides his cases of shock into those of nervous shock, who receive saline infusions, and hemorrhagic shock, in whom the transfusion of blood by Jeanbreau's method is practiced, provision being made for both in this room. In the preoperating room the patient is prepared for operation, and when he is prepared he is carried by the litter bearers who are on duty through the corridor to the waiting ward for cases to be operated on. From this ward he passes by the corridor when called for operation to one of the radiograph rooms, where radioecopy or radiography is done. If some one is being radiographed when he arrives, a small waiting room next to this one is provided for him. This being completed, the patient is moved into one of the operating rooms. There are two operating tables in each one of these rooms, and they are very simple and well lighted, but not at all large. No instruments were kept here at all, but were all kept in the sterilizing room, which was the distributing depot for instruments and dressings, furnishing two sets of three operating rooms each on either side and which connected directly with the autoclave truck sterilizer belonging to the auto chir, which was stationed outside the building and communicated with this room directly. As the sterilizing of gloves, instruments, and dressings is done in the central plant, this sterilizer was only used in time of emergency to reinforce the central plant and to attend to pressing emergencies. One of the three operating rooms on either side was set apart for septic cases. Just beyond this group a covered way led to a group of administrative buildings of this operative group—the names on the plan indicate the purpose for which they were employed. One of the end rooms was used for the laboratory. This laboratory was very simple. In fact it was only a field mobile laboratory, and everything in the room could be packed in six small chests which form the regulation laboratory equipment of the French Army, but the quality of the work here was most excellent. The bacteriologist on duty took cultures always before operation and also at the first dressing, as well as thereafter up to as many times as he was required to take them. In the first sowing of cultures one tube was inoculated for aerobes; it was a simple agar slant. Another was melted in the form already described by Doctor McGrou—the Veillon agar for anaerobes, and a third, the Vignal capillary glass tube was filled with a more diluted culture of the same Veillon agar to enable the bacteriologist to get isolated colonies of anaerobes. At the same time a careful count was taken from smears in cases where such numerical counts ought to be made to make up the bacteriological curve, which was kept much as a fever chart would be kept. The bacteriologist here, however, gave much more importance to the presence of streptococcus and in general to the qualitative culture than he did to the number of bacteria. The bacteriologist stated that he watches the staphylococcus pretty carefully, especially when it is combined with another organism, but when the streptococcus appears he always advises keeping the wound open. In a case treated by the Carrel method he noted that the microbes were reduced from 20 in a field to 1 in 4 fields within 4 days. This operative group filled 880 beds, referred to as the beds kept for hospitalization.

We visited from here some of these wards and they were clean and exceedingly well administered, the surgeon in charge of this group being an unusually liberal-minded and bright young man. A few fractures had been sent there by accident (as the hospital does not usually receive fracture cases) and they were put in suspension with Balkan frames; but it was evident that in spite of the fact that he believed in closing joints primarily, he was afraid to mobilize them under 10 days and kept them immobilized up to that time in plaster with iron supports. He did state, however, that he believed in early mobilization and considered that 10 days preliminary immobilization was the least that one could do to put it into practice. It was in this hospital, however, that for the first time I saw a liberal comprehension of the discoveries of modern military surgery relative to the treatment of wounds. This surgeon apparently had no prejudice, nor was his enthusiasm for one or the other method so violent as to prohibit his using one or the other as they seemed best. For instance, in one case a man had multiple wounds. The smaller wounds were primarily sutured in one thigh, but in the leg of the same side there was also a large wound which was prepared for primary delayed suture; a third, in the buttock, was already receiving Carrel-Dakin solution. There was also evident a complete coordination between the bacteriologist, the surgeon, and the radiologist. In another case there was a gunshot wound of the knee and ankle from a grenade attack, with

profuse hemorrhage, requiring Jeanbreau's transfusion of blood. The capsule of the joint was closed by primary suture and some days later the muscles and skin were closed when the bacteriological examination was satisfactory, but the ankle was being treated with Carrel-Dakin solution. When cultures are taken in a Carrel-Dakin case, the solution is suspended two hours before they are made.

There are 20 operating tables that can be used for fresh wounds in this hospital.

From the surgical wards we passed by the pharmacy to the central sterilizing plant. This plant was not as complete as the one at ———, but was very clean and neat and the pharmacist in charge had a very clear idea of administration. Some very neat-looking French nurses were making dressings. The difference was that in this place not only the dressings but the instruments and gloves were sterilized and that they were sterilized in the same box. The contents were covered with a piece of gauze upon which was sprinkled 200 cg. of formal powder, and this went into the autoclave and was kept at 80° of steam for 45 minutes. It seems to me as though there would be a serious change in the chemical composition of formal when exposed to steam which might damage the instruments. The pharmacist states that he dries all instruments by a vacuum of 45 mm. They were very well satisfied with the central sterilization system, which they said gave infinitely better results than the old one. It was far more economical of men and fuel, prevented confusion in the operating groups, and never broke down. All dressings, instruments, etc., had their own particular sort of metal box, and the cotton and gauze was sterilized in larger ones, generally biscuit tins.

All gas cases go directly to the quarter for the gassed without going through the triage. As will be seen this has a capacity of about 550. There was a separate receiving tent for asphyxiated and vesicated patients, as the treatment was totally different. Asphyxiated cases were more liberally supplied with oxygen, and were lying patients. They were admitted as rapidly as possible, put to bed immediately, and given oxygen and other treatment described in the appendix. The treatment of the vesicated, of which there have been a great many cases recently, differed from all other we have seen in that they were attended to first and inscribed last. This gas reservation was the most perfect that we have ever seen. It was scrupulously clean and ideally arranged for large groups of men. Preparation for an influx of many patients was more necessary in this part of the hospital than in any other, because when there is a gas attack patients come in large numbers, all at once and all need to be treated as soon as possible. They were admitted into a long barrack with cement floor. First, they were disrobed, the clothing being thrown out through a flap door into the open. Then they rapidly passed into another room for bathing. The water was alkalized and an alkaline soap was furnished them; there were 16 showers provided. From this room they were passed into another containing alkaline solutions and sprays for eye, nose, throat, etc. The nose was irrigated by the familiar glass nasal nozzle attached to a rubber tube fitted to a white enamel irrigator and the fluid was admitted at low pressure, but it did not seem to me to be very safe for an excited man owing to the danger of the fluid being forced into the eustachian tubes. We heard here that the gomenol, 10 per cent in oil, spray was used for the nose and throat after the alkaline gargle. There was, however, no steam closet for the respiration of alkaline vapors, which would have been a fine addition. In the next room the patients were dried and given clean clothing. In this room provision was made for treating shock, and patients who had become exhausted could lie down. Next was a large rest room in which was a bureau for the taking of the man's history, booking him and inscribing him in the proper form. On the side for the asphyxiated cases there was a barrack building fitted up with 40 enameled iron beds, along one eave of which, behind the beds, was a long pipe with a distributing branch at the head of each bed for attaching a rubber tube ending in a rubber funnel for the administration of oxygen from one tank to 20 men at a time. It was a rather crude way of giving oxygen, and the Haldane apparatus seen with the English, supplied to groups of 4, seemed much better.

We now saw the radiologic outfit—not the one which belongs to the auto chir and which is installed in the operating group—but the one for the entire hospital for more formal and deliberate radiologic examination. This was not comparable to the one at ———, but was good and efficient.

We now saw the section devoted to disinfection and the salvage of dressings. This was in a hut. There were several large tubs filled with water or solutions. The gauze is treated as follows: It is soaked 24 hours in cold water; then 24 hours in another tub filled with chloride of lime solution, 1 to 1,000; then 24 hours in water again; then it is boiled, then laundered and folded, and, finally, sterilized in a steam sterilizer at 134°. The cotton was picked and only the apparently unsolded portions were saved. These were packed and shipped to the salvage depot, the dirty portions being burned. At another portion of the barrack was a concrete floor with a place for washing stretchers with hose and brush. They were kept wet with water for some time to get out the blood stains. At a distance from this plant was a circular closed incinerator of brick, 12 feet in diameter and 8 feet high, with two grates, one above the other, the lower one being 18 inches from the ground, and a high smoke-stack. To reach this incinerator, a narrow-gauge track had been extended, with cars like coal cars, which ran round the top of the incinerator and dump directly into it. It was the nearest approach to the British incinerator that we have seen, but it was pretty expensive in fuel, and the object for which it was constructed—the concealing of smoke from the enemy—was not attained, as the smoke was not destroyed. It did not burn anything but the camp waste.

We now saw an advance medical supply depot for advance troops which carried a six months' supply of dressings and medicine and 20,000 gas masks.

In passing by we noticed the quarters for nurses and for officers of the hospital. The officers lived in small huts, mostly of pasteboard, and their kitchens were separate for each "popette."

The garden, we were told, yields 25,000 francs a year. We saw in the center of the reservation, fenced in by barbed wire, a Bessonneau tent and operating group, especially for prisoners of war. The Bessonneau tent was partitioned off, by canvas painted white, into separate rooms for officers, noncommissioned officers, and enlisted men. The floor was sanded and it was in the pink of condition, clean and wholesome. Everything that the French soldier had was furnished them—every medical and surgical comfort as far as I could see. The latrines were of the usual squatting type, but an attempt had been made at some rude sort of sanitation. The latrine consisted of a canary-colored building open on one side, built upon a cement base, with 10 or 15 places to squat. The feces fell into a gutter in the cement which discharged through a pipe, emptying into a deep cesspool, which was turfed over. The gutters were filled with cresol solution, which seemed rather strong, and the dropping of the feces into this solution must have caused some rather painful burns. We were told that once a day they pulled out the plug and let the accumulation of 24 hours flow into the cesspool. That is to say, everything that floated went and everything that got stranded stayed. None of these latrines are fly proof.

The kitchens were exceedingly clean and the food they were preparing was certainly appetizing—good fried potatoes, nice vegetables, good meat; everything was perfectly orderly and clean. The floor was of cement. This kitchen cooked for 800 hospitalized patients, and the ward orderlies came up in white caps and aprons for the full amount of food consumed in their ward. This kitchen had eight cooks. At this place was also a cooking school, I understand.

The recreation hall was furnished by the Red Cross. It was very pretty and clean and well decorated. It had a scheme for darkening the windows at night which was interesting. It was simply tar paper roofing tacked on frames which were suspended on small rods or wires, and could all be lowered at once.

An apparatus for distilling water was seen near one of the big boilers; the exhaust of the steam pouring out of a 2-inch pipe was chilled by an inside pipe containing flowing cold water, an inch in diameter; this cold water circulating in the inner pipe caused condensation of the steam, and the distilled water was collected in a large vessel.

THE SECTION FOR EVACUATION

This also was the best that we have ever seen in any army. There was a large Bessonneau reception tent to which were directed all the slightly wounded, and in time of a push these were defined as all those able to walk, in whom there is no wound of a large joint nor

fracture of the thigh, leg, humerus, or skull, nor any wound involving any of the "splanchnic organs." As a matter of fact the most of these are able to walk and they are brought into this large Bessonneau tent. This floor was sanded and the whole interior absolutely clean, woodwork and all, and completely ready to functionate at a moment's notice. On entering they passed to the left and were made to sit down. From here they were called and passed to be bathed in the sections facing them. They then entered the dressing room where they were given clean clothing and from that compartment were sent to the refreshment section where they received hot drinks and food. Then their "particulars" are taken at the office which is at the center of the tent. They were then directed to sit on the benches on the other side of the tent. Six litter trestles are kept for patients that are not able to sit up any longer. If, however, any one of these men suddenly needs an operation he is taken immediately across to the two operating compartments for emergencies and operated upon on one of the four tables. If the crowd is not too great, as many of these men as possible, or only the more seriously wounded ones, in a great rush, are passed through a corridor into an operating group for the slightly wounded next door. Eighty such patients can be operated on in 24 hours per table. It is noticeable that this operating group is complete, as it has its radiologic and bacteriologic departments and wards in buildings near by. It is also noticeable that the wards connected with the evacuation plant are fitted up with iron beds in the place of trestles. All of them are clean and only in those wards next to the station which housed the outgoing, a train load, did we find the trestles supporting litters. It was explained that this was done because long delay on a litter is hard for a wounded man and these patients have to stay sometimes 48 hours or more awaiting a train. While they are here they are made comfortable in beds and are not kept on litters. They are promptly transferred to the litter supports when they are ready for evacuation, a short time before the train arrives. There is also a large Bessonneau tent for the sitting cases. This entire evacuation department was especially clean and neat and ready for instant use. It was the most poignant object lesson we have seen of preparedness for large crowds of slightly wounded at an evacuation hospital. Barracks were being prepared for the reception of the wounded of an English corps who had a semi-independent existence under the general supervision of the commanding officer of this hospital. The French took great pride in making this English quarter as perfect as possible. It was all freshly painted; it was stacked full of all sorts of supplies; and it had an operating group for the hospitalization of patients of this H. O. E.

Near this large evacuation department is the train shed which runs along the whole east front of the hospital; patients are carried out here on the litters and prepared for entraining. Two trains can be loaded at the same time here. Ordinarily, there are two trains a day in a push. During this push 120 medical officers are required for the hospital at ——— but only 40 during quiet periods.

We now visited a large Bessonneau tent near the track which served to store a reserve mobile evacuation hospital of 400 beds for the advance echelon of H. O. E.'s. It is said that there are four of these hospitals kept always ready to move in each army. It consists of 4 Bessonneau hangars and 32 Bessonneau tents, No. 2. This store hangar was completely filled with the matériel for this hospital, and it was being prepared to move out the next day. It was absolutely complete—dressings, instruments, even down to a fire extinguisher; nothing was missing, and when it was set up it could functionate completely. Its personnel was 200; 100 were here to ship it and the other 100 had been sent ahead to receive it and set it up. It needed for transportation thirty 10-ton railway cars, or 100 motor trucks, and the time required to transport it 15 kms. and set it up was 8 days, but, naturally, the hospital could be functioning in one or two days with the setting up of the first elements that arrive. This is the nearest approach I have seen in the French or British Armies toward a mobilized evacuation hospital, and anyone who has seen the Bessonneau tents can realize what an extremely practicable thing it is.

The last place visited was the group of specialists' centers. There were three huts; one occupied by the dentist, one by ophthalmologists, and one by the otorhinolaryngologists. The ophthalmologist was running a dispensary and fitted glasses except for astigmatic cases. Even the latter can be furnished if the patient remains in the hospital a sufficient length of time, as he has a lens grinder here. He has a little operating room and a special X-ray outfit

next to it, but he states that this is not an operating center for the eye and his operating outfit is only for such cases as he might have in the course of his practice. He has, of course, hospital accommodations for his patients. The otorhinolaryngologist was very well equipped with instruments, operating room, dressings, etc. The dentist showed us, with considerable pride, a portable stomatological outfit in a truck and a dentist chair, donated by American dentists. There was a prosthesis room which seemed to be complete for the making of bridges. Two sets of teeth could be turned out a day.

The pharmacy of this group was very well equipped and had a large number of trusses.

NOTES ON THIS HOSPITAL FURNISHED BY ITS COMMANDING OFFICER

This H. O. E. is in the third sanitary echelon of the army, the first being of divisional formations, the second of corps. That is to say, this is one of the largest and most important of the evacuation hospitals of the French Army. The French have recently adopted the plan of having three lines, or echelons, of H. O. E.'s or their equivalent, one behind the other.

It retains for hospitalization:

- I. In the quarter for hospitalization—
 - (a) The intransportable.
 - (b) Those who may be returned to the front in four or five weeks.
- II. In the quarter for evacuation—
 - (a) Evacuable wounded or sick who will probably not be fit for duty at the front within four or five weeks, whether operated upon or not.
- III. In the quarter for the treatment of gas—
 - (a) Patients suffering from suffocating gases.
 - (b) Those suffering from yperite.
- IV. In the dispensary quarter for the army—
 - (a) The slightly sick, indisposed (*écloppés*), and those requiring dental treatment.
- V. In the quarter for prisoners of war, for boches; it evacuates the *écloppés*—
 - (a) To the zone of the army.
 - (b) To the zone of the interior, to nearby or distant units, the evacuable wounded and sick.

According to the results of military operations, in provision for an attack, for example, where it is ordered that a maximum number of beds be held in reserve, the duration of convalescence can be lowered to 15 days, or even increased, the condition of the hospitals being the same as in the better hospitals in the interior which permit a prolonged stay.

This H. O. E. is well situated on an elevated plateau, which permits the rapid drainage of surface water, and yet is protected from the north and west winds by the chain of hills near by. It is reached easily by a number of roads.

It is large and occupies an area of 25 hectares, is connected by a double-track line with ——— and Paris, the station of the main trunk being 500 m. away, and it is not in proximity to supply depots and ammunition dumps. It presents, therefore, relative security against aerial bombardment. Black crosses 30 m. from tip to tip and 5 m. broad are visible to any aviators at more than 3,000 m. A conduit from a spring on the near-by hill fills the cement reservoirs, each of which have a capacity of 20 c. m. They distribute water to all operating wards and to the different quarters.

The entrance of the H. O. E. is marked by large signs which are visible a long distance by day, and by lights during the night, in addition to which there is a police post with an orderly at the entrance and others between it and the triage. Aside from the wounded that arrive in motor ambulances, some arrive on foot and must be directed rapidly toward the reception wards of the triage. For the reception of a great number of wounded at one time it is necessary to provide large receiving stations, "reservoirs for the reception of patients," well lighted, provided with benches for the sitting and with trestles or litter supports for the recumbent, with a station for hot drinks, and at the same time a reservoir of hot water, with installation connected therewith for washing patients. Lastly, there is provision made for the heating of shocked patients. Nothing is more distressing than to see the roads encumbered with motor ambulances full of wounded and without a place to go for comfort and cover. Prevent blocking.

DISTRIBUTION OF THE DIFFERENT SERVICES IN AN H. O. E.

Groups of operating buildings are needed for the preparation of the wounded so as to leave to the surgeon the exclusive mission of operating. It is necessary to operate quickly and well before evacuating.

1. Wards for hospitalization.
2. Wards for evacuation in which the wounded man is to be lodged only temporarily; tents may be utilized and are easily set up.
3. General administrative offices, storehouses, workshops, etc.
4. Quarters for officers, for female nurses, and for enlisted men of the Medical Department.

Pharmacy, surgical sterilization plant, laundry, tea house, chapel, and morgue.

All technical administrative and working parties are divided into teams in order to carry on their services continuously, as follows: First team on duty from 9 p. m. to 5 a. m.; second team on duty from 5 a. m. to 1 p. m.; third team on duty from 1 p. m. to 9 p. m.

In times of inactivity only one triage is needed for the hospital, but in times of activity the triage is divided into triage for sitting and triage for lying patients, the two being separated a sufficient distance to avoid disorder and confusion. In case of a grand rush of patients, hangars can be utilized which will contain 200 lying or 500 sitting. The vesicated cases are directed immediately to their special gas stations so as not to contaminate the reception wards ordinarily destined for other patients.

THE OUTPUT OF THE HOSPITAL

The number of beds is 3,380, and these are designated as follows:

	Beds
For hospitalization, 22 wards, 40 beds each	880
For evacuation lying, 20 wards, 40 beds each	800
For evacuation sitting, 20 wards, 50 beds each	1,000
For écloppés and the vesicated, 5 wards, 50 beds each	250
3 Bessonneau hangars for the vesicated and prisoners of war, 150 beds each	450
Total	3,380

The necessary personnel will vary according to the necessities of the moment. When the hospital is functioning at its full capacity, it needs:

	Officers	Enlisted men
3 auto-chairs	39	102
20 surgical teams	40	60
10 field ambulances	80	380
Sections of evacuation hospital	12	52
Reinforcement H. O. E.	12	250
Specialists:		
(a) Otorhinolaryngologist	1	1
(b) Odontologist	1	1
(c) Radiologists	3	3
Total	188	849

To this it is necessary to add: For litter bearing, 240 territorials; for automobile transport, 60 enlisted men; for the supply train, 52 chauffeurs; female nurses, 104.

Total to be rationed about, 1,500.

The service of an operation table is provided by two teams which alternate on the tertiary system as follows: Team No. 1 from 5 a. m. to 1 p. m. and from 9 p. m. to 5 a. m., a total of 16 hours; team No. 2 from 1 p. m. to 9 p. m., 8 hours. The next day team No. 2 does the 16 hours' duty and team No. 1 the 8 hours.

Average number of patients operated upon per table, for 24 hours: Badly wounded, 20; lying wounded (moderate severity), 30; sitting wounded and slightly wounded, 100.

Six tables for hospitalization yield 120 operations on seriously wounded in 24 hours.

Six tables for lying wounded to be evacuated yield 180 in 24 hours.

Six tables for sitting wounded, slight cases, 600.

This makes 900 wounded operated upon at this hospital in 24 hours.

According to the intake of wounded, the H. O. E. can functionate at different rates of speed, either accelerated or intense, by reason of the number of surgical teams placed at its disposal by the chief surgeon of the army. If a number of wounded superior to the operative capacity of the H. O. E. should arrive, the commanding officer of the hospital, in constant communication with the chief surgeon of the army, would receive reinforcements or would evacuate wounded not operated on upon neighboring surgical centers. After having received notice from the consulting surgeon of the army as to where they may be sent, these wounded would be evacuated by auto or by train. The commanding officer of the hospital ought to be always in liaison, first, with the group of the field hospitals of the corps, and with the fourth bureau of the general staff to request mixed trains in case of necessity for *éclopés* or permanent trains for the wounded; second, with the regulating station by means of its regulating commander of trains (*commissaire régulateur*) and the sanitary regulating center.

SURGICAL LIAISON

The commanding officer of the H. O. E. should place himself in communication:

First. With the centers to which he must evacuate in the zone of the lines of communication, which are in this case 1,000 beds, with the idea of deflecting the motor ambulances arriving with wounded to them when the operative capacity of this H. O. E. is exceeded.

Second. With the regulating station, through its military regulator of trains (*commissaire régulateur*) and the regulating sanitary center.

Third. With the chief surgeon of the army. From the moment when the operative capacity for 10 hours of work in periods of calm is going to be attained the chief surgeon will then send reinforcements or direct evacuation on a neighboring center.

Fourth. With the groups of field hospitals of the corps.

Fifth. With the fourth bureau of the general staff, to requisition permanent trains or mixed trains for *éclopés*.

Sixth. With the surgical centers on which will be eventually evacuated the wounded not operated upon at the H. O. E. receiving them, by liaison with the consulting surgeon.

SERVICES OF TRIAGE

"Triage" means the reception and inscription of those patients admitted and their distribution in the different quarters for hospitalization or evacuation. The wounded and the sick brought to the triage by the motor ambulances come: First, from advance sanitary formations—(a) from divisional posts; (b) from the groups of field hospitals of the corps. Second, directly from their corps; that is to say, units which are not parts of divisions.

The motor ambulances are always waited for and discharged rapidly and with due precaution by the litter bearers of the triage under the supervision of a noncommissioned officer. The patients admitted are deprived of their arms and equipment, taken to the room for change of clothing, and only preserve their personal effects, which are examined to avoid the entrance of explosives into the hospital. Those admitted sitting take their place on benches holding four. Those lying are placed on the litter supports. The medical officer in charge of this service then sorts them into different categories: First, the sick, sitting, or lying—(a) those with acute diseases not contagious; (b) the tuberculous cases; (c) the venereal and cutaneous diseases; (d) the contagious diseases, etc. Second, the wounded—(a) the evacuable cases, sitting and lying (these are sent to the quarter for evacuation); (b) the nonevacuable cases, sitting or lying, are sent to the quarter for hospitalization. Third, the *éclopés*.

The clerks commence the inscription for admission by making out the "carnets de passage" (admission slips) appropriately for each category. The carnet de passage is made out in triplicate; one copy accompanies the wounded man, another is sent to the War Office, and a third remains in the archives of the H. O. E. During the inscription the medical officer in charge hastens to determine the most serious cases of wounds and illness to give them first attention. He assures himself that the wounded have received the antitetanic serum, and if they have not he gives it to them himself in the dressing room.

SERVICE OF EVACUATION

The service of evacuation executes the order for the evacuation of wounded and sick received at the H. O. E., according to the manner prescribed by the ward surgeons. Wounded and sick can, as a matter of fact, receive many destinations, either:

First. They may be sent to formations in the zone of the interior (Z. I.) or the zone of the army (Z. A.) for the continuation of their treatment.

Second. They may be evacuated on sanitary formations of the army specialized for the treatment of certain medical or surgical affections (contagious diseases, venereal diseases, fractures, etc.).

Third. They may rejoin their units at the front after cure, with or without leave of absence on account of convalescence.

EVACUATION BY SANITARY TRAINS

Sanitary trains are of many categories:

(a) The permanent sanitary trains (T. S. permanent). These are for the exclusive use of gravely wounded lying patients that are transported in beds, and are always sent to Paris.

(b) Semipermanent sanitary trains (T. S. semipermanent) for the wounded and sick, sitting and lying, directed to the zone of the interior or the zone of the army (Z. I. or Z. A.).

(c) Mixed improvised sanitary trains (T. S. improvisés mixtes), sitting or lying, or only for sitting or for lying. These do not function except in intensive periods, in which the destination is the same as for the semipermanent trains.

(d) Ordinary or commercial trains reserved for the transport of *éclopés*.

The permanent sanitary trains do not receive any but French lying wounded. There is an absolute exclusion of the sick and all Mussulman or native patients.

The semipermanent trains for the zone of the interior receive all sick or wounded, lying or sitting, French or foreign, who can not be returned to the lines within five weeks. These trains also evacuate the prisoners of war.

The semipermanent trains for the zone of the army receive all sick or wounded, sitting or lying, French or foreign, that can be sent back to the lines within five weeks.

According to necessity, the sanitary trains are requisitioned for directly by the commanding officer of the H. O. E. on the regulating medical officer and the regulating station of the Army. The call for a train should state (1) the category of train demanded (T. S. permanent, semipermanent, etc.); (2) its composition (number of sitting or lying); (3) its destination (Z. I., Z. A., and, in the latter zone, whether Paris, or a unit near or a unit far from the H. O. E.).

In periods of moderate activity the service of evacuation does not make any special requisition for trains. It sends to the medical officer regulating the trains by telephone every day, at 4 o'clock in the afternoon, a statement as to the number of evacuable patients from the H. O. E. The regulating station receives a like notice from the H. O. E.'s of the whole region and provides, according to necessity, a train called "*de remassage*" for an expressed category of patients.

LOADING OF SANITARY TRAIN

When the regulating station has announced the arrival of a sanitary train, the hour, and the character of the evacuable patients to be loaded thereon, the service of evacuation advises the ward surgeons to prepare their sick and wounded. At some time before the hour fixed, those to be evacuated are taken from the wards by the bureau of evacuation and conducted to the evacuation wards near the railway platform. There a medical officer sorts these cases as follows:

(1) According to destination: (a) Sick; (b) wounded; (c) cases requiring attention of a specialist.

(2) According to the mode of transport: (a) Sitting; (b) lying.

(3) According to the character of the patient: (a) Officer; (b) lying; (c) Mussulmen; (d) natives.

This officer assures himself that all of those to be evacuated can endure the fatigues of the trip; he verifies the details of the diagnosis, the fact as to whether they have received antitetanic injections or not, the care to be given them in the course of their trip, their diet en route, etc. The patients to be evacuated will be properly fed and provided with clothing and foot covering. From the moment of the arrival of the sanitary train at the train platform for embarkation the loading is performed by the H. O. E. and the train force by mutual cooperation. The embarking officer gives a nominal list of the sick and wounded to be evacuated to the commanding officer of the train, who verifies its correctness in his presence. The convoy once under way, the service of evacuation notifies the regulating medical officer of the load, with its classifications, numbers of officers, Allies, Mussuhnen, and prisoners of war, and indicates the hour of departure of the train.

EVACUATION UPON SANITARY FORMATIONS OF THE ARMY BY AMBULANCE

Certain sick and wounded are evacuated on sanitary formations of the Army—to specialists in the treatment of medical or surgical affections, such as wounds of the eye and orbit, fractures, venereal cases, contagious diseases, nervous complications. The transportation of these patients is made by automobile ambulances of the motor ambulance convoy (S. S. A.), on duty at the H. O. E. Mental cases are always accompanied by a medical department soldier charged with their surveillance en route. A constant liaison between the H. O. E. which evacuates and the sanitary formation that receives is maintained; the evacuation of every sick or wounded man is announced by telephonic message. The motor ambulance convoy (S. S. A.) is also employed for the transportation of sick or wounded from the units which are not part of a division and which request transportation from the commanding officer of the H. O. E.

EVACUATION BY REASON OF CURE

It is the slightly wounded and slightly sick proceeding from the field hospitals of the corps, or from units which are not part of a division, able to return in a few days—eight at the outside—that are directed to rejoin their corps after cure. On admission, the services which have treated them give the details for their evacuation to the bureau of evacuation, which inquires into the whereabouts of their unit of origin, and thus is in a position to secure their return without fail to their units when they are cured. The service of evacuation assures itself in addition that these men are equipped, except when they have to pass through the regulation station to rejoin their unit. In such cases they are rearmed and reequipped by the depot of reequipment of the regulation station. Each man leaving the H. O. E. on account of cure is furnished with an order to rejoin his formation. This order expresses the hour of departure and the route over which he should go. The bureau of evacuation consists of a medical officer, an officer of administration, and six clerks, divided into two teams, which perform their duties at eight-hour intervals.

MANNER OF FUNCTIONING OF THE PHARMACEUTICAL SERVICES

This station comprises, in addition to the preparation of medicaments, all the technical service required for surgical sterilization, for the general hygiene of the H. O. E., for the salvage of cotton and gauze for dressings, for the manufacture of ice, and, by assimilation, the surveillance of the vegetable gardens and farm created for the purpose of bettering and varying the food of wounded and of the personnel of the hospital. The pharmaceutical service, properly speaking, comprises: (1) The central pharmacy of the hospital; (2) the special pharmacy for the specialist's infirmaries; (3) the reserve supply of drugs.

THE CENTRAL PHARMACY

The central pharmacy of the hospital prepares and delivers the medicaments prescribed by the ward surgeons, as well as the dressings, ligature material, sterilized dressings, etc., necessary in the surgical service. The pharmaceutical and surgical preparations vary according to the preference of the physician or surgeon, as far as drugs and antiseptics are concerned. However, certain products are prepared daily in large quantities, such as liquid soap, iodized benzol, used for the general cleansing of wounded in the preoperating room, and liquid antiseptics of current use, such as the solution of Manciére and Dakin's solution.

For the treatment of the vesicated the central pharmacy furnishes to the gas quarter bicarbonate solution, alkaline powder for burns, calcium soap liniment, and solution of sucrate of lime.

The central pharmacy cares for all rubber goods, such as oxygen balloons, ice bags, hot-water bags, rubber tubes, etc.

All of the teas for the wounded are prepared at the tea house, which is a dependency of the pharmacy. The drinks usually prepared are coffee, milk, tea, lime-juice drinks, herb teas, tartarie lemonade, and the vinous tartaric lemonade.

A chemical analytic laboratory, an annex of the pharmacy, permits investigation in clinical chemistry, besides the analysis of some foodstuffs and all drugs in a doubtful state of conservation. The chief pharmacist has to secure compliance with the law concerning poisonous substances. He has to inspect the different services of the hospital with a view of verifying the good state of preservation of some drugs and antiseptics on constant use in the wards.

THE PHARMACY FOR THE SPECIALIST'S INFIRMARIES

This is a special pharmacy installed in the barrack quarter of the special medical and surgical consultants, which is charged with preparing and delivering to the consultant surgeons from the phtharmological and otorhinolaryngological and dental services the medicines prescribed by these specialists. The pharmacy is also in charge of the delivery of trusses for hernia, elastic bandages, required stockings for varicose veins, and the suspensory bandages required by the consulting surgeons, to those who present prescriptions signed by the medical chief of their formations.

THE ADVANCE RESERVE SUPPLY OF DRUGS

This is installed in a special barrack building and hangar and is for the purpose of delivering to sanitary formations of the Army, to regiments, to isolated services, to cantonment infirmaries, to sanitary teams, to parks of artillery, and aviators, etc., those drugs and disinfectants that they need. This formation prepares and delivers, also, dressings and therapeutic products for the treatment of the vesicated and issues all of the preventive apparatus against asphyxiating gases. This latter material, such as masks, Tissot apparatus, Draeger apparatus, oxygen tanks, spare parts for these various apparatus, etc., is regularly verified and carefully looked out for.

SERVICES OF STERILIZATION

The service of sterilization, which will be made the object of more detailed study, furnishes to operating groups, to the dressing rooms, to the ward surgeons, etc., all sterilized material, such as cotton, gauze, compresses, gloves, instruments, syringes, operating-room linen, etc.

GENERAL HYGIENE

This complex service solves all the questions which concern directly or indirectly the rules of hygiene, such as: Javellization of drinking waters; general police of the camp; hygiene of the cantonment; police of kitchen and inspection of food; disinfection and deodorization of latrines; disinfection of men's effects, all personal linen, bed linen, and other linen for different uses; disinfection of ambulances used for contagious cases; incineration of old dressings, linen hopelessly stained with blood or rust; the police and deodorization of the morgue; campaign against rats, flies, and microbes.

SALVAGE OF COTTON AND MATERIAL USED FOR DRESSINGS

Cotton bandages, compresses, and objects for dressings, susceptible of being again used, are recovered, sorted with care, and sterilized. The bandages, compresses, operating-room towels, etc., are immediately washed with care, rinsed, and folded or rolled again for fresh usage.

MANUFACTURE OF ICE

An ice manufacturing plant can produce 500 kilos. a day, and works near the hospital. The ice thus prepared is intended for surgical and medical uses in the hospital and for the sanitary formations which are near the hospital.

THE TRUCK GARDEN AND FARM

In order to employ the idle moments of certain working parties, there has been created on land appertaining to the hospital a truck garden comprising 2 ha. of land, for the cultivation of potatoes, peas, lettuce, beans, cabbages, carrots, turnips, parsley, spinach, etc. These vegetables permit of variation and improvement in the régime of the sick, and provide fresh food for the enlisted men among the personnel. Greasy water, garbage, etc., is used to fatten pigs, rabbits, and chickens.

CENTRAL STERILIZATION

The central sterilization plan comprises a Geneste-Hercher autoclave, which also furnishes steam for two boilers, and another autoclave, O. M. 34. The larger door of the Geneste autoclave opens through a partition entirely separating the interior of the sterilizing plant properly speaking, which itself is divided again as follows into, first, a room for the preparation of dressings, etc.; second, a room containing a reserve of sterilized dressings and instruments; and third, a distributing room.

Sterilization of dressings.—The compresses, the cotton batting and absorbent cotton, the operating towels, etc., are placed, each in its own class of boxes, and all sterilized in the Geneste autoclave for an hour and three-quarters at a temperature of 134° C. with a registering manometer and capillary glass tubes, testing efficiency of the disinfection by a color test in the center of the dressings (sulphur and a trace of methylene blue which fuses at the proper temperature for sterilization). At the end of this time a vacuum is created for 10 minutes to dry the dressings, and then the boxes are removed, care being used to close the openings through which the steam has passed previously.

Sterilization of instruments.—The gloves are well cleaned and dried, the fingers and thumb of the hand are slightly dampened with a solution of formol of 40 per cent and the glove turned inside out. A cuff is turned back for the purpose of leaving the hand of the glove open and the glove is wrapped in gauze with pieces of same between the fingers and placed in a metal box which is placed in the autoclave and subjected to a temperature of 80° for 45 minutes, just as the instruments were.

Sterilization of syringes.—The syringes are cleaned, boiled for 15 minutes and dried. They are then separately wrapped in filter paper, leaving one end open, into which one introduces 10 drops of ether before closing. They are now sterilized for 20 minutes at 110° C. and are dried in the autoclave by a vacuum.

The central sterilizing plant sterilizes every day the dressings, instruments, and gloves necessary for the hospital wards of the operating rooms.

BACTERIOLOGICAL LABORATORY, AUTO-CHIR 19

When the wounded man arrives at the auto-chir, specimens are taken, either from the serum at the bottom of the wound, or from a bit of clothing or projectile extracted by the surgeon during his intervention. These are sown in cultures: First, cultures for aerobes on an agar slant; second, cultures of anaerobes on Veillon agar which grow in the deeper portions and, separately, dilute agar cultures for anaerobes in the Vignal tube.

These cultures are left in the incubator at 37° C. for 12 to 14 hours, and the result is then communicated to the surgeon.

Cultures at the time of dressing.—In the course of the various dressings performed, specimens are taken of the pus, which is examined first, by smears on glass slides, which serve for the enumeration of the microbes and the establishing of the bacteriological chart; second, by cultures taken from the pus to determine the quality of the infecting microbe.

For the primary and the primary delayed sutures the surgeon has at his disposition first, cultures that show him the quality of the microbes in the wound, particularly with reference to the presence or absence of streptococcus; second, a bacteriological curve giving him the quantity of the microbes contained in the wound, in the course of its healing.

THE SPECIALISTS

The otorhinolaryngological services

This service functions in such wise as to permit of a dispensary as well as the hospitalization of wounded or sick.

The dispensary service.—This takes place every day from 9 to 12. There are received sick from the corps, the divisional depots, and divers organizations in the neighborhood. After examination of the patient the result is inscribed on an individual diagnosis tag that remains at the dispensary, and also on a slip called a "consultation slip" taken back by the patient to the surgeon that requested the examination. This slip also bears an indication to this surgeon of the method of treatment which should be employed at the organization from which the patient came, the decision as to the nature of the disease and the precautions to be taken, with the exemptions from duty which may be permitted. Prescriptions, if such are necessary, are filled for the patients by the pharmacy for the specialists installed in this barrack quarter. In this wise are examined also the sick of other services of H. O. E. and also some civilians.

The hospitalization section.—The wounded are received as well as the sick and they get special care where it is impossible to give it to them in their corps, and in such cases where the patients need operative intervention. The time of hospitalization varies from 15 days to 3 weeks. If a patient is intransportable or needs long treatment, he is evacuated. In short, these services permit treatment of sick and wounded of the Army, the great majority of which can rejoin their corps directly, and it facilitates the salvage of these men to their troops.

Service of the gas center

The vesicated and those suffering from yperite.—The composition of the gas: The vesicant gases employed by the Germans are generally on a base of dichlor-ethyl-sulphide, associated with other substances, particularly with the tetrachloride of carbon.

Immediate effects: Vesication of the mucous membrane of the conjunctivæ, and the nasal and pharyngeal mucous membrane. Also vesication of the skin, particularly of the neck and armpits, and the folds around the anus and the scrotum.

Late effects: Ulceration of mucous membrane, tracheitis, bronchitis, bronchopneumonia, edema of the lung, and death.

Treatment: Should be given as soon as possible to limit the effects of gas and to prevent complications, such as bronchopneumonia, etc. To this end—

a. We should disrobe the patient entirely, taking away his outer clothing and soiled underclothing loaded with yperite. He should pass under a warm douche of soapy water, or, better, one which contains carbonate of soda (1 to 1,000), or limewater.

b. The mucous membrane should be washed, such as the eyes, nose, mouth, pharynx, with one of the following warm solutions: (a) Lime solution, composed of limewater and distilled water, equal parts; (b) solution of saccharate or sucrate of lime, composed of sugar, 15 gm.; slack lime, 15 gm. to 1 liter distilled water; (c) solution of bicarbonate composed of chloride of sodium, 14 gm.; bicarbonate of soda, 40 gm.; distilled water, 1 l. These lavages are repeated two or three times a day as long as it is considered necessary.

c. In case of vesication of the skin it is necessary to dust with neutralizing powder as follows: Tale, 40 gm.; carbonate calcium, 20 gm.; carbonate of magnesia, 20 gm.; oxide of zinc, 20 gm.

Gassed patients are examined and treated wherever necessary by the ophthalmological or otorhinolaryngological services, and these specialists are notified in all cases where lesions are produced in the organs in which they are specialized.

In general the following remedial agents are employed: The various collyria and inhalations, and fumigations with eucalyptol and benzoate of soda, also spraying with gomenol oil (10 per cent in the throat, nose, etc.). The duration of the treatment varies, according to the gravity of the lesion, from some days to a month. The preparation of the sweetened solution of the sucrate of lime is as follows:

1. Dilute with greatest care 12 gm. of slack lime, washed in 150 c. c. of distilled water.
2. Dissolve 25 gm. of sugar in 50 c. c. of distilled water.

3. Mix the milk of lime with the cold sugar solution and leave it in contact for 24 hours.

4. Decant with care or filter and place in a flask.

Prepare the solution of the succrate of lime for washing out the eyes of the yperited by diluting the mother liquid of the succrate of lime in the proportion of 40 c. c. to 1,000 c. c. of water.

Disimpregnation of the clothing.—The clothing of gassed cases is handled by enlisted men of the Medical Department properly protected by masks, waxed clothing, and mittens. The clothing of those who have been gassed lightly is assembled, beaten, hung up, and exposed to the air for 48 hours in an open drying shed. That from the severely yperited is soaked in water at 80° or 85° for an hour and then dried in the air.

Disimpregnation of arms, leather articles, and munitions.—Rough dirt is removed by rags, which are immediately destroyed. The contaminated articles are powdered with dry chloride of lime, which is left on two hours and then washed in plenty of water.

Disimpregnation of ambulances and trucks.—All that have been used to transport gas cases are disimpregnated with the Vermorel apparatus, by a solution of chloride of lime, 1 to 4. For the disimpregnation of certain localities the same process is used.

Gas intoxications

These intoxications are especially due to suffocating gases, palite, superpalite, arsine, bromacetone, chloropierine. They can be light or serious.

(a) Treatment of light or medium intoxication: Ipecac to the point of nausea, inhalations of oxygen, wet cups, or blood letting to 500 gm. cardiac stimulation by sparteine or camphorated oil in large doses.

(b) Treatment of serious intoxication accompanied by acute edema of the lung: Repeated blood letting, cardiac tonics—sustained at regular intervals—oxygen subcutaneously and frequently repeated. In all of this treatment there should be complete abstension from opiates, especially morphine.

Dental services

The dental service of the H. O. E. has a double rôle to fill.

1. An operating dental office for extraction, filling, and cleaning teeth, etc., for the personnel of the H. O. E., for the sick and wounded of the hospital, and for the formations which are not in a division cantoned near by.

2. The prosthetic workshop, which furnishes bridges to those of the enlisted men who lack teeth for mastication.

THE GENERAL PRINCIPLES OF TREATMENT OF GUNSHOT WOUNDS

By M. L' Medecin-Major seconde classe terracol

The surgeon on duty who dresses a wound of war ought always to bear two objects in mind: First, to prevent infection; second, to make an anatomical, and especially a functional repair of the parts damaged by the projectile.

1. *To combat infection.*—(a) Every wound produced by a projectile in war ought to be considered as infected by the projectile and the clothing that it carries in with it.

(b) The only treatment that can be employed to combat infection consists in opening up the wound to the air and surgically cleaning it by cutting instruments.

(c) In general, up to the sixtieth hour, there is comparatively little reaction "phase de sideration", from there on the germs multiply and are diffused.

(d) The quality of the microbe in the wound is more important than its quantity. the streptococcus is to be especially feared, whether alone or associated.

The conclusions to be drawn from these axioms are as follows: The operation should be done early and completely with extraction of the projectile, with removal of the contused and devitalized tissue, the debris of clothing, etc. This should all be controlled by bacteriology. There is only one contraindication to this procedure—that is to say, shock, with the exception of hemorrhagic shock, if it is possible to separate it out clinically from simple shock. In the case of shock we have many means at our disposal such as heating, transfusion, and tonics, and we should lose no time in bringing a patient to surgical intervention to avoid the consequences of delay.

2. *The anatomical and functional repair of the tissues.*—(a) These are the easier when infection has been prevented.

(b) We must avoid extensive removal of soft parts and bone.

(c) Intervention is all the more efficacious and complete when it is done early. The matter of sutures following the operation should be under the control of the bacteriologist.

FUNCTIONING OF THE SURGICAL SERVICES

On account of the specialization of the services at this hospital and its distance from the line, the wounded treated are those of the soft parts and the articulations, some fractures, rarely brain or cranial wounds, never abdominal nor serious open thoracic wounds, except when these accidents are produced in the zone near this formation.

Arrival of the wounded at the triage of the operating group.—(1) Examination by the orderly officer of the day.

(2) Undressing and general cleansing.

(3) Transfer to the preoperating ward.

(4) Examination by the surgeon on duty, who determines whether the wounded man is operable or not.

Nonoperable wounded.—Transfer to shock room and proceed with antishock treatment, such as heating, lowering of the head, administration of adrenaline and normal salt solution under the skin, the administration of cardiac tonics, and the transfusion of blood according to Jeanbreaux's method under the supervision of a medical officer.

Operable wounded.—(1) Cleansing of the borders of the wound; shaving.

(2) Transfer to the radiograph room, where every wounded man is examined under the X ray.

(3) Transfer to the operating room.

Radioscopic and radiographic examination.—In the majority of cases radioscopy suffices. The localization of the projectile and its exact position in the tissues is determined by Strohl's method, which is excellent from its rapidity, its facility, and its exactness. In cases where there are multiple fragments or where those fragments are in difficult situations, they are generally extracted under the operating screen or "bonnet" on the X-ray operating table.

In a wounded man with serious wounds requiring rapid action, the fragments which are in difficult surgical position are removed later on under the guidance of the Hirtz compass, in which case a radiograph has to be made and radioscopy also employed.

In case of fractures, a radiograph is taken, front and side views.

OPERATIVE PROCEDURE

Soft parts.—Application of methods in actual general use: Removal of the borders of the wound, débridement plane by plane, excision of ischemic tissues, removal of the projectile. The principles which should govern are: Remove wounded tissues if the sacrifice of such tissue does not produce too much damage and does not wound any important organ. Another principle is to open well the chamber of attrition. These principles should be applied to all shell bursts. In the treatment of wounds by bullets there are two situations.

(1) The wounds with punctiform orifices: If the borders are clean, paint them with tincture of iodine and put on a dressing. If the borders are lightly torn, excise the skin and suture immediately.

(2) Large orifices: Procedure is the same as for a wound caused by a shell burst, but with the difference that the contused tissues are more superficial and the muscles bleed immediately upon cutting; there is no debris of clothing. When there are not too many of these wounded at one time primary suture should be done, but when there is a great rush the delayed primary suture should be considered.

To suture or not to suture?—The ideal that one pursues when the wound is wide open, the flesh well explored, and the projectile removed, is to suture primarily, after cleaning with ether. When dusting with Vincent's powder one should not suture hermetically if the wound is deep, but should leave a drain at its most dependent part. The drain is best composed of silkworm gut permitting capillary drainage.

A quantitative bacteriological examination, and above all, a qualitative, to determine the presence of streptococcus.—It is necessary to watch the temperature, but better the pulse and general condition. If streptococcus is found, open the wound. If straphylococcus, watch it carefully. If other cocci or banal germs, wait. At the end of three or four days remove the capillary drain and examine it bacteriologically. The important thing is to secure a complete hemostasis. If the wound is deep and rather old, the cleaning is difficult and one must drain. Apply a Menci re dressing, Vincent's powder, or Carrel tubes. Make a bacteriological examination immediately at the first dressing and make a qualitative and quantitative analysis of the deep and superficial parts of the wound. When you find only 1 microbe to 4 to 10 fields after two successive examinations, suture immediately (primary retarded suture). If there are bacteria in a quantity superior to the above, irrigate with Dakin's solution and after sterilization do a secondary suture. The important thing is to rapidly close with suture to avoid formation of fibrous tissue, adhesions, a puckered scar, necessity of resection, and the risk of opening up new foci of microbes. Powder of Vincent should be placed on the suspicious parts of the wound where hemostasis might not be complete, and the capillary drain should be withdrawn after 48 hours and should be subjected to bacteriological examination. The deep suture should be of catgut; suture of the skin should be performed with silkworm gut or metal clamps.

Fractures.—Same treatment as for the soft parts. Removal of the edges of the wound, excision of contused tissues and, in general, except when there are too many wounded at one time, make a radiograph. Removal of splinters freed from the periosteum. Adherent splinters should be subperiosteally resected when they prevent access to the medullary cavity. Strict immobilization, either in plaster apparatus with metal supports, or, frequently, by the suspension apparatus of Blake, with traction to permit irrigation and disinfection by Carrel's method. It is not advised to do a primary plating of the fragments. In general primitive sutures in fracture cases are not advised except in the case of fractures with few splinters and with osseous damage that is well exposed and superficial.

Articulations.—The principle is to close immediately or nearly immediately, under the control of a bacteriologist. For the knee, except in the cases of deep-lying projectiles or serious shattering of bone, a lateral or bilateral arthrotomy is advised, with a thorough cleaning of the wound cavity by ether. Generally, no division should be made of the patella tendon. In case there is a "laparotomy of the knee" in the above mentioned cases, the patella tendon should be perfectly sutured, followed by immobilization either by plaster reinforced by a posterior splint, or by suspension. The knee should be early mobilized and the patient should be gotten out of bed soon. No other articulations require any special mention.

Cranial wounds.—Exploration of every wound of the scalp and application of a primitive suture. When there is a lesion of the underlying bone, trephine or enlarge with biting forceps. In case of a lesion of the bone, without opening the dura, suture immediately. For intracranial projectiles, extract under the screen; extract all foreign bodies with an ear forceps, and in the case of projectiles that are accessible and well seen, extraction should be immediate in order to profit by the track of the projectile.

Amputations.—The conservation of a limb is imposed to the extreme limit except in cases of very extensive destruction of the soft parts or of the bones, or in case of lesion of vascular organs which compromise the vitality of the limb, or in grave infections. The object is to preserve the maximum of length of a limb in order to apply a prosthetic apparatus. For patients who are suffering from shock, a circular amputation is done. Recovery being rapid, a prosthetic apparatus should be applied temporarily—best a plaster apparatus.

Gas gangrene.—This is now exceedingly rare. There are light forms and localized forms known as gas phlegmons. They disappear after being opened up to the air (*perfringens*). Vincent's powder or Dakin's solution can be used and secondary suture practiced later.

There are no cases of tetanus in this hospital, and injections of serum are repeated twice.

There is no particular method followed for the wounds of the vessels nor of the abdomen, or chest, except that in the latter it is well to extract large shell fragments in the lung which might cause complications.

VISIT TO H. O. E. 22

This hospital is situated near the H. O. E. at ——— and has more tents than huts. It is a comparatively new hospital and its capacity is 2,800 patients. It was originally intended for slightly wounded, but now receives all kinds, as it is comparatively near the line. It is a beautiful place, in rolling country, and very clean, being well administered. There are 80 Bessonneau tents and 4 Bessonneau hangars. The medical officer in command had been gassed by CO from riding in a French ambulance and was unable to go about with us. We were taken about by a major, his second in command.

The triage consists of four barracks parallel to each other, as at B———. One for sick, one for recumbent cases, one for sitting cases, and one for pack store, in which to put equipment and clothing, but, in addition to this there was a Bessonneau hangar for a large number of sitters—300. The floor was sanded and it was noticed that in place of trestles for litters they had square frames of scantling, very solid, for two litters each. The seats and trestles had been painted white and were neat and clean. It was temporarily being used for a shelter. The grounds are well parked, with solid roads, good gutters, gravel walks, and flowers in every direction. There are three operating groups in this hospital, which has four operating tables for serious operations and two tables for dressings. The general arrangement of these operating groups is the same for all three. On either side are two large Bessonneau tents and farther away some barrack wards for hospitalization of nonevacuable surgical cases. One of the operating tables for serious cases is in the X-ray operating room. There an operation can be done on an aluminum table by means of a fluoroscopic bonnet. It was stated 12 teams could work in each group. The ward on the left, as one entered, was used for badly wounded or cases recently operated upon which could not be moved immediately to the ward. Bessonneau hangars are set up in 3 or 4 days by teams sent from the army. The small Bessonneau tents for wards require three hours to set up. The floors were generally sand or gravel, but now and then of wood. These tents held from 15 to 20 comfortably, with iron enamel cots, but in a push, using litters, they will hold 30. There is a *groupe complementaire de chirurgie* that has a radiologic outfit yielding 110 volts which is sufficient to run the X ray and 400 lights at the same time. In the surgical wards, which were neat and clean, we noted the following cases:

Case 1. Two penetrating wounds of the knee; immobilized.

Case 2. An occlusion of the rectum by a neoplasm and cirrhosis of the liver.

Case 3. A man with a watch blown into his buttock.

Case 4. Compound fracture of the humerus.

Case 5. Multiple wounds and severe shock. Compound fracture of the humerus, a large missile in the tibia, and wound of the buttock. At the time he was received he was well advanced in gas gangrene. Local débridement was done and the Carrel solution begun.

Case 6. Tuberculosis of the cecum, with successful cecectomy.

They state that they can handle 1,200 surgical cases a day in this hospital. The evacuation portion is distinguished from the hospitalization quarter. There are 21 Bessonneau tents for the slightly wounded and a Bessonneau hangar for the overflow. The slightly wounded remain only 24 hours, as a rule. There are separate tents for the medical cases and a separate tent and room for the slightly wounded. In all there were 42 evacuation wards. The patient must be sent to the evacuation ward an hour before train time. They were all beautifully clean and in good order.

The laboratory was equipped with a laboratory outfit contained in six chests. These chests are the regulation equipment of the French Army for a mobile laboratory.

THE PHARMACY

This is one of the best pharmacies we saw. It was a large frame building with windows for dispensing prescriptions and supplies to ward orderlies, thus preventing their roaming around through the prescription room to the interior of the building. Everything had its place and was in its place, and there was plenty of room for flowers, which decorated the tables. We were told that there were three classes of articles which could be supplied in this pharmacy which was strictly for the H. O. E. and not an advance medical supply depot.

- (1) Articles on the supply table which are always kept on hand.
- (2) Articles on a list which can be sent for on demand.
- (3) Articles kept to suit the individual practice of the surgeons.

We were told that each division of the Sixth Army has its own advance medical supply depot.

THE CENTRAL STERILIZATION PLANT

This was the best of its type that we saw. This is a new thing in the French Army and is added in order to relieve the operating and surgical wards of the labor and confusion of sterilizing their dressings and instruments. A similar plant, but not so large nor complete, was seen at H. O. E. 32 and H. O. E. at ———. The French gamelle is here used, not only for gauze squares, but rubber gloves also. On entering the plant, which is separate from the rest of the hospital, one goes into a corridor into which opens two windows, through which are passed, from the room within, the dressings and instruments needed. This room is kept for a distributing room, to which all of the sterilized material is sent when completed. It was very clean and orderly and filled with tin boxes containing sterile dressings, etc. We then entered the room for making dressings, into which opened the rear door of the autoclave (Geneste-Hercher). This room had a large table on which were prepared dressings by some Red Cross nurses dressed in white. A sharp saber was used to cut gauze squares the proper size. It cut through a thickness of 4 or 5 inches. This gauze was packed into a gamelle or French soup tin with handles, a layer of cotton batting is placed over it, and after sterilization the cover, which lies loosely and which is tied to one of the handles, is forced over the rim covered by the cotton batting to prevent air infection of the contents. The Geneste sterilizer here was somewhat differently arranged from that at ———. There was an automatic cylinder for recording the temperature variation on a chart. Into the center of the dressings or linen placed in the box for sterilization was the usual small capillary tube containing methylene blue and sulphur for checking on the degree of heat reached in the center. The dressings were subjected to two and one-half hours at 134° C., the air being previously expelled from the interior of the autoclaves before the steam was let in. Gloves and hypodermics were sterilized here also in separate containers. At the end of the building was a large storeroom with extra dressings, cotton, bandages, gloves, etc.

Note on the autoclave and the manner of its use: This autoclave is horse drawn and was originally intended for clothing. It is very well made. It is known as the "machine Geneste-Hercher," 4 Rue de Chemin, Paris. The cage holds 250 gamelles at a time. It burns 4,000 kilos of coal a month.

In this hospital we noticed a case of pneumonia in which they injected turpentine into the thigh to produce an abscess and increase the number of leucocytes in order to combat infection.

Army Sanitary School No. 86.

ORTHOPEDIC SURGERY

Lecture by Major Allison

The splinting and care of the wounded man from the time he receives his wound until he reaches the evacuation hospital has fallen under the direction—that is, the professional side—of the division of orthopedic surgery. This, of course, is because of the splinting, which is necessary. Along with the splinting comes the treatment of shock. The recent work done by Major Cannon and others on shock has shown that the important stage is the early stage—that is, a zone exists which might be called the zone of shock—shock and hemorrhage. The wounded man receives his wound and has to be carried to a battalion aid post. In this transit most of the severe shock arises, and it is interesting to us to note that Major Crile, who has for many years made a study of surgical shock, has recently stated that in his opinion the most important factor in lessening surgical shock where fracture exists is the application of traction to the fractured extremity through the Thomas splint. Along with this are the other elements—fear, loss of blood, and cold. It is in regard to this particular region or zone through which the wounded man has to pass that I want to bring out some points, if I can, of what we have learned and are learning since our 1st Division went into actual combat in January.

The surgery of a combat division.—The surgery of a combat division may be put, I think, briefly, under three heads. Transportation of the wounded is, perhaps, the most important head; the treatment of fractures and shock and hemorrhage are next; and, third, is the care of troops, the orthopedic care of troops, who are in the field. Under this last head comes the prevention of trench foot, and the inspection of shoes and footwear, in the rest areas when a battalion or a regiment is in rest. The battalion surgeon is the man with whom we are chiefly concerned. The battalion surgeon, to my own point of view, occupies one of the most important positions in the care of the wounded. His duties call for a high type of character, and call upon initiative and invention; he is the man on whom the principal stress falls in the treatment of the wounded in this area of shock and hemorrhage. His post is insecure; he has to use great judgment as to how long to stay in his post, for as I will show you later, in the last week two of our battalion aid posts fell into the hands of the enemy and one of our battalion surgeons with the medical men at the post were captured. The battalion surgeon is a man who has to have great courage, cheerfulness, and set a very high example. I look upon the battalion surgeon as being the man whom we must chiefly depend upon from the standpoint of true military surgery. The things that occur in the back area are interesting and, surgically speaking, more what we are in the habit of dealing with in civil life; but the position of battalion surgeon is something that is new to most of us; and I must say in passing that the men who are doing this work in our divisions are doing it with the greatest possible credit. In passing, an incident occurred in the 2d Division about 10 days ago. Lieutenant Gordon, who was associated with the work that we have been doing in these divisions, was in a battalion aid post situated in a quarry. Considerable shelling took place and they had to stay under cover. The story of what happened comes from one man who escaped. This man doesn't speak English very well; I think he is probably a Swede. He was in the same post. After the shelling had been going on for some time it ceased, and the next thing they knew they were surrounded by Germans. He and Gordon were taken prisoners and were started back toward the German lines. This Swede who tells the story says he became tired and said he was not going any farther, and the German who had them in charge grabbed him by the seat of the trousers and threw him about 10 feet—an actual fact, he tore the seat out of his trousers. Then Gordon said to him "If you do that again we will both be killed. Just keep quiet; I am going to get this fellow." They walked along farther, and Gordon who had a .45 Colt concealed somewhere about him seized his opportunity and shot the German and they both ran. The Swede got in and Gordon did not get in. What has become of him we do not know. His belt and coat have been found, but not his body. This brings up the question of the battalion surgeon being armed. I have nothing to offer on that point. I admire Gordon's courage tremendously. I fear that he was killed. Of course, he had his chance to escape and he had the Colt, and he used it.

In many of these battalion aid posts that I have visited the question has come up in conversation. When shall a battalion surgeon leave his post? I can not offer any solution of that question. It is quite necessary for him to leave his post, but he must not leave his post before it is necessary, and there is the question. No rule can be laid down. As I have told you, in the 26th Division last week, two of our battalion aid posts fell into the hands of the enemy at S ———, and remained so during 24 hours, when they were retaken, so you see it is quite evident that the position of the battalion surgeon is one calling for considerable judgment and courage in addition to his duty in the care of the wounded.

The next point of importance is the question of stretcher bearers. A combat division, I believe, should have about 1,250 men of the Medical Corps. There are 40 Medical Corps men to each regiment. Of these, 35 are litter bearers. These men should be in the battalion aid post and in the front-line trenches at all times when the regiment is engaged. There should be in addition 35 litter bearers at each ambulance dressing station. These men come from the ambulance companies. With a brigade of Infantry and a corresponding Artillery organization there should be about 200 litter bearers on duty at all times. At the same time in a division there will be 300 litter bearers in rest positions, but available for service in case necessity arises. In addition to these, in each division there are 8 bands of about 30 musicians each; counting out the noncommissioned officers, this would add

about 200 more men available as litter bearers in time of emergency. This makes a total of 700 men available and instructed as litter bearers. These men have all been instructed in the application of splints and in the carrying of wounded and in first aid. Thus there are 700 men for the Medical Department to a division to use as litter bearers. This isn't an adequate number to meet the demands of any sudden offensive, or defensive action, so that in several of the divisions various plans have been taken up. Colonel Shaw, in the 1st Division, procured from his general 100 men per regiment to act as litter bearers in case of necessity. These men are designated, but not instructed. Colonel Shaw looked upon it as simply a question of getting men who could carry wounded men out. This is one solution.

In the 42d Division, Colonel Grissinger has had 700 men, 100 per regiment, designated by the general's order, and these men have been instructed in the application of splints and first-aid treatment.

So there are 1,400 litter bearers in these two divisions who can immediately be called upon. Of course, these men I speak of last are combat men, men from the regiments, 100 men per regiment, who can be called upon in time of necessity to act as litter bearers. The placing of litter bearers is of great importance, in this zone of shock, this zone between the evacuation hospital and the place where a man may be wounded. Two men ought to be with each battalion in the trench or in the position that the battalion may occupy. These men ought to be men of the Medical Corps who understand the application of splints and first aid, and the use of the trench litter and the ordinary litter, and who stay with the battalion in its position. This, of course, is anterior to the battalion-aid post. These men are under the direction of the battalion surgeon. With these two men in the trench, the question arises whether they should come out of the trench—that is, it would take two men at least to make the carry of a wounded man to the battalion-aid post because this distance varies—sometimes it is a thousand yards and sometimes it is over that. It is often a very difficult carry and may take two hours to get a man back that far. If these men leave the battalion in the trenches for two hours to carry back one wounded man, the battalion is left uncovered. Perhaps, a better way of handling this is for the battalion surgeon to send forward men to carry out the wounded man or men. He has 10 men in his battalion-aid post and he can call upon the ambulance company which is stationed near there. This gives him an adequate supply of litter bearers who can go forward, and who can relay each other and relieve the two Medical Corps men with the battalion to attend to the wounded and apply the splints. The arrangement of these details is one of the duties of the battalion surgeon; he must see to it that this relaying and carrying out of wounded is done properly. It is often very difficult—the men become exhausted in these carries. They do it with great courage, or they have in the recent engagements that we have had, and they do it up to the point of physical exhaustion. Some of these men in the last two or three engagements that we have had had to go back to the rear because they were exhausted. I don't mean by that that they were "shell shock" cases. One man that I know of came back with a diagnosis of "shell shock" in the fighting of last Saturday. He had carried a litter I think for over 24 hours. He didn't have "shell shock" at all, he slept for 24 hours without turning. He had all the symptoms of exhaustion. He lost his bearings, he became confused, and didn't know which way he was going, and he was sent back with a diagnosis of "shell shock." This diagnosis hastily made we want to avoid. The man in question had simply passed beyond his physical strength and couldn't carry on any further.

The instruction of stretcher bearers, and the general morale of the stretcher bearer, depends a great deal upon the attitude of the battalion surgeon. The battalion surgeon should, I think, during quiet times instruct these men; have them practice with splints when there is not much going on. The hours of quiet can be used in having the men practice with the splints and get them ready to use and give them various other points, they are keen to learn—they are very much interested in what they are doing; they take pride in the fact that they have a good supply of splints and can get men back in good time. This attitude is a valuable asset to the battalion surgeon in caring for the wounded of his battalion.

The following general order was issued by the general of the 42d Division regarding this so-called zone of shock.

The document closes with following:

The following points are emphasized:

(a) Surgical operations are prohibited except in a hospital. Treatment at the front and during evacuation to the hospital will be limited to the first aid, splints, control of hemorrhage and shock. Probing of bullets or fragments of any sort is expressly forbidden. Every effort will be made to secure delivery of the patient at the proper hospital at the earliest possible moment after receiving injury; saving of time during the early period of injury may mean life or death to the patient. During the evacuation of the patient he must be kept as comfortable as possible. He must be disturbed as little as possible, and in any event after the first dressing and splints are applied only so much shall thereafter be removed as is necessary to see that the dressings, splints, etc., have been properly applied in good condition and are in good shape. Warmth will be continuously applied. It will be secured by hot-water bags, alcohol or other stoves, hot bottles, etc.

By command of Major General Menoher:

DOUGLAS MCARTHUR, *Chief of Staff.*

That is a very remarkable document and covers the situation in a most simple manner, given by the commanding general of a combat division.

We know that in times of the stress of attack and defense all plans are more or less disturbed, and it is interesting in passing to note that it may change at any time. We have settled down into positions that are well established, trenches that are more or less well built, varying a good deal in certain sectors; in some parts of the front that we are holding now the battalion-aid posts are very close to the line; they can be usually evacuated by ambulances, especially at night; the dugouts are very excellently built, suggesting that they were going to be used for a generation. This may change entirely, as it has changed in Flanders and in the Somme in the last six weeks. Things that were well established, casualty clearing stations that were operating were lost, battalion-aid posts, advance dressing station were given over; an advance of 30 or 40 miles made, everything was changed; the fighting as it exists to-day is on a different basis entirely from that we are talking about here, which applied to trench routine, not to fighting in the open, which is not at all the kind of thing that we have become more or less used to in the last three years of war. At the present time our divisions that are serving in sectors of the French Army are met with the conditions of trench warfare and we have to carry on in that way. There have been engagements that have tested this system that we are trying to develop. In the 42d Division, on the 5th of March, the enemy commenced a violent bombardment of the position held by the 1st Battalion of the 168th Infantry, at 4.30 a. m. and continued it until 6.20 a. m. The evacuation of wounded through the battalion-aid station commenced at 7.30 a. m. All the severely wounded, except one man, had passed through the battalion-aid post by 10.30 a. m. Patients requiring the Thomas leg splint had had the splints applied were found by the litter bearers. None of them were moved before the splint was applied. Lieut. Charles H. Moore, M. R. C. personally examined these patients as they passed through the aid station and found that the splints were properly applied, requiring only slight adjustment. All splints were applied within one-half hour after the action ceased and within three hours after the first wound was received. Because of the intensity of the fire it was inadvisable to attempt to move the wounded until the artillery action had ceased. In that particular action the bombardment was not followed by an attack. Usually a shelling of that kind gives every indication that immediately following it will be an attack, but in this case it was simply a shelling which he gave this particular battalion. The wounded men as they came back to the hospital were in very good condition. Their average time in reaching the hospital was less than six hours, which is very creditable.

On April 12, in the 26th Division, in a battalion aid post back of the 104th Infantry, located in the A—— Woods, I observed the evacuation myself. The wounded reached this battalion aid station in the morning at about 10.20 a. m.—some 25 in number. These men had endured heavy shelling and encountered a raid put over in force by the enemy. It was a hand-grenade party after the Germans got over. This had been going on from sometime early in the morning. Many of the wounds sustained were from hand grenades and 15 of them were slight in character—that is, wounds of the soft parts. There were 10 seriously wounded men and 2 men died in the battalion aid post. The character of splinting and transportation given these men was, under the circumstances, beyond criticism. Captain Dudley was the battalion surgeon at this post. An unfortunate thing happened to his

supplies. He had his supplies in a cart—they had just moved into the position the day before—which came up from the ambulance dressing station, about 1,800 yards down the road. The cart was placed in front of the battalion aid station, with the splints and cotton, etc., on it; a 77 shell scored a direct hit on the cart, so there were no splints or dressings or anything left. Captain Dudley had to send back for more, which came up promptly enough, and he got them forward into the advance post in the line. There was considerable shelling of this battalion aid post, some of the shells being gas shells. In spite of this, an additional supply was brought forward from the ambulance dressing station and sent forward to the advance posts. As the men came back they were given hot drinks and were wrapped in warm, dry blankets, notwithstanding the severity of the artillery fire. The wounded were evacuated to No. 1 Evacuation Hospital at S——, where they arrived in good condition considering the long ambulance journey. There is a battalion aid post in this town and up on this hill is another battalion aid post. The battalion aid post, being on a hill, was a very good mark. An unfortunate thing happened. The battalion's supply of rockets and trench-signal stuff was in a small shed and a shell hit this shed and the whole outfit went off—red fire and all kinds of things. Of course, that gave the German artillery a very good mark to shoot at; so the rest of the time they shelled the battalion aid post. It is a very good post, however; quite well protected. The wounded had to come down this road by litter. An ambulance could just as well have taken a chance and gone up there, and the ambulances did go up afterward. Ambulances should take the chance, I believe, on a road of that kind, and in all engagements they have done very well with this dangerous task.

On April 20 to 21, in the 26th Division, an action began at 4 a. m. Cases began to arrive at Field Hospital 102 at about 8 a. m. on April 20. This hospital is at A——. Gas cases were treated here at 102; all wounded men were evacuated to Evacuation Hospital No. 1 directly. There passed through 102 the following:

8 a. m. April 20 to 8 a. m. April 21:

Wounded.....	172
Gassed.....	46
Sick.....	36
Total.....	<u>254</u>

8 a. m. April 21 to 8 a. m. April 22:

Wounded.....	45
Gassed.....	60
Sick.....	23
Total.....	<u>128</u>

The wounded arrived in from one to eight hours after receiving their wounds. As the battalion aid stations, of which there were two, were in the hands of the enemy for a time and were the scene of hand-to-hand fighting, and as the ambulance dressing station at X—— and its lines of evacuation were under constant and severe shell fire from 4 a. m. of the 20th until 4 a. m. of the 21st, this was excellent work in getting them out. Only the organization work on the part of ambulances and stretcher bearers made this possible. Ambulances ran through this shell fire and brought in wounded. Lieutenant Abbott was with the ambulance dressing station at M——, which was struck 12 times by direct hits. Those of you who have been to that station know that it is in a house at the corner of the road, a perfect mark for artillery fire. It had a Red Cross flag on it and a German aviator flew low enough to shoot the Red Cross off the hospital with his machine gun, and they got 12 direct hits on this house. The dugout wasn't completed and they had a close call. They were all gassed. The wounded who came in there, in spite of the shelling, were in very good condition so far as dressings and splints were concerned. This station was abandoned at midnight on April 20. All the officers and 15 men of the Medical Corps were gassed, but none seriously. Capt. Frank Dickson saw all cases which came through 102 from 8 a. m. 20th to 8 a. m. 21st. Only a few cases received any additional treatment beyond what they had already received, except to be given hot drinks and warm food. Only one splint was changed, and that was a compound fracture of the tibia, which was splinted, but not sufficiently. Only a very few

cases came in without having received antitetanic serum. The work along this line was excellent. The fact that these men got A. T. S. under these conditions, with the advance aid post out of commission, ambulance dressing station shelled directly, yet when they reached the field hospital at M—— they had antitetanic serum, I think is very creditable.

Three cases died at Field Hospital 102. These men arrived almost moribund.

On April 21 a number of cases came in who had been wounded for a number of hours. This delay in evacuation was due to the fact that many men were wounded in isolated places. Evacuation by ambulance was carried on as far forward as S——, which was partly in the hands of the enemy. They got into one end of the town in great strength. The number of Germans that came over has been stated at 2,000. They did come over in great force; they drove our men from the trench and back into S——. They fought all that day in the streets with hand grenades and with rifles. The ambulances ran up to this town and were considerably shelled. The evacuation from Field Hospital 102 to Evacuation Hospital No. 1 was carried out in good order. At the evacuation hospital it was stated the patients arrived in good condition.

Details of evacuation methods.—We have been trying out various types of trench litters, as you know the necessity for some type of trench litter that is light and durable and can be adjusted quickly is mandatory in this type of trench warfare. The pole and stick arrangement that the French use has had ill success with our troops. The poles usually get broken. The Butler trench litter is made of wood, having the disadvantage of not being very durable. Trench litters, of course, get wet, and a wooden litter covered with a veneer is very apt to warp and go to pieces quickly. We have had reports from the division surgeon on this matter and they have reported that this type of litter, which was designed by Major Garcia, regimental surgeon of the 16th Infantry, has worked out the best. It is durable and is not easily broken. It will stand water and mud; it is light, which is, perhaps, its chief advantage. The straps and tapes should be black in color, or brown. In the illumination of a star shell white cloth shows up very brightly. Perhaps one of the class will volunteer to get on the litter? [One does and the operation of the litter is then practically demonstrated.]

That is all that is necessary to fasten the man on the litter. It gives pretty good support for injuries of the arms and legs just as it stands. If some of you will help me lift this man. Just put that end on the floor. [Stands patient up.] I don't think anyone could complain of the pressure in the crotch. Does that hurt?

Answer. Not at all.

They are as comfortable as it is possible to be, I believe. It can be carried sideways, face down, or slid around a corner, without much disturbance to the wounded man. Does your weight seem to rest on your legs or in the crotch?

Answer. About equal.

The question of handles. That's a difficulty. The man who carries at this end has the weight forward on his shoulders, and they complain considerably of that. He gets tired carrying a heavy man, because the weight breaks forward on his shoulders. We are trying to obviate that and the last ones that are coming out carry a strap that a man can throw over his shoulders and get the weight on his back, and two rods for the hands at each end.

Some one has asked about putting feet on the litter. We have found that anything projecting from the side of the litter makes it difficult. As you perhaps know, some of these trenches have trench wattling, and anything sticking out will catch in this as you try to go around a corner; and then the walls of the trench are very apt to catch against the feet or anything sticking out on a litter, so it is much better not to have anything that protrudes from the litter.

There are various modifications of this thing that will come along as we desire them. We have already found that we will have to put handles on it. It is very difficult for the stretcher bearers. The man at the feet does pretty well, but the man at the head has a considerable load to carry. But, on the whole, I think it has been found to be a very satisfactory type of litter. Its predecessor in the litter field is the Stokes litter used in the Navy. The credit, I believe, is due to Major Garcia for designing this litter—Major Garcia, U. S. M. C., of the 16th Infantry. It is called the "trench litter—Garcia type," or the snowshoe type of trench litter."

Question. Could you clamp folding handles on the end?

Answer. Yes; that could be done, but it hasn't been done as yet. We are trying the canvas loops now. The question of labor and complication mechanically is very important. Anything that's simple—that can be made by a fairly unskilled person, as it stands there. Now the minute you add feet to it, handles to it, it becomes a thing requiring skill to make; and this thing as it stands costs about 120 francs per litter, and so anything added to it runs up the expense tremendously and makes it difficult to make them. We have tried quite a few now in the divisions engaged and, though it isn't ideal in all conditions, it is satisfactory for most.

Another point in battalion work. In the battalion aid posts and ambulance dressing stations in the three divisions that we now have in this locality, this little card has been placed regarding the prevention and early treatment of wound shock. This is a compilation of things that you all know so much about that it is not worth while to dwell on it. We have had criticism about blankets—the folding of blankets. I think most of you men have heard of that. These men should have the blankets folded properly in the methods that you know so well, and the battalion surgeon is the man to enforce this thing. He can't do it himself; he can't give hot drinks himself; he is too busy, and he has got to instruct the men who are there with him, the Medical Corps men, in doing these details. The question of hot drinks can be arranged; hot drinks and cigarettes. Most of the wounded men like to smoke a cigarette when they get to the battalion aid post. They are craving a cigarette at that time, and it is a good idea to give it to them. Somebody has to give the cigarette to the wounded man and light it for him, also give him his hot drink, and it is well, I think, in times of stress to detail a man to that particular duty. In Field Hospital 102, when the wounded came through the other day, the commanding officer made one Medical Corps man responsible for hot drinks and cigarettes; and keeping the hot water supply on hand. That was his duty. It was put into his hands to see that every wounded man who wanted it got a cigarette and that it was lighted; that every wounded man got a hot drink immediately on his arrival. Somebody else was placed on the question of stoves and heating, by putting the Primus stove underneath the man, with the blankets folded down on the side of the stretcher so he has four folds below and four folds above. This card pasted on the wall is not for the instruction of the battalion surgeon, or for the ambulance surgeon, but for the instruction of the enlisted personnel in these two places. They see it and it acts as a constant reminder to them of the things that they should know about. It says here: "Consider the general condition of the wounded man first and treat his wounds second. Keep one dry stretcher with three dry blankets always in readiness." Give the wounded man a hot drink with a tablespoonful of sodium bicarbonate dissolved in it as soon as he arrives. Sodium bicarbonate is advised by Major Cannon; if we were to go into it, it would bring us to the question of whether the sodium bicarbonate raises the alkalinity of the blood or does not, and I don't think that concerns us particularly. Major Cannon found in his experiments on the British front that sodium bicarbonate was a practical thing to give the wounded and seemed to have a beneficial effect on the acidosis of shock. He regards shock as being an acidosis and especially where muscles are lacerated and torn. The acid is thrown into the circulation from muscular activity and sodium bicarbonate is a possible thing to give. One thing is, it is a nauseous sort of drink in tepid water, and perhaps something else in the drink would help. Put it in a weak tea, if you have tea, or some other flavoring. Sodium bicarbonate we believe should be given.

When the wounded man is well warmed and quieted, dress the wounds and apply splints properly for the ambulance trip. The ambulances carry hot-water bottles. Turn the blanket ends over so he is well tucked in. Finally, just before the patient is sent out give him another hot drink. Above all, antitetanic serum should be administered in the battalion aid post.

An attitude of cheerfulness and encouragement is of great importance. As I have already seen it in my limited experience, I think that the battalion surgeon has a wonderful opportunity to buck these fellows up a bit. They have had a very hard trip. They have a fractured bone, a lot of them have been fighting and they are still angry, and they all are stirred up. I know after this A—— Woods affair 10 days ago, when they brought the wounded in they brought in at the same time into the open space in front of the battalion aid station 21 German prisoners. In order to show you the state of mind these wounded

men were in, I say you never heard such cursing in your life as came out of the battalion aid post from our wounded fellows. One fellow had lost a foot and had a compound fracture of the tibia on the other side, but nevertheless his only desire was to get up off the stretchers and go after these Germans whom he saw crowding toward the door of the dressing station because the shells were falling pretty close. The battalion surgeon has a wonderful opportunity to tell them they are "all right," that they have been brave fellows and got away with it fine, and all that sort of thing; and it helps them a lot. And a lot of shock, I am quite convinced, is associated with the extreme mental disturbance that these men are in. Of course, that is very apt to become fanciful if you go too far with it, but it is true, practically. They need to be encouraged and quieted, and this is one of the difficult duties of the battalion surgeon.

The question of morphine. I think that the men who have studied the use of morphine in these conditions feel that too much morphia is harmful. But I believe that each man ought to have a quarter of a grain. I think the tendency is to give half a grain. I believe that is too much as a rule. Every one of them ought to have a hot drink or two, and preferably a lot of sugar in one. In passing, I don't believe that a battalion surgeon ought to go beyond his battalion aid post. He is too valuable to go forward. He is needed as a directing agent in the post. His men that he sends up can get the wounded back all right. They have been instructed; they have the courage; and they will do it. The battalion surgeon must stay in his post and carry on there. That's his place. He has to check the splinting and also keep up his supplies and make the difficult decision as to when a wounded man should be sent back from his post.

Now, there are certain variations in our splints from the type of splints that are used in other armies. We have a splint which has worked out admirably—the Blake-Keller modification of the Thomas splint. Then there are these dressing packets in three sizes. The red one is the small one; the white, the medium size; and the blue, the large size. Everybody wants the big one. An American characteristic.

Question. What do you think ought to be the relation of the issue?

Answer. This packet here (red) will dress almost any wound that comes back. The middle size will dress a very large wound; the blue is rarely needed. The bandages in these packets are bias-cut bandages, a very valuable thing, because such a bandage will lie on any surface and doesn't require any fancy bandaging. It will stick to a knee joint or elbow joint. We issue them 6 red, 3 white, and 1 blue, as the requisitions come in. The requisitions usually ask for the large packets. The medical supply depot exhausted itself of large packets and only small ones were left. There is no reason for this. It is better to use the small ones. They are much easier to carry, and they are perfectly adequate for most of the wounds.

Before we close, there are one or two things that I would like to speak of briefly. The wire gauze put on a Thomas splint makes a very good sling, and it can be quickly done. This is much quicker than tying of triangular bandages or using safety pins. The leg can rest in that perfectly well. Most of the men are doing it that way.

Another way is to have the bandages pinned or tied along the side bar of the splint. In the 42d Division they are doing this. In quiet times they pin a lot of slings along down the side bar. Always pin them on the short rod.

Ladder splint: This is the most important splinting material we have outside the Thomas splint. With this thing you can make a very good box splint for injuries of the soft parts, or injuries of the knee not involving fracture. Wherever there is a fracture and it is possible to get at it, it is necessary to put on traction. It can be applied to fractures very low down in the tibia. The easiest thing to apply and the best traction device I have seen is that of Poliquen. Just two throws around the ankle. If the fracture is low down in the tibia that's an excellent way of putting on traction. The various ties, the clove hitch, and that sort of thing, you are familiar with.

Finally, the question of the tourniquet comes up. As I have gone around I have had a lot of questions asked me about the use of the tourniquet. It is the most dangerous thing we have in our possession, I believe, and also it is a very necessary thing. A battalion surgeon has got to use his judgment promptly as to how long he is going to hold a man at the bat-

talion post. The wounded man should not be started back before he makes a turn on his shock. If he is going to die, if it is impossible to save his life, he had better die at the battalion aid post than in the evacuation hospital or in the ambulance. Those of you who are battalion surgeons should not let the fear of criticism get the better of your judgment. Of course, everybody wants to get the wounded man back as soon as possible, but he must be held until he has made the turn; that is, until he is warm and quiet and able to travel. He can then go back and arrive in condition to be operated upon; otherwise he has to be treated for a long time before he can be operated upon, or he dies. The same thing applies to a tourniquet. I don't believe a tourniquet is very frequently necessary in these wounds. They are usually the kind of wound that doesn't require much, but when it is necessary it is very necessary, and that's where the battalion surgeon has to use his judgment. I will say that no man ought ever to leave a battalion aid post with a tourniquet on. Don't send a man back in an ambulance with a tourniquet on. If he is bleeding to the extent that he has to have a tourniquet, you had better hold him a while.

Question. How about tying the arteries?

Answer. I don't think that should be done either. There is no provision for it in any battalion aid post I have ever seen. Of course, if a man has a big artery spurting and you can pick it up, it should be tied—but that's rarely the case.

There are two or three things that have been lately developed that I would like to show you. This sort of package can be made with 2 Thomas leg splints, 1 Thomas arm splint, and 1 Cabot splint, 3 or 4 dressing packets, and some triangular slings; this can be carried into the trench by one of the enlisted men who serves as a Medical Corps man with the battalion. It is rather compact and can be carried along with him when he goes in. In the battalion aid post a similar supply can be kept to send up at any time that the advanced supply is exhausted. These buckles and straps go with it. I think they are very useful. The buckle and strap can be used to strap on a splint, it can be put over the dressings that are applied inside the traction splint so as to hold them in place. It is much quicker than bandaging, and there are plenty of these available. This splint rest goes on the Thomas splint, can be put on the Thomas splint at the battalion aid post so that if a man is taken down from the bar on the litter, traction can be kept up. The splint rest was modeled after the British device. The British device had the two loops running the same way, so that when you put it on the splint you could push the splint out; this is made—it springs out that way and thus you can not push it out. By putting this loop that way it holds. It will go on any part of the splint.

This splint, the Cabot posterior wire, we found much more useful than we thought at first it would be. It is a very simple thing to make and a very useful splint. Before it is covered with the bandage it is well to spread the splint, stretch it, and then pull your bandage in so that it comes to look like that, and then the bandage won't slip down. In slack times the men in the battalion aid post can fix them up. This splint is very useful in certain soft part wounds of the lower extremity. It is much more comfortable for the man. He gets back in better condition.

We had recommended the use of Thomas splints for transportation and we found in the 26th Division last winter, in going over these splints, that you couldn't get a man in a Ford ambulance with a Thomas splint on him, and as most of the divisions were supplied with Ford ambulances there arose quite an obstacle. The stretcher goes into the Ford ambulance and the tailboard comes flush with the stretcher, and a Thomas splint, even on a short man, goes out beyond the end of the canvas so you couldn't close the tail gate on the ambulance, and this litter bar was got out to meet that necessity. The litter bar goes on an ordinary type of our stretcher; it is a little bit difficult to get on I find. One man has to hold the stretcher up and another slips it over. It goes above the handles. The bar goes toward the head of the patient, just above the two stirrups or feet, toward the patient's head. Of course, the elbows on the stretcher have to be fully extended, or else the stretcher will collapse. The screw is tightened up and brought very tight, and thus the bar will stay in position. We are using this bar on the G. M. C. ambulance because it is better to have the thigh flexed with a fracture of the femur than to have it out flat. The wounded man will ride more comfortably. The ambulance companies have them, the field hospitals have them, evacua-

tion hospitals have them, and the director of ambulance service has to be constantly on the lookout to see that exchanges are made and the supply kept up. You see, with a large number of wounded going back all the splints would be in the evacuation hospitals in a short space of time, but the evacuation hospitals that we have started and are starting have a sufficient supply of all these things to give the ambulance driver a stretcher, a Thomas splint, and the whole outfit when he leaves the hospital, in exchange for what he has left. The Ford ambulances in this division carry one Thomas leg splint, one Thomas arm splint, and wire ladder splints constantly in the ambulance, so that the driver always has a certain amount of supplies and splints in case of accident. For instance, a battalion aid post or an ambulance dressing station falling into the hands of the enemy might cause us to lose all the supplies we have there and we have got to have something in the ambulance to meet the emergency when it arises. We look to the battalion surgeon and the battalion aid post as factors of great importance in the care of the wounded. The regimental surgeon comes next; his duties, as you well know, are multiple and very exacting. The chief of ambulance companies has a lot of responsibility on his shoulders; and it is these three persons—these three medical officers—that can help most by cooperating with each other and with the medical supply officer of the division in keeping up a constant flow of these supplies from rear to front to counteract the flow from front to rear and in getting men through this zone of shock where their condition is most precarious. Most of the men who die, die in this zone, and it is here that the highest degree of surgical judgment and skill can be put into force and made effective.

Another thing to the men who are working in this zone: Operating is what most of us think of as surgery. Operating—a good operation—that's the end of it so far as the surgeon is concerned. But that isn't all of surgery. The surgical activity in the advance zone is to my mind of equally great importance. The question of skill and judgment in handling men, in handling the wounded, are greater than those that the men in the evacuation hospitals have to meet. There, things become more routinized. They have nurses to help them; more surgical personnel to help them; they aren't on their resources as men nearly half so much; and, in closing, I want to say that the battalion surgeons that we have had so far, with very few exceptions, have proved to be perfectly trustworthy and very capable, and have gotten away with difficult jobs in a very remarkable way. Two or three failures in application of splints have occurred. One of them I looked into in the 1st Division. The medical officer was killed in his dugout. A patient came out of there with no splint applied. Another instance was where a man shot himself—a self-inflicted wound—through the thigh and fractured his femur; and the battalion surgeon in this particular battalion, when this man was brought in and the story was told about shooting himself intentionally, he told him to go back without any splint; that he wouldn't splint him; wouldn't have a damn thing to do with him. You can see his point of view very clearly, but, of course, that doesn't look very well from a medical standpoint. We have had one or two other instances where men have come back without splints due to conditions of stress and lack of supplies, but in every instance, so far as I know, there has been a perfectly adequate explanation. It hasn't been due to carelessness or excitement or lack of the proper kind of courage in carrying out a very difficult piece of surgical work.

Army Sanitary School No. 87.

H. O. E. ———, MAY 6

There are 3,275 beds, plus 900 for *éclopés*. According to the commanding officer of the hospital, an *éclopé* is a man who is incapacitated by some cause other than a wound received in battle, generally he is just a little sick. No man wounded in combat is referred to as an *éclopé*.

The triage of Bouleuse had four Adrienne barracks at the entrance to the hospital, with a large driveway leading to them; one for lying patients, one for sitting, and one for sick. The fourth one (*magazin des armes*) is to keep the men's equipment and clothing in. We were much interested here in the booking. If a man has been evacuated from an ambulance, he brings a slip which practically corresponds to the field medical card of the English, and which the French call a "*billet de hospitalization*." If he comes from a regimental or battalion aid station he brings only a diagnosis tag, called a "*fiche*." The triage consists in merely sorting out these patients from the diagnosis on the tag and the general appearance of the man. At

present there is only one triage running, which takes everybody, because there are only a few patients. In this triage the man is booked by a sergeant; there is also an emergency room for anything that might happen while the man is being held there. There is here no provision for dressing, nor is there any attempt at same; only the records are made here.

The necessary facts concerning the man are transcribed into a book called "carnet de passage," each page of which consists of 10 slips for inscriptions for 10 men, which are torn off and distributed as described further; the paper is perforated for this purpose. These inscriptions are made in triplicate by carbon paper, and one detached slip accompanies the man, one goes to the office of the H. O. E. to be kept in the archives, and the last is sent to the War Office. His hospital number is put on this carnet slip, and forthwith this number is affixed to him. In addition, a whole page is taken up in giving him a register of entrance, which is also made in triplicate for each man in a separate book. One of these is torn out and sent to the man's regiment immediately, one to the surgeon general's office in Paris, and one remains on file. This triage, therefore, is absolutely nothing but booking, and the real triage is done on the operating table. Nevertheless, the patients are sorted according to the diagnoses they bring. Antitetanic serum is administered in the emergency room of the triage if the man has not already had it. There is also a buffet here for hot drinks and there are litters set on trestles for the men unable to sit up while the booking is taking place. I am told that only about $1\frac{1}{2}$ per cent of the patients received here had not received antitetanic serum before arriving. The personnel of this triage is 1 sergeant, 2 secretaries who are sergeants, and 4 litter bearers. There are two sets of books for the carnet de passage and the register, one for even numbers and one for odd. This is done to allow the booking to proceed more rapidly. A card index is kept at the office of the evacuation department also, and a numerical list of the patients admitted per day. The card index consists simply of squares of paper of the same size in a box and they contain the names, arranged alphabetically, with diagnosis, etc., so their histories may be used by the evacuation bureau, which is the other end of the office work—that is to say, where the man is booked out. It has 1 military surgeon, 1 administrative officer, and 2 teams, each of 1 sergeant and 4 men—1 for day and 1 for night duty. They make a check of all the patients in the hospital at 8 a. m., at midday, and at 6 p. m., and get the number present, the number of evacuable, those not possible to evacuate, and the number of empty beds. The evacuable are further classified as to wounded to be transported recumbent and those to be transported sitting. In times of activity and in preparation for a big offensive all are evacuated that can be. In times of calm they keep all they can. Upon the information being obtained by this checking, a telegram is duly prepared and sent; one to the responsible officer of the general staff, fourth bureau, at headquarters, and a duplicate to the regulating train officer (the commissaire regulateur), giving the number to be evacuated, lying and sitting, etc. All this is placed on a blackboard and gives the actual state of the hospital in the last few hours. This blackboard is for the purpose of helping in the make-up of trains. Only those who can not recover in four weeks are sent back. Those sent to the zone of the interior may get from 10 days to a month's leave of absence, and at the end of their leave they report to the base division for instructions. The headings on the blackboard are as follows:

ZIELA—Zone, interior, distant, lying, and sitting (interieur, éloigné, legers, assis).

ZIELC—Same, except last letter, which means couchés (lying).

ZIESA—Same as previous one, except last two letters, which mean serious, sitting (serieux, assis).

ZIESC—Same as the last, except the last letter, which means lying (couchés).

ZIRA—Zone, interior, near by, sitting (zone, interieur, rapproché, assis).

ZIRC—Same as last, save last letter, meaning lying (couchés).

Following this is a column for "TB," for cured "gueris," for seabies ("galeux"), éclopés, and "on leave of absence."

These last, beginning with TB, are generally evacuated by means of motor ambulances. At the end of all is a résumé—the total number of evacuable and nonevacuable, grouped according to whether French, allied, or prisoners of war.

From all of this graphic statement the entraining officer makes up his train. He gets from the bureau of admission the man's slip (carnet de passage), and pastes it, with all others

to be evacuated, in a little book with a folder, to hand to the commander of the hospital train, who receipts for it. Thus is a full description of all patients who will go on the train rapidly provided. He, himself, does not know where his patients are going, but when the train commander distributes them at their destinations he enters record thereof on each carnet de passage in the folder given him, and sends back this folder with the destination entered, to the officer in charge of evacuation at the H. O. E., with his indorsement. Thus the completed record returns to the H. O. E., generally in a week or 10 days, and remains in the archives of the hospital. In this way the details of the whereabouts of patients, in case they are requested by relatives or by the War Department, is on hand at the H. O. E. from which he was evacuated.

It takes about a half hour to load the sitting patients on trains, which hold 150 to 200; one and a half hours for lying patients. Before the patients leave the H. O. E. the evacuating officer places in an envelope, properly inscribed, larger but similar to envelope bearing our field medical card, the "billet de hospitalization," in addition to any clinical notes from the ward surgeon, giving details concerning the case for the benefit of the next medical officer to receive him. This includes drawings, X-ray pictures, etc., as well as recommendations for treatment, and contains all that has happened to the man before he came to the H. O. E. and during his stay there. The patients are sent for, from the wards in which they are, one hour before train time and are taken to the train shed, all ready. Walks are laid down from the evacuating wards near by to this train shed.

In this H. O. E. there are 800 beds for hospitalization and the nonevacuable. There are also 800 beds for those to be evacuated sitting, 775 for those to be evacuated lying, and 900 for the *éclopés*, giving a total capacity of 3,275. There are two Bessonneau hangars near the train shed which take 150 lying and 300 sitting. Actually there is but one in use holding 84 beds, which makes a beautiful ward, with enameled iron bunks and sanded floor. The other hangar is used as a theater, temporarily. They are models of cleanliness and order. There is a group of barracks for the *éclopés*. The Bessonneau hangar receives the lying cases from the surgical wards to be evacuated.

There is an ophthalmologic center here which is very complete. Its team was at the front on the ——— and it was closed.

The medical barracks are all together and under the supervision of M. Guilan. In one of these barracks are placed medical cases to be evacuated, and this is near the train shed. At present these wards have very few cases and were chiefly filled with severe cases of bronchitis. One was devoted entirely to Italians, a number of which are working here on roads.

There is a new center here just opened for the sterilization of dressings, etc., and their preparation. Here are two large horse-drawn autoclaves, weighing about 12,000 kilos, marked "Geneste-Hercher." They are more complete than the Thresh apparatus and were originally intended to disinfect clothing. On entering the plant one finds a window leading out from the distributing storeroom which is filled with standard tins of dressings, and there is a large storeroom for raw stuff, a room for the making up of dressings, and a room for the separate sterilization of hypodermics, which are all of glass. In the room for the making up of dressings was a long table, slashed where the gauze was cut into short pieces, by a very sharp saber. Six inches of thickness could be cut at one slash.

The standard container for gauze was the "gamelle." It is a deep soup tureen with a tin top and handles holding about a pint, and is part of the personal equipment of every soldier. Here these are also used for sterilizing rubber gloves, which were wrapped in gauze, the fingers being separated by strips of gauze. These gamelles for gloves also contain two hand towels, and are sterilized at 110° to 115° C. for 40 minutes. All cotton material was sterilized for two hours at 150° C. The containers for towels, cotton, etc., are biscuit tins. There was also here a glove and rubber bag repair shop, the repairing being done with bits of rubber cut from old rubber goods and bicycle tire glue.

In the interior of the packets of dressings there is placed a fine capillary glass tube containing sulphur and a small quantity of methylene blue. This fuses and gives a beautiful ultramarine blue at 140° C. They have a manometer attached to the steam autoclave which registers also the variations in temperature within a cylinder run by clockwork.

At this hospital they depend on sulphur fumes to exterminate lice and their eggs, but the clothing of cases suffering from scabies is put through the steam sterilizer.

FURTHER NOTES ON THIS HOSPITAL, FURNISHED BY ITS COMMANDING OFFICER

The triage of the medical cases divides all sick admitted into a group for evacuation to be treated until the leaving of the train, and into a second group to remain at the hospital. Surgical triage is made as follows: All cases are sent to Surgical Group 15, Professor Lemaitre, where he retains all for primitive suture, where this can be done, and sends to Group 10 only wounds of the skull, thorax, and abdomen (for M. Roux-Berger) and wounds of the articulations (M. Leriche). In a period of great activity triage may be made entirely administrative, on the diagnosis tag, and the wounded will be distributed as follows: Group 70, slightly wounded, capable of being evacuated immediately; Group 40, moderately wounded, sitting and lying; Groups 15 and 10, nontransportable wounded, for sutures of the soft parts which require them to remain in the hospital for at least five days before being evacuated. The individual register for each man referred to in the body of the description of this hospital is not made out except for men who remain more than 24 hours in the hospital. The card index ought to contain, under each name, the hospital ward he occupies, the date of evacuation, and the formation where he will have been hospitalized after leaving the H. O. E. For this purpose a blotter should be kept from day to day at the triage registering all admissions. The bureau of evacuation contains all the data concerning the discharge of patients:

- (1). Men rejoining their corps.
- (2). Contagious cases or cases requiring specialist treatment evacuated by motor ambulance on certain neighboring formations.
- (3) Men departing on leave of absence.
- (4) Men leaving by sanitary trains.

At the end of each day the bureau of admissions transmits to the bureau of evacuation the blotter of the carnets de passage of those entering, papers which are kept until the patient leaves the hospital. As soon as a man is marked as evacuable the retained slips of the carnet de passage, bearing a number coinciding with the number borne on the billet d'hospitalization, are pasted on the folder made up for turning over to the commander of the train or auto, this folder being prepared in advance according to the category of the trains. A list of patients designated in each service for evacuation by the ward surgeon is made up each day at 8, 12, and 6. A full statement is made for each ward of the number of occupied beds, number evacuable by train, sitting or lying, or by motor ambulance, the nonevacuable and the number of beds which are empty. At the same time they take up the envelope from those to be evacuated in which there is the billet d'hospitalization.

In normal times the following are evacuated by train:

- (1) The sick and wounded transportable, which can be cured in less than four weeks; they are sent to the zone of the army.
- (2) The sick and wounded that need more than four weeks for their cure; these are sent to the zone of the interior.
- (3) Those evacuated to the zone of the army to rejoin their corps directly after leave of 10 days. Those evacuated to the zone of the interior after cure are sent to the corps depot.

In times of exceptional activity all are evacuated into the zone of the interior, except those that can be cured in 10 days or those who are intransportable, who have contagious diseases, who have venereal diseases, or who have seabies. As this is a time of exceptional activity, this is the present régime.

Every day at 1 p. m. a telegram is sent to the commissaire regulateur and the fourth bureau of the general staff of the army, advising them of the number to be evacuated, according to categories elsewhere stated.

The commanding officer of the H. O. E. now requests a train of the commissaire regulateur by wire as follows:

Send a train to-morrow. Station of loading.....

ZIEL { sitting. } Load.....hour. Depart.....hour.
 { lying. }

When this is sent, the bureau of evacuation advises the wards, the kitchens if there is necessity for a meal before leaving, and the sergeant in charge of the litter bearers who are to carry the patients aboard the train. The wards' sergeant in charge of litter bearers must

also be given a list of the patients he is to get out of each ward. The folder upon which the train has been made up is verified once more and signed by the medical officer and administrative officer of the bureau for evacuation. There is required for each patient a certificate that the man has not drawn any pay at the hospital, or one should state if he has done so. The men to be evacuated are assembled in the special barracks for evacuation, near the depot, 15 minutes before loading. They call the roll and each name is checked off, the folder made up for the train commander, and then each patient is inspected to see that he has the envelope bearing his particulars tied to his button. When the loading is finished the medical officer of the sanitary train checks up his list with that which remains at the H. O. E. and must telephone to the fourth bureau of the army the number of patients he is evacuating. He can give a receipt to the H. O. E. of the number of patients evacuated. This receipt is required for all persons under the authority of a court-martial.

The cases that go to the zone of the army are reissued their equipment, but those that are Z. I. cases have their pack broken up and sent to the different departments which issued it. These take no equipment with them when they leave the H. O. E. for the interior. The pack store is open day and night. Litters brought by ambulances are always replaced here. It is forbidden to remove a man from a litter until he reaches a hospital bed. This hospital can evacuate 3,000 cases a day. There are three trains a day, each accommodating 150 to 200 cases. They load the train from the rear forward.

Army Sanitary School No. 88.

STATEMENT OF COMMANDING OFFICER OF ARMY SANITARY SCHOOL (COL. BAILEY K. ASHFORD) TO ARMY SANITATION CLASS, AT OFFICERS' LIBRARY H. O. E., JANUARY 27, 1918

The class was divided into two groups and one-half was invited to visit ———. We proceeded by train for 5 miles, by horse ambulance for another 5 miles, and from there we walked in. A portion of the city is totally destroyed, a portion bears evidence of heavy bombardment, and still another portion bears very little trace of shell fire; but we were told that most of the houses were damaged even though their exteriors presented the aspect of being in good condition.

We visited here a hospital which was, in fact, a field ambulance, receiving cases from sector guarding ———. It was situated in the municipal hospital of the city which apparently was intact, but on entering we saw evidence of some bombardment. In spite of the handsome building, and good accommodations, only the cellar was considered safe to use for patients. This cellar was very well lighted by electricity furnished by the radiologic outfit of a *groupe complémentaire de chirurgie*. Artificial ventilation was secured by aspiration twice a day.

Nearly all injured in this sector are brought to this hospital before being transported farther back. It was in an out-of-the-way locality. Despite the fact that only the severely wounded, abdominal cases and certain cases of shock and wounds of the chest, were kept there, there were accommodations for 60 patients. An oven stood in the center of the receiving room, which, besides heating sandbags and blankets for patients, contained a couple of compartments in which a whole litter could be placed, but leaving the man's head outside.

This was a typical "ambulance de triage." I do not understand why patients should be taken there before being sent to the rear, as it was only 2 km. from the line, was unsafe, hard to get to, and was out of the way. There was no special surgical team at this ambulance, which was rather frequently changed, nor could any special purpose be served by having an advanced surgical hospital at that point. It was very clean and very well administered, but the cave itself was only splinter proof, and not at all protected from shells, as any direct hit would pierce the cellar. This really happened in a cellar of this very hospital near by; at that time, fortunately, not occupied.

Army Sanitary School No. 89.

SUMMARY OF A TRIP THROUGH ADVANCE ZONE ORGANIZATIONS MADE TO THE STUDENTS, SECOND SESSION ARMY SANITARY SCHOOL, AFTER A VISIT TO THE TRENCHES, JANUARY 28, 1918

The portion of the class which did not go out to-day will go out to-morrow. There will be two groups and we will assemble at 6.30. We will have coffee promptly at 6.15. Remember what I said the other night about overcoats. You had better take your overcoats

and keep them on while you are riding, but when you do any walking leave your overcoats in the ambulance. You will get overheated and it is well not to wear your overcoats in the trenches. The same preparation in overshoes and boots.

As to our trip to-day, I am going to tell you something about it for the chief reason that I think these things ought to be committed to paper before the memory becomes dumb, while it is still fresh in the mind, and, secondly, because the class that's going there to-morrow will have some other things to see, and if they have an idea of what they are to see they will be able to profit the more. I am going to talk from memory and I will ask Major Rushford to mention any points that I leave out.

We left this morning in automobile at 6.30 to study the organization of the sector nearest ——. We met the division surgeon at X——, and he explained to us that he was going to show up a typical regimental aid post, two battalion postes de secours, two special surgical hospitals, two advance posts and the groupe de brancardiers divisionnaire; he, himself, had his headquarters at the central post of the G. B. D. The very first thing we found there was a matter of intense interest to me, as I didn't know that the French had done it: They are copying the English in dividing this front up into sanitary sections which are permanent and whose personnel does not change. No matter how many divisions come in and go out, it is always the same. Each section consists of 1 surgeon, 1 pharmacist, 1 corporal, and 15 men, some of whom are carpenters, others tinsmiths, others workers in iron, etc. They build sanitary appliances, latrines, bathhouses, etc., seeking assistance from the engineers when the work becomes too heavy. They really had a very good installation at this G. B. D. We noticed there, among other things, a hot-air sterilizer built of concrete and brick for the disinfecting of clothing. You should by all means see it, because it is improvised and therefore valuable. It is of metal, and the temperature is raised to 90° C. by a charcoal fire in a pan, and the things that are disinfected in it are those that can not be steamed, like outer clothing, etc. They had very decent baths, and as a general thing, gentlemen, all through this sector I noticed that the baths were very good. They were clean, with provision made for the issuing of clean clothing, of disposing of dirty clothing, which was taken in, disinfected, and washed, and for undressing and dressing rooms. The water in the tub baths was heated. The latrines were of the usual squatting type.

It was explained to us that the road from X was in plain view of the Germans, but that it was camouflaged very heavily—of course the boches know where the roads are, but by camouflaging them they never know when the roads are occupied by troops, save through aircraft. At the time of our visit they were making a change of divisional troops—those at the front retiring and being replaced by others, always a time of some uneasiness, and we could hear certain evidences of activity in the distance. We went up the road for perhaps 4 km., and reached, first, an advance station of the G. B. D. (ambulance company, in our language, and groupe de brancardiers divisionnaire, in French). It was interesting for several reasons. It was directly on the main road of traffic between the rear and the front, a road which, by the way, was in excellent condition. It was well up near to the lines, and it was sunken in a cut. Into that cut they had built their dugouts. At the time we were there they were converting their G. B. D. into something very interesting. Remembering what we were told the other day by the regimental surgeon that the G. B. D. station, and especially an advance post of the G. B. D., was a collecting and forwarding point—it is interesting to us that they have made at the site of the advanced post of the G. B. D. a special hospital for the reception of nontransportable cases. I was curious to see what this was and we went into it. It was in the process of construction. They had dug into the hill or little rise of ground, right behind the dugout and the G. B. D.; in other words, it was an extension into it. It went right down and they thus got very good cover; I guess about 18 feet. It was well constructed, the angle of descent was not sharp, and it was ample in width, with well-made steps. There was a vestibule with space between the two curtained doors for a litter. When we reached the bottom I was very much surprised to find a very well-equipped set of galleries. The galleries were the usual kind; they had large wards dug out for patients, and a very good operating and sterilizing room, each separate and painted white; both of these rooms were lined with corrugated iron. There were the usual kitchen, offices, etc. I should say there were 20 beds.

It was a special surgical hospital, he said. "In other words, we are entirely independent of our poste de secours, and it is necessary here to have a surgical hospital for the treatment of cases that are held by tourniquet, or by deep shock, or by reason of abdominal wounds; a place where they can be kept until safe to send them back." It occurs to me that such a place in a battle would be rapidly filled, and I think they would be bad off in half an hour for room.

We then went to the regimental post, which was a good one and just across from the G. B. D. It was well protected, being built into the side of the hill, which ran in far enough to give a good outer entrance, a vestibule, and an inner entrance and then descended down a gentle grade with broad steps until they were—about 20 feet—below the surface. It was perfectly protected from direct hits. This station was interesting because it was mainly galleries—there were no wards—with plenty more that were offshoots from the main ones and which were converted into operating room, dressing room, hot-drink room, medical officers' room, Hospital Corps men's room, and so on; the main gallery accommodated the patients and along the wall instead of having beds they had racks that they let down. The racks were pushed up against the wall and when a patient came in a rack was let down and the litter was placed upon it. Their capacity was 60 lying and 40 sitting. The place was extremely clean, very well ventilated, and had three exits—in fact, all through this sector they insist on three exits. It was well whitewashed, quite well supplied, had a telephone, and the place was well heated and well lighted. At the farther end one walked right straight into the regimental commander's office. In this, the regimental commander's headquarters, the regimental infirmary, and the aid station were in one and the same dugout. The medical officer was a most pleasing character, a man with an alert expression in his face and a military bearing; he had everything well administered, and was on good terms, undoubtedly, with his commanding officer. Everything went on nicely there, they said.

I omitted to mention that at the advance post of the G. B. D. there were two automobiles kept standing all the time. These two automobiles were sent out from the G. B. D. post at X——, and were from the S. S. A. (Service de Santé Armée ambulance section), which consists of 20 ambulances. There were 16 at X—— and 4 out—2 at this advanced post and 2 at another.

Now, near this regimental station in a separate dugout was a group of litter bearers belonging to the G. B. D., on the principle we have seen initiated by the French that every regimental aid station should have near it a receiving and forwarding station manned by litter bearers of the ambulance company. When they get pushed they just simply evacuate into this substation, which is made commodious to receive patients. That is the only thing it does and it is their extreme forwarding limit.

From here we struck out for the trenches. Up to this time we had been on an open road—the regimental aid station is on the side of a road, and although in a dugout it was approached in the open, but now we started up an approach trench to the communicating trench, and we very soon came to where the ground was stripped and all vegetation blown away by shells. We were in territory that had been wrung from the Germans and, naturally, it bore marks of it. I should say we must have walked at least 2 km. before we reached the poste de secours of the battalion. The trenches were very well drained indeed. The earth helped that. It was a little chalky, but was frozen. They complained bitterly about the mud there, but we didn't see very much. They were very free from water in those trenches, which were much deeper than the English ones and gave much better cover. We saw many evidences of bombardment and picked up some fresh pieces of shell. The trenches were very well marked with signs pointing out routes, especially in the vicinity of the poste de secours. The division surgeon who took us was evidently not very well acquainted with these trenches, which were, however, well labeled with fanciful names, changed from time to time. He lost his way two or three times, but we finally got up to the battalion aid post "St. Jean." It was an old German aid post which was built evidently a good while ago, and it had no place for the litter to rest between curtains. Of course the object in having a vestibule long enough for a litter to rest in is that in times of gas when they get in they want to close the curtain behind them before they open the second curtain. Nothing of the kind is possible in this battalion aid post. It is a sheer descent at an angle of certainly not less

than 60°, right straight down. It is almost like climbing a ladder, and was in very bad repair and badly organized. Approaches to dugouts ought not to be at more than 30°. Our regulations call for 45°. You can not get a litter out at that angle without danger to the patient and without exceeding difficulty, and there should always be steps.

This aid station was one of twins; it was one of two battalion aid posts for the same battalion. Two were needed because the battalion was spread out over so great a distance that one was not enough. The officer in command of the place showed us his gas curtains. He seemed to be more exercised about gas than anything else. Evidently they did very little in a surgical way, nor would it have been possible to do anything in a place of that sort. The only thing that they spoke of there in connection with surgery was tourniquets. That seemed to be about all; but the young fellow was only a medical student at any rate. But he did speak a great deal about gas and about a gas curtain he was inventing. I don't think his gas curtain could be used with any degree of safety because it took too long to put it on.

From there we went across through the support trenches on the edge of the line to the *poste de secours de Maline*. That was the other twin and was in very much the same condition. What can be said of one can be said of the other. The inherent trouble was that they had accepted old German stuff that did not give adequate protection against gas. They were small and badly supported.

We then returned on the third leg of the triangle and took the automobile for "grouperment" of field ambulances. I invite your attention to this particular group because it was a revelation to me. I have seen a good many of these units, and it undoubtedly represents, as far as I have seen, the ideal and model of the French triage system. It is an ideal which is very rarely obtained apparently. The three field ambulances here grouped together from one large immobilized field hospital, reinforced by certain modern field hospital equipment to make it complete enough for this war; it is near the front, perhaps 5 km., in a fine château, with ample, more than ample, buildings, barracks with ample tentage, good roads, and unusually extensive protection against bombardment. It was right at the side of an abrupt hillock, a formation we have read of as the "kopje" of South Africa. Into that hill they have run tunnels which afford protection for all that may be in the hospital, and are constructing covered ways to get there from the wards. In addition they have built splinter-proof tunnels beside the wards and made of corrugated elephant iron, linked together at the top; these are covered with sandbags and earth, making them splinter proof. The first thing that struck me about this group of hospitals was its commander—a keen looking man who was evidently a good administrator; a man with common sense, very direct manner of speech—but not at all verbose; and a man that had a decided opinion about everything without being intrusive with it. All of his assistants were just about the same sort of men—as you may expect when you have a good leader. The first thing that we saw was that portion of the hospital which I have referred to as the advanced surgical hospital for nontransportable cases. That was in barracks. The wards were exceedingly clean, very cheerful—the most cheerful and the cleanest wards I have seen in a French hospital. They have female nurses and fine decorations around the walls, all in good taste. The place was clean and it smelled clean. The operating was done in a barrack behind the triage.

Here we began by inspecting what we have had described as the *groupe complémentaire de chirurgie*, the portable motor truck radiologic outfit and operating hut drawn on a trailer. It furnishes one hundred and fifty 32-candlepower lights and does the radiologic work at the same time. It carries a complete operating room and radiograph room. Here we had explained to us what a surgical "équipe" was. It is an operating team and consists of 1 operator, 1 assistant, and three male nurses. There were in the place 3 operating rooms and 3 sterilizing rooms, and they were large. I do not believe they need 3 sterilizing rooms, still they seemed to think they did. An interesting feature of those operating rooms was that they were always kept warm. I noted that their thermometers read 33° C. They had gone to the expense of putting in a hot-water central heating system, but they had stoves in addition, in case the central system broke down. They had lots of electric lights from power furnished by the town near by. I suppose it is run by the military government, but arrangements had been made in case it broke down for switching on the lights of the radiograph outfit, and in case that breaks down they have a third recourse to oil lamps, which are large. They kept 3

operating teams there, but in time of intense activity, in order to run 3 tables, they need 9 teams, each team working eight hours continually. Before a man reached the operating room he went through the receiving and the preoperating rooms, and I think these were fully as interesting from our standpoint as anything we saw. The preoperating room was a room where the man was cleaned up; his clothes taken off and mud scrubbed off him, and as soon as he was made clean he was taken into the room for heating. Now, they had 9 or 10 litters on supports, covered by canvas hoods—canvas spread over barrel hoops and closed by a wooden bar at the bottom but perforated by a little stovepipe 2 inches in diameter, stopping about a foot from the floor. The man was put under this hood, and a blanket thrown over the hood and drawn round his neck. A lamp was put under the chimney while we were there and within a few minutes it was tolerably warm—a thoroughly good way of heating a patient. There they were heated and from there, of course, they went to the operating room; that is, after passing through the radiograph room for a radiograph. After operation they were put in one of two wards which held 24 beds each.

In time of action this preoperating and heating room was under the charge of a medical officer, who remained there on constant duty. He doesn't do anything at all but watch these patients and see that they are put in shape for operation. That is his sole duty. If they needed stimulation he gave it to them—whether it was hypodermic or whatever it was. He was the man who decided when patients were fit to be examined in the radiologic room. In other words, he had full charge until they were delivered to the surgeon.

We next passed to that part which has always interested me, the evacuation section of the hospital and triage of same. It was a group of tents whose whole capacity, I should say, was not less than 1,000. These tents were double lined, very clean, very comfortable, easily warmed and remaining so longer than barracks. They had sanded floors, and were well fitted up with beds; there were not any cots, or blankets on the ground; they were beds and they were good beds. In connection with this evacuation group there was a triage room. Patients were received there, their dressings were taken off, and a medical officer made an examination of the wound, confirming or disapproving the diagnosis. He decided what should be done; whether the patient should be moved on to the rear or operated upon in the hospital. If he was to be moved to the rear he was sent to one of these tent wards; that is, a lying patient to a recumbent ward and a sitting patient to a hangar. At its very best this elaborate triage didn't appeal to me as being a thing that was absolutely necessary unless this was to be the principal surgical hospital. If it had been just a few that were to be sent back it would have been all right, but just to get a few to be kept it wasn't all right, because it delayed things. It was absolutely clean, apparently orderly, well administered, and undoubtedly if the plan wouldn't succeed there it wouldn't anywhere. The medical officer told me he didn't know whether it was a good thing or not. He intimated that this triage ought to take place at the hospital where the operating could be done, on the majority that needed it, but he didn't say so.

Now, these double tents are known as Bessonneau tents. The Bessonneau tent is the tent. There is no question about that at all. It is the non plus ultra of military tents in France. The Bessonneau hangar, braced on the principle of a cantilever bridge, is an enormous tent. There is one here at ———, but to see one of these things fitted up with beds is really a sight; it was really a most beautiful hospital. Here was an enormous tent, warmed comfortably by a central heating system, with 125 beds, and sanded earth floor.

We now came to their center for gassed cases, which was new, as in this sector they had a good deal of gas. All are more afraid of gas than they are of wounds, and the majority that they get are gassed. An English C. C. S. we saw (No. 23) has a shed, open on one side, for these cases. The French have an open shed, but that open shed is simply for the purpose of triage. They handle the gassed by chlorine and those suffering from the vesicating gases in separate wards, as the two are treated quite differently. The chlorine cases are taken immediately and put comfortably to bed. We saw a whole ward of them, and the medical officer in charge called attention to their universal slow pulse, 40 to 50 per minute, which remains that way for days. The vesicating gas cases have to go through a much more elaborate process. There is a long building, with cemented floor and well warmed. The patients remove their clothing in that room—the receiving room—which is well warmed. In the next

room they bathe under a shower of warm water. In the next room they are laid on a table; are given an alkaline rinse and their eyes are washed out with the same solution. Finally, in the next room they get new clothing. This suite of rooms took up the whole barrack. That's one thing about this place: Where they needed a room they provided it and it was big. Then the man was evacuated; he didn't stay there like the chlorine cases. He was put away in other barracks. These gas cases can not be transported very far back. The field hospital is where they should be; no question about that at all.

The bathrooms are like everything else in this station—well administered. There were shower baths with hot water. There was a dressing room where men took off their dirty and put on clean clothing; and a window through which dirty clothing was discarded; a place where they put away their outer clothing, little racks which extended through and through the wall into the dressing room. For instance, No. 24 put his clothing in No. 24 cubby-hole and went into the bathroom and bathed. While we were there some were soaping; others washing off. When he finished bathing he went into the dressing room, where he got clean underclothing and received his disinfected outer clothing. They ran 75 an hour through that bath. There were about 20 shower heads.

Here is something worth considering: It was a disinfector, a "Purey," type 4, model Exshaw & Co., of Bordeaux, and there was a great deal of mystery about this thing. It was enormous, weighing about 11,000 kilos, and it was supposed to travel under its own steam. It had a hot-air sterilizer—dryer they call it—which had very large capacity; at the rear it had a steam apparatus for clothing; so you turned steam into the back part and hot air into the front part of the dryer. Of course, it was too huge to carry over the country, and it burned 500 kilos of coal a day—entirely too much. They also used coke in it at times. It is too heavy, it costs too much, and the French have no use for it at all. Later on we saw one that they did have use for.

At this hospital the nontransportable in an attack are held here for operation, the gassed at the gas quarter, and the rest are hurried to the rear. The last place visited was the tent bathing outfit for a cantonment, known as the section d'hygiène corporelle (which is elsewhere described). There were 7,000 units of underwear kept in stock here for issue.

Antitetanic serum is rarely ever given at the aid station in this sector; it is given generally at the triage, but it ought to be given at the aid station. We can do it, and we ought to do it.

I want to say two or three words about this hospital; just a few things. This grouping of field hospitals is manifestly a better way of handling the situation. If you group three field hospitals together—I am assuming an immobilization of hospitals—if you immobilize them, this is the proper way to do it, provided the place has a proper tactical value and all other advantages. If they can be grouped I believe you get the best results, because if you group them, one radio-surgical outfit will do for the whole thing—will attend to all of the radiology for you—beside a whole series of economies in other services.

We had a very good illustration to-day of the difference between a mere doctor and a man who was an administrator of a hospital. There is no question about it, gentlemen, that one of the most important things that we have got to learn is how really important a director of a hospital is; and when you commence to talk about administering a hospital you have got to combine all the qualities of good common sense and professional ability in one. This man was thoroughly on his toes. There was not a part of this building that he didn't know about, nor a detail of its professional work. Everything was perfect, and there he was in mud 4 or 5 km. from the front.

The last place we visited was the other advance station of the G. B. D. We there saw installed an emergency surgical hospital similar to the one we had seen in the early part of the day, but drawing from another part of the line. From one direction this place was reached by going over exceedingly rough country and very much exposed indeed. On the other side they had the canal. So at each of these advance posts of the G. B. D. there was a special surgical hospital, as we have mentioned. This one didn't differ except that it was in a barrack and the other was in a dugout. I think it was a mistake to put it in a barrack. The personnel of this surgical hospital is, at first sight, strange—1 chemist, 1 corporal, and 4

Hospital Corps men. I asked why there was no medical officer, and he said this advance post of the G. B. D. is next to a battalion aid station. When wounded come in they are very apt to be from that battalion post and their doctor is near. If they are bad cases he telephones to the field ambulance for an operating team. The operating team comes up and immediately starts to work with what the enlisted personnel prepares for them.

The noncommissioned officer said he was a chemist. Colonel Porter wanted to find out how much chemistry he knew. As a matter of fact, he is probably a drug clerk. But they are pretty good men. With what they knew before and what they learn by experience they are able to help out. They do very well in carrying out work that is laid out for them, but they can't usually originate anything; they appear to have no important administrative duties.

The Vermorel apparatus that we were shown in the trenches is not very much used for the purpose it was originally intended—to neutralize air. It is a sort of a hand-grip apparatus, supposed to spray the air with a hyposulphite and bicarbonate of soda solution, and this is intended to clear the air of chlorine gas; and it is also supposed to wet the curtains. It is all right for wetting the curtains; you can't use anything better, but French officers say it is not worth very much for clearing the air. The Tissot apparatus is nothing but the English box respirator, but it is better and lasts longer. An oxygen tank is, of course, kept in all of these stations. The poste de secours will have 500 l.; a regimental poste will have 2,000 l. They also have a large number of rubber bags that they can pump up with oxygen. They seemed to be very much afraid of gas. They bore a hole in the French mask and put a little piece of gas tubing through it; then the mask is connected up with the oxygen bag direct. If the oxygen fails it don't hurt, because the man is protected from gas. This was really very ingenious. Of course, there are other ways of giving oxygen; the English give it by the Haldane apparatus.

Army Sanitary School No. 90.

NOTES BY GROUP OF STUDENT OFFICERS OF SECOND SESSION, ARMY SANITARY SCHOOL,
VISITING RIGHT SECTOR, JANUARY 29, 1918

Group under Lieutenant Colonel Shookley, M. C., United States Army

(This group visited the same sector as Colonel Ashford's group, described by him in a summary made to the class on January 28, and detailed elsewhere. Additional notes are here added covering features not previously dealt with.)

Group consisting of 8 medical officers left ——— at 7 a. m. in ambulance and after a run of about 10 km. to the northwest, made its first halt at the group of field ambulances previously described. It consists of three field ambulances in one group with a groupe complementaire de chirurgie. The hospital had a capacity of 500, but was capable of being expanded to 1,500.

In the receiving room of the triage was an arrangement for heating up cases who were shocked—canvas hoods, and hot air from a lamp which burned beneath a pipe leading thereto. The ward itself was heated by the "cloche" stove upon which were kept tins filled with sand for filling bags. Here the man was cleaned up, shaved, and a definite diagnosis made if possible. The wards were some of the "Adrian" type and others of the Service de Sante, the latter being far superior and warmer. One of the patients (and he was asleep) was a wounded German taken in a small raid the night before. The radiologie plant was installed just outside the operating rooms, which were in a long barrack building, but it was connected with them by a covered way. They had removed the partition in the portable operating hut and were using it all as an X-ray room. There were two Bessonneau hangars, each with over a hundred iron bunks all made up in case of a rush. They were heated by an outside hot-water heater whose pipe ran along one side of the tent and had many metal disks threaded upon it to increase the radiating surface. They were perfect in their neatness and were comfortably warm. Here was also the headquarters of the G. B. C. (groupe brancardiers du corps), the litter-bearer group of the army corps.

There was also a supply depot which was well stocked, although the Thomas splints were scarce. There were about 500 hand and many wheeled litters which later were folded

up and were packed in motor trucks for immediate delivery to divisions. Here also were kept the supply of reserve masks for the corps (both Tissot and M²) and in connection therewith was a small repair shop for remedying slight defects.

There was a small water analysis laboratory in charge of a pharmacist, a commissioned officer, who had devised an automatic feed of Javelle water to a reservoir so that just the proper amount was added to sterilize it. There was a constant chemical check made on results.

The scope of this group of field ambulances is as follows:

1. Triage.
2. Operating center for slightly wounded.
3. Operating center for severely wounded.
4. Gas center for treatment.
5. Laboratory for water analysis.
6. Medical supply depot.
7. Dental dispensary, fitted up much as is our own portable outfit.

The hospital was served by female nurses.

A bathing establishment was now inspected. It was the new tent outfit for cantonments and divisions in the line known as the section d'hygiene corporelle. (This is elsewhere fully described.) The clean clothing issued is of three sizes—large, medium, and small. Uniforms are disinfected in about 20 minutes by the autoclave. Men go directly to this bath from the trenches before occupying billets. Near this bathing establishment was an advance operating station (previously described). There was a total capacity of 30. Even this had its bath and system for issuing clean clothing. There was no good reason for having such a station here, as the field ambulance group, previously described, was near by.

The city of — was now visited and lunch was served in the field ambulance formerly occupied as a civil hospital. As a relief was in progress in the sector of the division surgeon who accompanied the group, he explained the necessity for showing the aid stations near this ambulance rather than carry out the more extensive program planned for a more distant tour through a sector passed over the day before by Colonel Ashford's group.

Before leaving for the trenches the ambulance, which served not only as a triage but as an advanced surgical hospital for nontransportable cases, was demonstrated. The entrance to the cellar was from the courtyard of the hospital down a broad-stepped stairway with a gentle grade for about 40 feet. The receiving ward was large and well heated by a "cloche" stove around three sides of which were built ovens. Every room was white-washed and well heated in this ambulance. The kitchen and messroom were on the surface. From this cellar one could descend some 30 feet farther down to some subterranean passages said to be of great antiquity and several kilometers in length in various directions. The tunnels were fully 6 feet square and were said to have never been fully explored. They were probably old wine cellars.

After traversing the destroyed portion of the city by a communicating trench, through back yards, under ruined walls, twisted railway tracks, and in and out of cellars, the trenches were entered directly from a street running north. After a short distance the regimental aid station was reached. Its entrance was at an angle of 30° to 35° and admitted a litter between curtains at the vestibule. This station was in the cellar of a ruined house and was not more than 10 or 12 feet underground. There were two entrances, but only one was seen. It was about 30 feet long and 6 feet wide and divided into a room for the regimental surgeon, one for office, dressing of patients, and supplies, and one to hold 6 or 8 enlisted men of the Medical Department on duty there and bunks for 5 or 6 wounded. This station was only a few feet from the camouflaged road to which patients were evacuated by a back stairs through a hole in the wall for transportation by ambulances at night. The light was electric; the air was dry and warm, but the station was overcrowded, small, and inadequate. Supplies were abundant—reserve of masks, 2 or 3 Tissots, 1 Vermorel sprayer, 3 or 4 Draeger oxygen apparatuses, as well as rubber balloons filled with oxygen. Thomas splints and tourniquets were seen, but no definite arrangements had been made for treating shock. The regimental surgeon's room was rather comfortable and had a metal bed. Eight to ten litters were kept here, but no heating arrangements were seen.

From this station the battalion aid stations were visited. They were close together and were, in common with the regimental aid station, all on the same communicating trench. The first, was a quarter of a mile away through unrevetted trench without any apparent provision for drainage, but clear of mud. Cement tanks holding 15 gallons of water were seen at intervals in this trench and were provided with taps. This battalion station was located just off the communicating trench under another ruined building with not over 9 feet of head cover. It also was within a few feet of the road, camouflaged by the wall of the house. The entrance was down an easy grade, but the dugout was small and extremely crowded. The main room was hardly 8 by 8 feet and connected by passageways with smaller ones. The first room contained supplies of drugs, bandages, splints, tourniquets, and certain gas defense stores. Some operating instruments were seen, but few facilities for operating. There was room for four patients in one chamber and for the personnel in the other. On the way out a higher level room was encountered little more than splinter proof. Here, owing to shelling, the party was held for a while before being able to return. It was noticed that the gas curtains here did not reach the ground by 2 inches. No latrines were seen in this trip. The second battalion aid post was much like the first and shared all of its defects.

Army Sanitary School No. 91.

THE MEDICAL CENTER AT ———, MAY 10

The hospital was a corps field ambulance, designated 12/2. This was not far from H. O. E. 32, and is one of the medical centers for the ——— Army. It is in a picturesque country, with a fine, old château in a beautiful park full of flowers, with many large trees, a little stream, and a lake. The patients are hospitalized in huts. The capacity of the hospital is 400 beds, and 3,000 patients have been received here since September, 1917, with an average stay of 10 days. The men are first admitted to the triage. Here they are deprived of their clothing and equipment, bathed, inscribed, and sorted into three groups:

- (1) The slightly ill who are not expected to remain in the hospital more than six days.
- (2) The incipient cases of tuberculosis and those under suspicion of having that disease who are sent to the interior as soon as their diagnosis is made.
- (3) All other contagious diseases.

We went directly to the huts set apart for the slightly ill; that is to say, for light cases of general medicine not contagious nor tubercular. The patients seen in the wards were chiefly suffering from respiratory diseases. There were many cases of bronchitis, some diagnosed as influenza, one with laryngitis, another with pleurisy, one with pneumonia, in a dying condition, and one with CO poisoning.

In another building were the infirm cases. These were only the slightly sick; heart cases are not taken here. In the rear of these huts we were shown the baths for the personnel of the hospital and for the patients, and a portable laundry of the type bought for the camp hospital of the 1st Division last year, it required 4 men to turn out 250 pieces a day. The baths were the usual ones—small, with undressing, bathing, and dressing rooms. Near the laundry was a large drying shed for sheets.

We next visited the section for cases of tuberculosis. This is separate from the rest; and as soon as a man is diagnosed and carefully examined as to the extent of his lesions, he is evacuated into the interior. Men with incurable open cases are sent to sanatoria, closed cases are sent to duty with the auxiliary troops in the back areas, but none are sent back to the active army at the front. In the diagnosis of tuberculosis, radiologic as well as laboratory methods are employed, and these are carefully checked upon by physical examination by medical officers.

The administration building was in the château. One motor ambulance stood in front of the building in case of any serious surgical situation arising among the patients, as there was no surgeon or operating room here. In this administration building was the radiologist and his equipment, which was limited to diagnostic and therapeutic application. There was a laboratory for the hospital which was only a clinical one. The pharmacy was clean and bright. It attended to the clinical examination of urine and other secretions.

THE CONTAGIOUS DISEASES SECTION

First ward—measles and scarlet fever; 6 cases of the former and 1 of the latter. They were separated by a partition and the same nurse cared for both.

In the next barrack were isolated all cases of enterocolitis, including dysentery and typhoid. They stated that they had only two cases of amebic dysentery since they opened and what they actually had in the hospital at the time was due to banal organisms.

In the next we found mumps and diphtheria. The same remarks apply to this as to the measles and scarlet fever hut. There were 8 cases of the former and 1 of the latter. They stated that mumps is the most frequent contagious disease they have to deal with. They have great faith in Vincent's powder to rid carriers of the bacillus of diphtheria. It is used locally, and they report that throats are freed in about two months.

The next hut contained all the anginas. They stated that Vincent's angina is a very common form. They treated it with injections of novarsenobenzol.

The next two huts were filled with venereal cases. Only patients in the first and second stages of syphilis and acute gonorrhea were received here. The treatment for syphilis consisted in 4 injections of novarsenobenzol, one each week, beginning with 35 eg. and ending with 90. They inject daily for 10 days, cyanide of mercury, beginning with 2 eg. and gradually increasing; then discharge them with a little potassium iodide.

We were now taken to the very handsome château of a champagne merchant of ———, a mile from this field ambulance. This was really a rest station for officers and noncommissioned officers and looked like a good type of English country mansion. It was situated on a height, in a large park, well laid out with trees and flowers, and has a high open portico commanding a superb view of the surrounding country, on which patients could sit and read. It was a most ideal spot for an officers' convalescent hospital, as it was quiet and near no town. The gatehouse, which was picturesque, was given over to noncommissioned officers, and here also luxurious house conditions met all of the necessities for sick men. English nurses had charge of both officers and noncommissioned officers. The big château was occupied by both English and French officers. The peculiarity of this hospital is that a man can not be evacuated to another formation in the rear without an order from G. H. Q.; he must return to his duty within three weeks. I saw my first case of acute articular rheumatism in France in a noncommissioned officer at this hospital.

BATHING SECTION (SECTION D'HYGIÈNE CORPORELLE)

We now visited a section for personal hygiene in a cantonment not far away into which English troops were pouring. The plan of this bath system will be found elsewhere, but its functioning at this place will be described. It was on the edge of a cantonment for 12,000 men. There are bathing facilities for 10,000, as 1,000 can be bathed a day; 40 can be bathed at a time, and require 20 minutes for the operation. An English company was going through as we reached the place. First, there is a disrobing room, fitted with latticed benches, the space thereon required for one man bearing a number corresponding to that assigned him by a numbered wooden check on admission. The outer clothing of the bathers was put into a large mesh bag bearing a number also corresponding to this number. The clothes were sterilized for 20 minutes, the time that he would require in getting his bath and his fresh underclothing. In addition he receives when he enters a small bag for his valuables, which bears the same number as the wooden check he has received. It is turned over to an assistant, after deposit of the soldier's valuables, to be put in a large basket, which is thereafter locked. This is sent to another tent near by from which he is reissued his bag after dressing, on presentation of his check. The men then pass into the bathroom proper, which has cubby-holes in a set of shelves, each cubby-hole being numbered with the same number as that upon the tag or check, into which he places his shoes and hat. Here are 20 shower heads; 20 men wet themselves under the bath, then step aside and soap themselves well while a second 20 wet themselves and so on, the first 20 bathing while the second 20 is soaping. They are given 10 minutes to take the bath. It requires 12 liters of water per man per bath. The floor is latticed. The men receive their soap before they go into the bath and a towel after they finish. They pass into a small drying and dressing room, where they are given a towel and a suit of

underclothing, and later they receive their own outer clothing from the autoclave which opens into the room in which they are dressing. There is also a tent near by for dirty clothing. This dirty clothing is all sterilized and sent down, to a nearby town for laundering.

The personnel required to operate the bath consists of 1 sergeant, 1 corporal, and 14 men. Every cantonment has one of these bathing establishments, and one is assigned to each division. This happened to be a corps establishment. It is to be remarked that the soldiers are bathed here by organizations and it is what the English call a "parade." They come in from the trenches and the first place they visit is the bath. As a result of this bathing system some very interesting explanations can be given concerning the assertion by the French that they are not so lousy as before. This, as a matter of fact, is so, and it seems to be so because all bathing and disinfection now belongs exclusively to the French Medical Department. There has been a sensational drop in the number of louse-bearing and itch-bearing French soldiers since this department has had charge of this important means of preventing disease, with an almost complete disappearance of trench fever, which is giving the British at present so much trouble.

MEDICAL CENTER ESTABLISHED BY A FIELD AMBULANCE

Here was installed another field ambulance that took care of medical cases in this region. This was a quaint old monastery, founded in 1126 by the Trappist monks.

This field ambulance accommodates, in Adrian huts, 600 medical cases and they have a triage dividing their patients into four classes: (1) General medical, (2) cardiac, (3) tubercular, and (4) contagious. Everything was much better than at the other place and better isolation was observed, because no two contagious diseases were put in the same barrack. The medical officer in charge was a most delightful man and thoroughly scientific. He was very interesting in his description of how he managed to find a place for the isolation of those admitted to the hospital who were not yet diagnosed. Rather than open a ward, he has found a room divided into stalls, which was used for silent prayer and in which the monks were confined at times. Sick men with suspicion of disease now occupied their place. The wards are all served by men, for the Trappist monks do not permit any women in the building, nor on the grounds or anywhere around. In conversation we found that there had been 115,000 cases of typhoid in the first six months of the war in the French Army because typhoid vaccination was not obligatory at that time. They hastily vaccinated the entire French Army by order, and it is said that at present they have not one case in any part of France. They use radiology here for diagnosis in chest and heart conditions very extensively, but there is no operating room. There was a little laboratory, which is merely a clinical one. It was at this hospital that I saw my first case of spirochetal jaundice. They said they had had 40 cases in this hospital at one time.

Army Sanitary School No. 92.

EVACUATION OF WOUNDED IN ZONE OF ADVANCE

By Major McDonald, Medical Corps

The work of the Medical Department in the divisional area during active fighting consists principally in the collection of the wounded in sheltered places, their emergency treatment, and rapid transportation to the hospitals in rear of the battle zone, with the minimum hindrance to military operations. The severely wounded man must be delivered at the evacuation hospital, the nearest completely equipped hospital to the front, in condition for immediate operation within 8 to 12 hours after the receipt of his injury, in order that he may have the maximum chance of rapid recovery and subsequent return to the front, or to civil life as an asset. Battles are won by man power, and the Medical Department is essentially a salvage department to maintain that power at the front. The effectiveness of man power in battle depends largely upon the physical force and the morale of the fighting men. Next to good health, good arms, and good training, nothing braces a soldier's morale so much in battle as his knowledge that an efficient Medical Department is at hand and ready to render him assistance in case of injury. Sympathy and humanity are not incompatible with the work of the Medical Department in battle, but its primary considerations are salvage and morale.

Paragraph 330, First Service Regulations reads as follows:

The personnel of the sanitary service in the zone of advance may be classified into two general groups, as follows: First, that attached to organizations smaller than a brigade, with functions under the immediate orders of the organization commander and accompanies it into combat; second, that attached to the sanitary train which functions under the orders of the divisional surgeon in accordance with such general or specific instructions as he may receive from the division commander. When necessary the sanitary personnel attached to organizations may be temporarily detached in whole or in part, and directed to operate with the sanitary train.

LINES OF ASSISTANCE FOR THE WOUNDED

1. The first line of assistance for the wounded on the battle field is furnished by the group of the sanitary service attached to regiments and smaller organizations. As noted in Field Service Regulations, this personnel functions under the immediate orders of the organization commander. The senior medical officer, designated "regimental surgeon," is a staff officer of the regimental commander and is held responsible for the proper care of the wounded at the front, and he supervises and directs the work of the Medical Department detachment. He consults with the regimental commander as to the time and place for establishing a definite or a provisional aid station, and as to the disposal of the wounded should it be necessary to leave them behind. For an Infantry regiment the maximum personnel of the sanitary service consists of 1 major, Medical Corps, and 6 captains or lieutenants, Medical Corps, one or two dental surgeons, and 48 enlisted men. Organizations smaller than an Infantry regiment have personnel in about the same proportion in accordance with their strength. This medical personnel is usually assisted by the addition of the regimental band and, in emergency, by details of men from the companies as stretcher bearers. Prisoners of war have been used as stretcher bearers in some battles of the present war.

The medical equipment for an Infantry regiment consists of splints, litters, surgical instruments and dressings, medicines (principally antiseptics and hypodermic solutions), and an oxygen-administering apparatus. These supplies are transported on three 1-mule medical carts. An additional box or more of surgical dressings and one or more litters are carried on each ammunition wagon. A regiment operating alone needs in addition 4 ambulances and an infirmary of 12 beds.

The function of the regimental sanitary service in battle is to render first aid to the wounded and collect them at an aid station in a sheltered place near the battle line, where they can be cared for and recuperated until removed by the stretcher bearers from the ambulance company. Whenever troops are advancing rapidly it is manifestly impossible for any definite aid station to be established, and the sanitary service can only render first aid to the wounded, collect them in more or less sheltered places near by, and leave them attended by one or two Hospital Corps men, to be picked up later by the ambulance companies. The sanitary service with organizations must stay with their organizations at all times. In trench warfare and at times in open warfare it may be necessary to establish battalion aid stations, since our Infantry battalions have been increased to more than 1,000 men. These aid stations are usually established from 400 to 1,500 yards in rear of the battle line, and they should be located in a place having some protection from fire. The Medical Department personnel collects the wounded at the aid stations from all parts of the battle field, but only in exceptional circumstances do the regimental stretcher bearers carry the wounded farther back than the aid stations. All transportation of the wounded in the regimental area is done by hand litters. The professional work done by the medical officers consists principally in the controlling of hemorrhage, application of splints and surgical dressings, and the treatment of shock and pain. Wounded should never be left on the battle field or allowed to fall into the hands of the enemy if it can be avoided, as the enemy will neglect them when he has all he can do to treat his own wounded. In retreat, especially if the losses have been severe, it may be necessary to leave some of the severely wounded, but sufficient sanitary personnel must be left behind to properly care for them unless competent civilians can receive them, as may be the case in friendly territory.

During attack in trench warfare the Medical Department personnel goes over with the last wave, or at the same time that regimental or battalion headquarters go over. When the military situation and the nature of the terrain permit, at least one well-protected aid station should be established for each regiment.

The requirements for a regimental aid station site are:

(a) Within 500 to 1,300 yards of the front line and near the area of the greatest expected casualties.

(b) In a place affording some cover from fire, such as dugout, a cellar, a gully or ravine, or a steep slope facing from the enemy.

(c) The site should have an approach from the front and to the rear under some cover.

(d) It should be in the natural line of drift of the wounded to the rear.

Unless such a site can be found, it is not likely that aid stations can be established during planned attacks until the advance ceases, the engagement terminates, or night sets in.

In defensive action, aid stations can frequently be established at the beginning of an action.

In Cavalry engagements, aid stations can only be established after successful action.

Of the wounded going to the rear from the aid stations, the severely wounded are transported by the ambulance company stretcher bearers to the ambulance dressing stations, while the slightly wounded are directed to walk back to the station for slightly wounded under the guidance of a corps man, or one of their number if a Medical Department enlisted man is not available. Frequently an officer or a noncommissioned officer may be found among them who can be put in charge of each group. It is forbidden for an uninjured combatant to accompany the wounded to the stations in the rear.

THE SECOND GENERAL GROUP OF THE SANITARY SERVICE OF THE ZONE OF ADVANCE

The sanitary train.—The sanitary train is commanded by the division surgeon in accordance with instructions given by the division commander. It consists of 4 ambulance companies, 4 field hospitals, 8 camp infirmaries, and 1 divisional medical supply unit. For administrative purposes the train is under direct charge of a lieutenant colonel of the Medical Corps, while the ambulance section companies and the field hospital section is under a major of the Medical Corps as director of field hospitals. The relation of the directors to their companies is very much like that of an Infantry major to his battalion, while the division surgeon bears a relationship to the directors very much the same as that of a colonel to the majors of his regiment. Three of the ambulance companies and three of the field hospitals are motorized and one of each is animal drawn. The eight camp infirmaries are animal drawn, each equipment being carried on one 4-mule wagon. The medical supply unit is transported on two motor trucks.

2. *The ambulance companies from the second line of assistance for the wounded.*—The personnel of each motor ambulance company consists of 5 medical officers and 122 enlisted men. The wheeled transportation available for wounded consists of 12 motor ambulances, each having a capacity of 4 recumbent or 8 sitting patients. In case of necessity the three 2-ton trucks used in transporting the company equipment may be used in transporting wounded. Likewise the touring car and three motorcycles may be pressed into this service in emergency. The only other means of carrying the wounded is by stretcher bearers on the standard litter, of which each company has 68. A wheeled litter has been proposed and will very probably be adopted.

The matériel which the ambulance company has for the emergency treatment of wounded consists of surgical dressings and instruments, splints, oxygen administering apparatus, medicines, blankets, heating devices, and medical comforts in the form of easily digested foods. The treatment given, such as the amputation of hopelessly mangled limbs, ligation of bleeding vessels, application or adjustment of splints and dressings, the stimulation and warming up of the wounded, aims principally to combat shock and enable the patient to be rapidly and safely transported to a hospital in the rear of the battle zone, where he should arrive in condition to withstand an immediate surgical operation. Ambulance companies form the second line of assistance to the wounded; hence on the battle field they must push up close to the rear of the fighting troops and as near the line of aid stations as possible and establish dressing stations in order to take over the wounded from the regimental medical personnel who must remain with their organizations. The ambulance companies operate over a zone of from $3\frac{1}{2}$ to 5 miles from front to rear, extending usually from the battalion

aid stations to the field hospitals. In the field operations the ambulance company is divided into a transportation section and a dressing station party, the latter including the stretcher bearers.

The stretcher bearers carry wounded from the aid stations, or farther front in necessity, to the ambulance dressing station, which is usually at a motor head. In some instances the dressing station may be established some distance in front of the nearest point reached by ambulances, and so an additional carry of the distance from the dressing stations to the motor head must be made by the stretcher bearers. Under certain favorable conditions the dressing station may be placed as far forward as the aid stations, in which event it takes the place of the aid stations; however, the distance to be covered in the ambulance company zone by litter transportation is usually from 1,000 to 3,000 yards, while the transportation of the wounded back over the remaining $2\frac{1}{2}$ to $3\frac{1}{2}$ miles or more to the field hospitals or other hospitals in the rear is accomplished ordinarily by motor ambulances. In exceptional circumstances animal-drawn ambulances must be used. When the distance to be covered by stretcher bearers is more than 1,000 yards it is of advantage to have relay posts for stretcher bearers. On all except very short carrying distances four bearers must be assigned to each litter. The bearer section of the ambulance company consists of a maximum of 80 stretcher bearers. Thus not more than 20 wounded can be transported at one time on litters by one ambulance company. In emergency, additional bearers may be sent up from sanitary units of troops in reserve. Ordinarily the ambulance company can not make use of the sanitary personnel of the organizations in the fighting line for stretcher bearing back of the regimental aid stations, as their time is fully occupied in collecting and caring for the wounded in their own area. It requires, on an average, one hour for four stretcher bearers to transport a wounded man 1,000 yards and return a closed litter to the starting point. In favorable circumstances it should not require more than two hours to transport a wounded man through the ambulance company zone, from an aid station to a field hospital. This permits half an hour at the dressing station for treatment and recuperation.

The ambulance dressing station is also a sorting station. The patients are sorted into:

(a) The slightly wounded, who are directed to walk back to the station for slightly wounded.

(b) The slightly ill and wounded not requiring immediate extensive surgical operations are transported to field hospitals.

(c) The severely wounded, needing immediate operation, are transported at once to the evacuation hospitals, or to a field hospital having a mobile surgical operating equipment.

From a tactical standpoint the following are the requirements for an ambulance dressing station site:

(a) Distance from aid stations should be from 0 to 3,000 yards. In trench warfare the average is 1,000 to 1,200 yards.

(b) In line of natural drift of wounded to rear.

(c) In a position known to the command or easily found.

(d) Easily accessible from front for stretcher bearers and wounded.

(e) As near as possible to the area of greatest expected casualties.

(f) Accessible to ambulances approaching it from rear along a covered or partially protected roadway which can be spared for the purpose.

(g) Cover from fire; should be out of rifle range and direct artillery fire.

(h) Shelter from cold, wind, and rain.

(i) Water, straw, and fuel.

(j) Usually the dressing station should be located at the ambulance head, where one or two ambulances should be stationed at all times.

(k) It should not be placed too near artillery positions, road crossings, munition dumps, and other points which are special targets for the hostile artillery.

Ambulance companies are responsible that all routes for evacuation of wounded in the divisional area are plainly marked. They are also responsible that all stations for the wounded are emptied as fast as possible so as to make room for new cases.

3. *Field hospital and stations for slightly wounded for the third and last line of assistance for the wounded in the zone of advance.*—Field hospitals are mobile hospitals, four to the infantry

division, each having a capacity of 216 patients. The field hospitals are established in a zone 4 to 5 miles in rear of the battle line, out of range of all fire except heavy artillery. Of the four field hospitals per infantry division, three are motorized, and the other is animal drawn. The transportation of a field hospital consists of eleven 2-ton trucks, one repair car, one touring car, and two motor cycles with side cars. This transportation is for the equipment and personnel of the hospital, but any or all of it may be pressed into the service of transporting the wounded in emergency. Tentage sufficient for patients and personnel is carried. The personnel of a field hospital consists of 6 medical officers (1 major and 5 captains or lieutenants) and 83 enlisted men. The animal-drawn field hospital has the same equipment and personnel, but seven wagons instead of motor trucks are furnished for the transportation of equipment. The nature of the surgical work done by the field hospitals is very much the same as that done at the dressing stations, though it is possible to do even major surgical operations in the field hospital. However, in the light of the recent experience in trench warfare, and due to the great advance in the surgical treatment of wounds, the evacuation hospital has become the principal place for definitive surgical treatment. Thus the rôle of field hospitals has become largely that of slightly wounded stations, rest stations, special gas hospitals, scabies and delousing stations. In open warfare it is very probable that the field hospitals will again have their principal work in the treatment of the wounded. Field hospitals receive the sick and wounded from the ambulance companies, and are evacuated by ambulances of Services of Supply organizations, known as evacuation ambulance companies, which convey the wounded to the evacuation hospitals located at a rail head 10 to 15 miles in rear of the battle field. The requirements for a field hospital site are as follows:

(a) Three and one-half to five miles from battle line, out of rifle and field artillery range.

(b) Accessible to ambulances from front and rear.

(c) Wood, water, straw, shelter, etc., such as may be obtained in a small village.

While tentage is carried for sheltering the wounded, it is very desirable to have buildings available for this purpose.

Stations for slightly wounded.—A station for slightly wounded is established somewhere in the field hospital area in order that the walking wounded may be directed to it for treatment in times of emergency when the aid stations and dressing stations farther front are taxed to capacity in caring for the more severely wounded. This station is established by a whole or part of the personnel of a field hospital, or ambulance company with the field hospital equipment, or with a camp infirmary equipment. If a camp infirmary equipment is used, 1 or 2 medical officers and 6 to 12 enlisted men must be drawn from an ambulance company or a field hospital to operate it, as no personnel is attached to a camp infirmary except one sergeant and a driver.

The station for slightly wounded should be established in a central location so as to be available for all the troops of the division, since only one station for slightly wounded is ordinarily necessary. It should be in the line of drift of the wounded to the rear, near the sector of greatest expected casualties, and should have cover from fire and shelter from the elements. It should be in a position easily accessible from front and rear and its location should be announced in orders.

The primary function of the camp infirmaries is to furnish dispensary facilities to organizations during field service.

The divisional medical supply unit has a personnel of 1 medical officer and 8 enlisted men. Its transportation consists of 2 motor cycles with side car and 2 motor trucks. Its function is to replenish the medical supplies of the sanitary train and organizations of the division.

The sick and wounded returned to duty from hospitals and other stations within the divisional zone return to their organizations, taking with them all their equipment. The sick and wounded of combat divisions returned to duty from evacuation hospitals are sent to a replacement division or to auxiliary depots of replacement divisions, which may be established in hospital areas. Sick and injured of organizations of the Services of Supply are returned to duty with their organizations.

Duties of medical officers on staffs.—(1) Advisory: Concerning all matters pertaining to the sanitary welfare of the command and concerning matters pertaining to the personnel and equipment of the sanitary service under organization commanders. A staff medical officer must be prepared to advise the chief of staff on the following points, per paragraph 4 of Field Orders:

(a) Time and place where sick of the command are to be assembled for transportation to the rear.

(b) Location of a station for slightly wounded.

(c) Location of dressing stations and field hospitals when it is possible to fix them in advance.

(d) The assignment of additional transportation for the wounded from the field train.

(e) The disposition of the remaining Medical Department divisional units until they are needed on the field.

(2) Administrative: In this capacity the division surgeon is in immediate command of the Medical Department personnel attached to division headquarters, of the sanitary train, and of Red Cross or other voluntary aid personnel authorized in some cases to perform service.

In order that the division surgeon may perform his work efficiently the staff must keep him informed of the military situation. In emergencies the medical staff officer may have to act on his own responsibility in matters that pertain to his department, for the commander and his staff are in all probability engaged in other important affairs at such times.

Number and classification of wounded.—Five to 25 per cent of troops engaged become casualties in a day's fighting.

The following table gives a classification of the wounded among 20,000 men engaged, assuming 10 per cent casualties:

Per cent of struck		Per cent of engaged	Per cent of wounded	Number in 20,000	Number of wounded
20	Dead.....	2		400	
16	Walking wounded.....	1.6	20	320	320
28	Sitting wounded.....	2.8	35	560	560
36	Recumbent wounded.....	3.6	45	720	720
100	Total.....	10	100	2,000	1,600

Sixty to seventy-five per cent of wounded will eventually be returned to the front.

Seventy-five per cent of wounds are produced by artillery or grenades.

Twenty per cent are produced by small-arms bullets.

Four and one-half per cent are produced by gas.

One-half of 1 per cent are produced by cutting weapons.

Twenty per cent of wounds are of the head.

Ten per cent are of the chest.

Five per cent of the abdomen.

Sixty-five per cent are of the extremities (one-fourth of wounds of extremities are fractures).

Army Sanitary School No. 93.

SURGICAL TREATMENT IN DIAPHYSEAL FRACTURES

Translation of summary of a lecture by Medecin-Major Leriche

There are two kinds of diaphyseal fractures: First, those produced by a bullet at ordinary range and causing punctiform wounds of the skin; second, those produced by other projectiles (high-explosive shell, grenade, shrapnel, or torpedo, and deformed bullets or bullets at a short range).

The first mentioned usually run the same course as a simple fracture, and no operative prophylactic measures need be taken. The others, as a rule subjected to the ordinary causes

of infection of war wounds (foreign bodies, fragments of clothing lodged in the traumatized region), must be operated upon prophylactically. We are here only concerned with these latter.

Perfect knowledge of the site of the fracture and its anatomical pathology is necessary for the good result of the operation.

I. ANATOMICAL PATHOLOGY OF THE SITE OF FRACTURE

Follow the course of the projectile. After going through the flesh it may: First, fracture the bone and stop there without penetrating the medullary canal (this is the fracture by contact); second, pierce the bone, splintering it more or less (these are the fractures by penetration, the real war fractures).

They may be of different types—transverse fractures, fractures with large longitudinal bone fragments, comminuted fractures with destruction of a whole section of bone.

Constituent elements of fracture by penetration.—Bone fragments: They differ according to their periosteal covering. Some are loose and more or less out of place; others are detached from the bone but still adhere to the muscle; others adhere to the diaphysis by the periosteum.

Fissures.

Involvement of medullary canal and marrow—specially important.

Condition of diaphyseal extremities.

Topography.

II. EVOLUTION OF THE SITE OF A FRACTURE

Spontaneous repair is possible even with grave injuries, provided the wound runs an aseptic course. This is the case with fractures produced by a bullet at ordinary range and causes punctiform wounds of the skin. An aseptic course is seldom seen in fractures produced by artillery projectiles, for fragments of clothing are often blown in.

Consequences of infection in fractures: First, gangrene; second, osteomyelitis.

The infection of the bone acts on all the normal elements of repair. Violent infection brings on complete destruction and pseudarthrosis. If it is less violent the marrow of the bone is destroyed and the periosteum grows abnormally.

The result is a central cavity limited by infected walls of bone and filled with small fragments. It suppurates endlessly and forms fistulas.

Conclusion: A prophylactic operation is absolutely necessary. One must be able to follow *de visu* the whole course of the projectile so as to thoroughly remove all food for infectious microbes and foreign material.

III. DISINFECTION OF THE SITE OF FRACTURE

First. Excision of the devitalized tissue as usual, with a special care for the seat of the secondary traumatism caused by fragments of bone.

Second. Cleansing of the site of fracture.

In fracture by contact, removal of all free bone fragments must be followed by surgical sterilization of the spot where the shell was lodged. Verify the medullary canal if it has been opened by a fissure. This generally suffices.

In fractures by penetration it is necessary to have an extensive view of the medullary canal, for there lies the danger. One usually has to detach two, three, or more adherent bone fragments, trying in the meanwhile to preserve an intact bridge of bone on the opposite side. Any amount of bone fragments may be removed as long as the periosteum is preserved.

Definition of the periosteum.—The periosteum of the adult is not an anatomical entity but a physiological one, made of fibrous tissue (anatomical periosteum) and of the layer of bone to which it adheres. This layer of bone is indispensable to the production of bone. Therefore, the operation will only have a good result if, with the fibrous periosteum, a thin layer of bone from the diaphysis is preserved.

Method of removing bone fragments.—Fix each bone fragment with a "davies," detach the periosteum from the bone with a very sharp rugine of Ollier. Cleanse the medullary canal.

Suture.—It depends upon the state of the tissues. Fractures by contact may often be sutured primarily. For fractures by penetration, delayed primary suture or even secondary suture is preferable.

In some exceptional cases primary osteosynthesis is advisable.

NOTES ON A LECTURE ON THE SURGICAL TREATMENT OF DIAPHYSEAL FRACTURES BY PROFESSOR
LERICHE

There are two classes of compound fractures:

1. Those caused by a modern, undeformed bullet at ordinary range, with punctiform wounds of entrance and exit.
2. Those caused by shell fragments, grenade and bomb fragments, shrapnel, and deformed bullets. These often bring about an explosive effect.

There are also two principal methods of treatment.

1. The closed, where foreign bodies and devitalized tissue can be removed and there is sufficient skin left to cover the wound.
2. The open treatment.

Let us trace the irregular fragment from the moment of entrance. It tears through the skin with a piece of clothing in front of it; passes to the muscle, bursting its fibers, and tears its way through the periosteum, leaving it frayed. Here it may be arrested by bone the "fracture of arrest" or "fracture by contact." This fracture is apt to be some modification of the "butterfly" type. Or it may enter the bone, lodging in or near the medullary canal, or it may perforate the first two-thirds of the diameter and blow out the last third.

The fragments.—(1) The aperiosteal. These are stripped of their periosteum completely.

(2) The fragment detached from bone but still holding to a bit of periosteum.

(3) The fragment still covered by periosteum throughout most of its surface.

Long fissures in a diaphysis radiate in any direction from the point of impact of the missile and need no special remark. The dangerous element is the condition of the medullary substance where a hemorrhagic zone extends up and down the shaft, thus reducing local nutrition in the bone in the vicinity. The fragments are usually pointed and jagged and partially deprived of periosteum.

Thus there is an intramedullary chamber of bone fragments between two chambers of muscle attrition, the one on the far side often containing blownout fragments of bone which not only act as secondary missiles but are carriers of infection as tiny bits of clothing hang to them. The reason why these fractures are difficult of healing is on account of the foreign substance carried in, especially clothing.

In 75 per cent of untreated cases immediate infection of destroyed muscle takes place by anaerobes generally with but one result—gas gangrene. If the patient should escape this fate he gets an infection of bone which is a true osteomyelitis, like that of adolescence. It extends up the medullary canal by bits of clothing or bone entangling fibers of clothing which have been blown in tangentially. The ends of the fragments die when these thrombi are infected and the marrow disappears by this process for from 4 to 7 cm. This takes away the main source of nutrition for the bone and a source of its regeneration. The final result is that the medullary canal is closed above and below the fracture. The live periosteum regenerates bone, but the nourishment of this bone is insufficient and it readily falls a prey in its devitalized state to microorganisms. Hence, bone is constantly being formed and as rapidly degenerated—fistulas form and may persist for life with all of their attendant chronic toxemia, etc. Leriche recently saw a man whose uncured bone fistulas dated from a compound fracture of the Franco-Prussian War.

Treatment.—In punctiform bullet wounds of entrance and exit, treat aseptically and do not operate, as these usually heal.

You can expect to get a good result from a primary or primary delayed suture in the shell wound or shrapnel cases if the fracture is by contact; i. e., without penetration of the missile to the medullary canal. But when penetration has occurred, always get at and cautiously remove part of the marrow with a curette—to the point just beyond which contamination has taken place. In such cases expose the site of the fracture by a large incision—clean out well. The gravity of a fracture of war is in inverse ratio to the size of the pieces of bone. Remove all bone free of periosteum, but do not remove splinters—especially long ones—which are attached to periosteum, except to get at the medullary canal, which you must see. Inspect each splinter well. Pick out patiently all foreign bodies and carefully wipe out of the chamber all comminuted bone with gauze-covered cotton sponges on forceps soaked in neutral soap solution (q. v.). This will get rid of pieces of clothing of

minute size which can in no other way be got at. The objection to removing a splinter attached to periosteum to get at the medullary canal is that you may have to do so at the risk of pseudo-arthritis; but osteomyelitis is worse. It is, however, indeed better to leave a bridge of bone between the fractured ends if possible. If you do all of this well you may be able to close in from two to six days, but this depends on what the bacteriologist says.

Now, when you decide to leave splintered bone which is contaminated, it is well to first rongeur off the contaminated surface. Also, if you decide to leave only the periosteum see that it is the physiological and not merely the anatomical organ that you leave. In other words, by Leriche's sharp rugine you should leave a thin layer of bone adherent to this anatomical periosteum to furnish osteo-genetic centers for the new bone.

Fractures caused by contact with the missile are the only ones that can be primarily sutured, but those penetrating to the medullary canal or perforating the bone, never. In the latter case always do a delayed primary suture or "submit the wound to the Carrel-Dakin method." The reason for this is that we never can be sure of what we leave behind if we close.

Plating and suturing of bones at the time of receiving the injury is discouraged. It retards the formation of callus and it has not worked well. We may apparently get a fine result and in a month and a half there is suppuration. If plates are applied see that it shall be on the least injured side.

Neutral soap solution (Leriche).—Castile soap, 2 kg.; hot water, 10 l. Dissolve by 12-hour contact; filter through double thickness of gauze, add glycerine and 250 c. c. of 90 per cent alcohol; and neutralize with boric acid.

Army Sanitary School No. 94.

ORTHOPEDIC TREATMENT OF FRACTURES

By Professor Leriche

SUMMARY

(Translation)

A fracture is really cured when the fragments of the bone are joined by a healthy callus and united along the diaphyseal axis, so that the muscles may have their normal play. Correct orthopedic treatment will assure this result.

The treatment consists in reduction and immobility.

I. *Reduction.*—Is it necessary? Study of the principal displacements that may occur at the site of the fracture.

(1) Longitudinal displacement—overriding of fragments.

(2) Displacement of fragments in different axes—angular deformity.

(3) Lateral displacement of fragments.

(4) Circumferential displacement of fragments (by turning on the long axis)—decalage.

How can reduction be obtained? Different sorts of reduction.

Surgical reduction—osteosynthesis. Its advisability.

Sudden reduction; its advisability. Exceptional method which can only be used when powerful muscles will not interfere.

Progressive reduction by continuous extension; choice of methods. Two methods are used; those that (a) act on the muscle; (b) act on the bone.

(a) Act on the muscle: Traction with weights by means of glued bands, as to leg or forearm. Traction with Hennequin's band.

The best rule is the following: Make the extension in the axis of the superior fragment and in the position which best overcomes the resisting muscles.

(b) Act on the bones: Nail extension. Methods of Steinman, of Codivilla, Finocchietto's stirrup. Traction with springs; Delbet's appliance and those derived from it.

Choice of a method: One must be eclectic. As a general rule, begin by traction with weights, by means of glued bands, and later, during the convalescence, use the spring appliance.

II. *Immobility*.—Its aim—to avoid pain; to avoid movements which disseminate infection. Principles of immobility and means of realizing it:

(a) A. Bonnet's principles. Fix the articulation above and below the site of fracture; splint, paillon, plaster of Paris.

(b) Immobility of the seat of fracture exclusively; osteosynthesis, Delbet's appliance.

(c) Immobility through suspension which overcomes the muscles and only allows the limb to be moved passively; American appliances, Hodgen's and Blake's splints, etc.

Which method must one choose?

It all depends on the fracture and on the moment when the method is applied. At all times of its evolution a fracture must be immobilized, but there are different ways of doing:

(1) An immediate immobilization for the time being, to go from the dressing station to the surgical ambulance.

(2) Another immobilization after surgical intervention.

(3) An immobilization for evacuation in the hospital train.

(4) An immobilization for orthopedic convalescence.

Different appliances must be selected for these different periods of treatment, as well as for each limb.

NOTES FROM LECTURE ON ORTHOPEDIC PRINCIPLES IN THE TREATMENT OF FRACTURES BY
PROFESSOR LERICHE

No fracture can be said to be cured until:

(1) The fragments are united by healthy callus.

(2) The axis is such that a normal strain can be borne.

(3) The muscles in connection with the fractured bone have their normal play.

There are two periods in the orthopedic treatment of fractures: First that of reduction; second, that of immobilization.

The difference between fractures usually seen in civil practice and the fractures seen in war is that the latter are more irregular and occur in any part of the bone. The muscles are torn as well as their attachments. War fractures are also much easier to reduce and give better functional results when properly treated.

Fractures between the supinators and pronators of the forearm cause, if unreduced, a period of forced pronation incapable of supination.

In fractures of the femur in its upper portion there is abduction and flexion of the upper fragment, with a forward or backward tilt (depending on the force which produced it, site, etc.), and adduction of the lower fragment.

Method of reduction.—(1) Open method. This is mentioned only to condemn it.

(2) Manual reduction with subanesthesia. Also a bad method. The only good results obtained have been where the bone is covered merely by skin and tendons, as in the region of wrists and ankles, and even here it causes much damage to soft parts if successful, which it often is not. It is exceptional, indeed, if good results can be obtained.

(3) Continued traction. This is the best. It can be secured by:

(a) Adhesive strips fastened to the skin and drawn upon by weights.

(b) Clove hitch on foot or wrist attached to weights. The principle of traction is to pull in the axis of the upper fragment, as the lower fragment is the only one over which we can exercise control. Therefore always bring the lower fragment in line with the upper and do not attempt the reverse.

(c) By direct pull on the bone (method of Steinman). This is accomplished by a pin driven through the condyles, to the projecting portions of which the pull is applied by cords, weights, and pulleys—or by the tongs, whose sharp points grip the condyles. Be rather careful of this method as the bones have suffered a reduction in vitality by tearing of nutrient arteries, hematoma, molecular shock, etc., and osteitis of the cancellous portion of bone is easily set up. The Scandinavians and recently the Argentinians have utilized a metal stirrup for fractures of the lower extremity (Finochietto's stirrup) which is applied to the heel. The main trouble with it is that it pulls in one position only.

(d) Separation of metal plates fixed to the limb above and below the fracture through two lateral metal threaded bars and thumb screws. Delbet's apparatus separates these metal plates by a spring tending to force the fragments apart, thus producing extension and counterextension and allowing the patient to get about early. It is a good device but does

not allow circulation to be cut off, and watch for ulceration where the epiphysis acts as a point of support against which the pressure is exerted. With a well-applied Delbet a patient with a fracture of the thigh can get out of bed with extension apparatus applied after 30 days. Even when the case is a bad one, the patient can get out of bed in from 40 to 80 days, and do his daily duties with the Delbet. But this apparatus should not be applied before the thirtieth day after the fracture; that is to say, it is an apparatus for convalescence. You can use it in fractures of the tibia and both bones of the leg, but the knee should always be immobilized. If only one bone is broken, use plaster of Paris and after 20 to 25 days Delbet. As a matter of fact, Leriche states that it is possible to use a Delbet 3 to 5 days after the injury, but he personally prefers the bed for his cases. He can not see the reason for this festination about getting a man on his feet before union has at least begun to take place and condemns ambulatory treatment of this sort. When both bones are broken he prefers extension by the Hodgen's or by a straight pull on the leg.

He states that the best way to prevent infection in compound fractures is by immobilization, and the surest way of touching off an infection of this kind is to immobilize too soon. The old principle was to immobilize the joint above and below the fracture. This principle is being superseded by the modern one of fixing the fragments.

(e) Immobilization by suspension, in which the body weight furnishes the counter-extension. This is the principle of the Hodgen and annuls the vicious effect of the muscular pull. Gutter, wooden and wire splints are all bad for femur and should never be depended on. The Thomas splint is excellent, but it should be only used for transporting a patient from the field of battle to the hospital where he is to finally convalesce. Here replace by a Hodgen. This is the best treatment in general. The clove hitch used in applying the Thomas must be carefully watched, as he has seen it cut through and bare the tendons when too tight or left too long without substituting glued strips to side of leg. He prefers the anklet. He is partial to plaster of Paris casts where possible to use them, and states that he knows no better way of getting a fractured thigh to the rear from an evacuation hospital, when this has to be done from military necessity before the normal time for such a transfer, than by making a plaster cast of the anterior surface of the whole lower extremity and making this continuous with a half cast of the belly, with infolding toward the flanks. Set this in place over the fractured limb and bandage over all. Thus the limb is suspended on a cradle of gauze bandage with an anterior immobile cast from which the limb is suspended, as it were. Such patients travel easily and safely.

Special fractures.—Humerus. Transfer to the hospital from the field with arm in a Velpeau reinforced by common splints. When he arrives and it is found that the deltoid abducts the upper fragment to put up at right angles to the body. If fracture is below the insertion of the pectoralis and the upper fragment is not abducted then, put it up in simple splints. He says here one may use the old gutter splint that fixes the elbow and shoulder. The Delbet apparatus here is painful and, in fact, it is not necessary to have any counter-extension in the axilla—simply suspend a weight from the elbow—800 gm. to 1½ kg. is enough.

Forearm: Here the worst results of ignorance are seen. If it does not unite there is muscular interposition. Put up in full supination. You will always provide this way for some pronation when the man leaves for civil occupations.

Thigh: These form the most serious of the fractures of war. Never use a gutter splint for them. As stated, the Thomas for transportation and the Hodgen afterwards is the proper treatment. In high fractures of the femur, abduct and bring traction on both lower extremities even if only one femur is broken, as if you abduct and extend only one the patient will unconsciously shift his position to ease himself of the abduction and thus destroy the alignment.

Fracture of the leg: Gutter splints may be used here, as they fix the knee, but should be used only to bring him to the hospital. Keep such a man in bed and use Hodgen. Plaster of Paris is no mean splint if split longitudinally after setting. In securing gradually increasing weights to get continuous extension, he calls attention to the ingenious device of hanging a pail on the traction ropes and adding water, a little at a time, to point of overcoming muscular rigidity.

NOTE.—The following statistics were handed me by a well-known French surgeon.

Statistics on primary suture of compound fractures due to war wounds

Bone	Number of cases	Sutured	Cured
Humerus.....	75	23	15
Forearm.....	81	19	14
Femur.....	43	3	1
Leg.....	73	13	9

Army Sanitary School No. 95.

TRANSLATION OF SUMMARY OF A LECTURE ON FRESH ARTICULAR WOUNDS

By Medecin-Major Leriche

Wounds of the joints in war are more serious than articular wounds in time of peace for the following reasons:

1. The projectile carries with it a fragment of infected clothing.
2. There often results an injury of the bone. Under these circumstances grave infections occur which it is imperative to forestall, on account of the difficulty of contending with them later on. There is but one method—the operative prophylaxis of all articular wounds, save those produced by a long-distance rifle ball with punctiform wounds of the skin, experience having proved that they generally run an aseptic course.

The period during which this prophylactic surgery can be practiced is rather longer than for muscular wounds. The synovial liquid retards the infection and the period of incubation is hence prolonged.

The basis of the prophylactic treatment is the immediate extraction (24 hours) of the projectile and of all foreign substances after excision of the traumatized tissue. The technic must be based upon exact knowledge of the anatomical type of the wounds, and the function of the limb must be kept in mind.

The principal anatomical types are the following: The simple synovial wound without lodging of the projectile; the synovial wound with lodgment of projectile; the synovial wound with a wound of bone; the synovial wound with fracture; the epiphyseo-diaphyseal splintering.

What course should be followed in each of these different cases?

I. *The simple synovial wound.*—Treat the wound as a flesh wound; that is to say, by complete excision (synovial edges included) and primary suture.

II. *The synovial wound with lodgment of the projectile.*—Three different conditions may occur:

1. The projectile may be near the orifice of entrance. In this case, excision; arthrotomy extraction of the projectile; primary suture.

2. The projectile may be on the opposite side from the point of entrance. Let us take the knee joint as an instance. You will first perform lateral arthrotomy at the point nearest the projectile; then excise the wound of entrance down to the synovial membrane. If you fail, raise the patella and bend the knee, examining the articular cavity. After cleansing, suture both sides.

3. The projectile is loose in the articulation or behind it. After excision of the wound, you practice lateral arthrotomy, and, if insufficient, the U-shaped arthrotomy (exceptional method). After extraction of the projectile and articular cleansing, suture the synovial membrane and the patella tendon very carefully, as well as the fibrous layers and the skin.

When the projectile is distinctly lodged at the back of the crucia ligaments, an incision in the popliteal region is preferable.

III. *The synovial wound with bone lesion.*—Practice the excision and arthrotomy as before stated. Respecting the bone lesion it is to be remembered:

1. That a wounded cartilage does not proliferate to repair a breach.
2. That a bone cavity does not fill by proliferation of its walls.

3. That a certain limit can not be passed if the articular function is to be preserved. Therefore, a small fragment of cartilage or bone can be removed, but if the cartilaginous wound is large, or situated in a groove, the articular function will be reduced.

If the removal of the projectile obliged you to create a cavity in the bone, the walls will have to be smoothed; if this is impossible, the cavity should be filled with a plastic mixture (bismuth or iodoform paste), or with a fat or muscle graft.

If the ablation of the lesions derange the articular function, the final result will prove unsatisfactory and primary resection is preferable. For example, if you remove a condyle of the femur, the result will be lateral dislocation of the knee.

IV. *The synovial wound with fracture.*—There are two methods to follow: (1) The removal of all loose fragments, followed by suture; (2) classic resection. Many surgeons think that the removal of all loose fragments should be done without troubling about functional result, but the results of resection are excellent, if practiced after the method of Ollier, which is based upon two fundamental principles:

First principle: The periosteum properly preserved produces bone.

Second principle: The capsule, the ligaments, and periarticular muscles mold the fresh bone and by their united movements create a new articulation.

To obtain this result, the surgeon must respect all tendons, muscles, and motor nerves. The periosteum must be kept attached to the capsule and ligaments; this will be possible by making use of a very sharp rugine.

Wonderful functional results have been obtained by surgeons who have faithfully followed Ollier's method—subperiosteal and subcapsular operations.

V. *Epiphyso-diaphyseal splintering.*—Extensive lesions may lead to important eliminations of tissue: One must learn to keep only the indispensable functional elements. Therefore, the technic will be different for an upper and lower limb.

The essential function of the lower limb being the support of the body, it is preferable to sacrifice bone, in order to obtain a better support and at the same time a painless one (for example; knee, foot).

The essential function of the upper limb being prehension, you must never amputate, what ever the anatomical condition may be; if you can preserve prehension, two fingers suffice.

NOTES ON LECTURE

Before this war these wounds were considered especially serious, particularly in agricultural regions, where bad infections took place, resulting in suppurative arthritis, the bogey of all military surgeons. This led to amputations. In fact, this outcome was so frequent that war wounds of this character brought about a policy of amputating above the injured joint immediately, without waiting for infection. The small punctiform openings into joints were considered to be favorable cases.

The reason why these joints were serious was that (1) the clothing was carried in with the projectile, and (2) the bone was injured as well as the joint, which brought about not only an arthritis but an osteo-arthritis.

Now we know that the synovial fluid has a deterrent effect on the growth of bacteria and that the interior of a joint is less liable to infection than the bone or the soft parts surrounding it. Hence to prevent these infections it is merely necessary to remove all foreign bodies and to accomplish a surgical prophylactic operation with removal of dead and devitalized tissue to avoid infection of the joint. In the old days we used a tampon in simple synovial wounds and drained those that were accompanied by fracture of the epiphysis. But now we do a primary excision and suture the joint first of all, following immediately, or a little later, when bacteriological examination has demonstrated that such closure is safe, by suture of the soft parts and skin. All work in a joint must be done gently, and extreme care must be taken that nothing of the projectile or clothing is left in the joint. As a matter of fact, Leriche indicates that one can leave a wound joint longer without operation than one can leave with safety a wound of soft parts and mentions the fact that he has gotten excellent results from primary and primary retarded sutures up to 24 hours after the injury. In suturing up synovial sacs, great care must be taken to secure absolute hemostasis, with ligation of all arteries. If not, there is danger of getting a bloody effusion into the joint which will furnish a favorable

medium for microbes always on hand to ruin one's work. As to the question of early mobilization of joints, Leriche states that Wilhelm's idea of mobilizing a joint early is nothing new. Cases of laparotomy have been early mobilized, but he says that he prefers to immobilize joints for 10 to 12 days and then begin movement. In this way he believes that one gets better results.

It is, above all things, necessary to preserve the statics of the joints, particularly in those of the lower extremity; that is, the laws of physics should be preserved. Also, in a knee, one can not make cartilage rub against bony tissues. He does not curet a damaged bone, but cuts away the contaminated portion just as is done in a primary suture of soft parts. When one does this the bacteriologist should at the same time make cultures by inoculating culture tubes with pieces of clothing, bone, and a few drops of bloody fluid. It was interesting in several cases to find that of the three elements mentioned the bone turned out to be the most heavily infected with anaerobes. It is necessary to make a distinction between wounds of bone and fractures, which latter should be interpreted to mean a solution of the continuity of bone. In a bone wound, where the projectile must be removed and the surgical sterilization of the cavity made, it may be possible to suppress the resulting cavity by smoothing away the sides enough to make a dimple, even smoothing it off flat. On the other hand, it is possible to fill up the cavity by Beck's paste if the cavity is sterile, or a small graft of fat or muscle can be used for this purpose, and this muscle graft will also act as a hemostatic. But one can not fill up the cavity of the epiphysis inside of the joint; that is to say, a cavity in the joint surfaces. Nor can one fill it if the cavity is very large. If the whole articular surface of the condyle is affected, it has to be removed. We must preserve the mechanism of the joint at all costs. For instance, if 40 kg. of weight is distributed equally between two condyles, 20 kg. on each condyle, the removal of one or the other will cause a dislocation, with a resulting genu varum or valgum. The same is true, but to a less extent, of the elbow. In these knee cases with hopeless destruction of essential parts of the joint, complete resection is advisable because, although a stiff joint results, the weight-bearing surfaces are not dislocated; the patient walks much better than he would with a weak joint, as the hip and ankle make up by increased motion for some of the stiffness of the knee. To this is opposed the opinion of some surgeons, who say that only a removal of the loose bone should be done, but Leriche believes that we should only remove bone in this manner when there is no resulting disturbance of the statics of the joint. That is to say, one can take out the head of the radius without disturbing the statics of the elbow joint or the condyle of the humerus, or the head of the astragalus, but not if the neck of the astragalus is affected, as function would be thereby disturbed; it would be better in the latter case to do an astragalectomy. Moreay resected joints in the first revolution and he had good results. Ollier shows that to get successful resections one must keep the periosteum with a thin bony layer adherent thereto to produce osteogenesis and also preserve with great care and without mutilation the capsule, ligaments, and periarticular muscles and tendons in order that they may mold the oncoming new bone and thus produce a functional new joint. Emphasis must be laid upon the fact that the incision must not destroy any tendons, muscles, or nerves over a joint, and the insertion of muscles must be retained in the capsule and ligaments, together with an ample blood supply. In order to accomplish this successfully we must use a very sharp rugine, and the best is the shovel rugine which he uses. This not only preserves the periosteum but conserves the continuity of periosteum with the capsule and all of its ligaments and tendons, which is just as important a part of the operation as any other.

The functional result in joint operations is much more important than the anatomical one. The upper and lower limbs have different functions; the leg is made to stand on, to walk on, and even at the expense of a stiff knee one should aim to get a painless, solid, weight-supporting limb. Do not resect a tarsus when a painful plastic scar is the result. It is better in such a case to do a Lisfranc operation. Use the heel to walk on if resection makes a painful stump. It is well to amputate above the knee if a resection is going to give a bad functional result. So much for the lower extremity.

The arm, on the other hand, is a prehensile organ and as long as we can save two fingers we should preserve it, even at the expense of a flail joint. It would be well in principle never to amputate if two fingers can be saved.

* * * * *

Comments on certain joints.—It is always better to do a bilateral arthrotomy than to cut the patellar tendon. If a resection of the knee joint is done, nail the femur to the tibia with an iron staple. Put up in plaster and do not allow walking for three months.

In destruction of shoulder joint the head may be resected, leaving the physiological periosteum. In this case the reproduction of bone is always sufficient for function. The position of immobilization is at right angles to the body with the forearm flexed.

If the projectile has lodged in the head of the humerus, passing through the cartilage, do a resection and sew up in 48 hours.

The reproduction of bone is so rapid in some cases that the callus must be even restrained by X rays to avoid permanently locking the joint.

Army Sanitary School No. 96.

DEMONSTRATIONS ON BONE AND JOINT INJURIES

By Professor Leriche, in his operating group, H. O. E.

The seance consisted of a preliminary talk on the general subject, illustrated by X-ray plates and stereoscopic X-ray pictures, and afterward a demonstration of skeletal specimens, and of patients themselves.

THE SHOULDER JOINT

It is always desirable to remove a lodged missile from the cancellous portion of the bone and the layer of bone in contact with it, filling in with a graft. When the whole joint is shattered, however, a formal resection is necessary. In one case shown he resected the head of the humerus, the head of the acromion process, and the outer end of the clavicle and still obtained a suitable joint with some movement. In such cases he removes all the fragments of bone and debris by subperiosteal resection, taking great care to preserve the continuity of the capsule and the periosteum without tearing. The end of the humerus is immobilized in the cavity. Five cases were shown with apparently good results.

In the first case shown the arm can be abducted to a horizontal level. He states that it is always better in such cases to do a primary retarded suture and to leave the wound open at least 48 hours, being guided by bacteriological cultures until safe to close. In the case in point, healing occurred in a month from the time the man was wounded. He was then given two months' leave of absence and was back to duty in three months. The charts of these cases show a normal course. You can generally figure on a month for healing in primitive suture and one to two months for complete convalescence. He states that a shattered joint that has been resected should never be moved for a month. In order to insure the immobilization of the lower fragment in the glenoid cavity, the arm is fixed to the side instead of at right angles from the body. (The cases shown do not give as great a range of motion as those we have seen that were ankylosed at right angles to the body. He seems to be more concerned about getting immobility and a solid ankylosis than movement as he fears a flail joint much more.)

THE ELBOW JOINT

He says that operations on the elbow joint are on the same principle as those of the shoulder. The first thing necessary is to obtain a minute radiosopic examination. He employs the scheme of plotting out areas, charted on a radiograph of a normal joint—that is to say, he charts the elbow joint as a map in order to localize the fragment. It is possible to remove certain parts of the joint without compromising its statics, such as the external condyle. The coronoid process of the ulna can also be excised without destroying the function of the joint, although whenever it is so excised there is apt to be luxation. He showed pictures of men with complete excision of these portions who had return of function.

The Interallied Congress has pronounced against a formal resection and states that we should only take out the free splinters, but he believes they have gone too far in pronouncing against formal resections in a general way. Leriche states that the removal of splinters

should be done only when it does not interfere with the mechanism of the joint, but that when that mechanism is seriously disturbed resection should be done. He has, however, seen results of resection that were worse than good ankylosis.

Can mobility and solidity of the elbow joint be obtained?

The answer to this is, Yes; if the periosteum can be kept intact and continuous with the capsule.

When the physiological periosteum and the ligaments are retained, a mass of new bone is formed so rapidly that the callus is apt to be excessive. The joint must be moved by the patient himself so as to take up early the normal function and thus bring about a reforming of the joint. Often in spite of this there is so much new bone that ankylosis may occur, even after complete function had apparently been restored. He states that complete resection of the elbow joint gave him in many cases, after six months or a year, perfect pronation, supination, and flexion, with marked solidity and mobility. Leriche prefers to keep these cases under his own supervision and not at a general physiotherapeutic hospital. He begins active movement 8 to 10 days after the operation, teaching the patient to use his own muscles, so that in 10 to 20 days he can hold his arm up without assistance. Massage is also given. At the end of two months there may be a period of immobility which makes it look as though the joint was going to ankylose, but by the end of six months things have loosened up and the final result is good. He emphasized the necessity for personal attention to these cases.

After resection of the joint by Leriche's technique, an anatomical restitution is gradually brought about, even to the formation of cartilage. If Ollier's method is strictly followed, the olecranon is reformed, but it may be two or three years before it unites with the main bone. This regeneration comes from a center in the biceps tendon. When the joint injury is confined to those parts which are not of functional value, such as the head of the radius, the head of the olecranon, and the external condyle of the humerus, we can remove such parts without fear of compromising the joint because they are of no functional value. But when the trochlear surfaces of the humerus or ulna are badly involved, a primary resection must be done. The arm should be put up in forced flexion and supination. Do not fear ankylosis; the thing to fear is a flail joint, and this does not occur in Leriche's practice. Never cut the triceps tendon, and use your rugine carefully to leave the outer shell of the bone in contact with the periosteum. It is of greatest importance to preserve the soft parts around the joint; more important than the conservation of the bony parts of the joint. Do not try to sew up at the completion of this operation. He does not use the Carrel-Dakin method, because he says it has no effect on the streptococcus, which is the only thing that he fears. Active motion should be commenced on the fourteenth day and continued to about the sixtieth.

X-ray pictures showed the regeneration of bone which had taken place. He says we should not be alarmed at the irregularity of the outline because these irregularities are all filled in with cartilaginous tissue, and the function of the joint is perfectly easy.

In his demonstration of elbow joints he stated that he does not believe in complete excision if it is possible to avoid it. He begins passive motion in 8 to 10 days and after 14 days the patient moves the joint himself to mold it. Only after six months it can be determined what amount of function the joint will have. He emphasized the necessity for a very clear conception of the anatomy of the part.

Incidentally in the course of this lecture Professor Leriche referred to attendant wounds of vessels and stated that no suture of arteries is ever done at the extreme front. The best thing is to put hemostats on firmly, note the same on the man's card, place on it a voluminous dressing, and send him in.

DEMONSTRATION OF PATIENTS

Case 1.—Reproduction of bone abundant, as shown by pictures. It was over-abundant and at the present time it has gone back to relative ankylosis, but movement will return. This should be looked up as a favorable thing, as excessive mobility is what we fear. He said this very man had a considerable amount of motion 2 months and 10 days ago, much more than he has now.

Case 2.—This was a shell wound of the elbow joint. Necessarily there has been a great deal of excision of the bone; nevertheless you can feel the bone which has been reproduced, and the sides have been filled up subperiosteally. He calls attention in this case to the necessity of preserving the triceps tendon which he considers important as it contains an osteogenetic center.

Case 3.—Wound of the elbow joint, received 15 days ago. We were unable to close this wound because the bacteriologist always reported the presence of streptococcus. The reason for this was that they didn't get hold of the case until the wound had become badly infected from handling and rehandling. These joints should be kept absolutely immobilized (he is always afraid of not getting a solid joint). After 14 days he wants the patient to move his arm himself. Movement need not be very extended as retarded movements are better than extended ones. They move the joint a little, every two days at first, then every day. He says the matter is very much simpler when you do not have infection and the wound is closed. The indispensable part of any resection is that the continuity of the periosteum (with its osteogenetic layer of bone) and its capsule be preserved.

DEMONSTRATION OF RADIOGRAPHS

These were all cases with complete resection of the elbow joints. He keeps all his patients here because if they are sent to other centers these joints are liable to be overtaxed. They all showed a considerable amount of regeneration of bone. He showed one man bearing a weight of 150 kg. from the injured arm; in this case there had been a complete resection of the elbow joint. He states that at the end of two months, when the motion of the joint becomes retarded from the overproduction of bone, he immobilizes it a while. It is at the end of six months that you will generally be able to see what the joint is going to be. He emphasized again that those are the injuries which require the constant, unremitting, personal attention of the surgeon. If that is not given, no amount of good operating or massage will prevent disaster.

THE KNEE

When the knee joint is opened it is not usually necessary to cut the patellar tendon, except in the very few cases where the missile has been lost in the wounded joint behind the crucial ligaments.

When the joint is resected it is necessary to fasten the tibia to the femur by an iron staple to secure immobility.

Case 1.—A piece of shell had lodged in the external condyle. The missile and the surrounding bone was removed, together with pieces of clothing. The wound was left open and three cultures were made—one from the cloth, one from the blood, and one from the bone. The cloth showed a few anaerobes, the bone many, and the blood was sterile. He left the wound open and mobilized the limb. After the fourth day he closed in two layers. The result showed both stability and mobility of the joint. This man received antitetanic serum before he reached the H. O. E. and again on the seventh and twentieth days.

Case 2.—This was a resection of the knee joint and a primary retarded suture, but in this case it was necessary to remove the silkworm gut sutures after nine days on account of infection.

When the iron staple is driven into the femur and tibia it is allowed to stay and the man is not allowed to walk for three months. If you do not nail these bones together there is a backward displacement of the tibia.

Case 3.—Previously sutured, but had become infected from the skin. The knee was opened and Carrel-Dakin solution used without result, except that a chronic synovitis was produced. Recovery will take place in time, with ankylosis.

THE HIP

Case 1.—Excision of the trochanter, neck and head of the femur by Ollier's method. The bone has regenerated enough to promise a good serviceable joint for weight bearing, if the man lives, which I doubt. In this case the joint cavity had to be drained and the cotyloid ligament removed, because if it is left it will die and be a source of constant suppuration. He demonstrated in this case the anterior plaster splints for moving patients with fracture of femur, referred to as ligature.

Gunshot wounds of the thigh are usually fatal. That's why he has no more to show.

BONES OF THE FEET

We should remember that the foot has three points of support, and the future of a member depends on the preservation of those points.

The os calcis: Fractures of this bone are common, but when the head is fractured, not only it but the whole astragalus must be removed.

It must be remembered that the periosteum of the bones of the foot has little power of regeneration; consequently you can not depend upon it. Make all incisions in the foot longitudinally and preserve all muscles and fascial attachments.

When Leriche removes the astragalus he dresses the wound about once every 30 days, because in this case immobility is an absolute necessity, and a moderate temperature for the first three days does not worry him. Clawfoot is due to contracture of the planter fascia, and is a common danger in wounds of the foot. It can be overcome by hyperextension of the toes when the foot is immobilized.

If it becomes necessary to remove the scaphoid or any two of the cuneiform, either a Chopart or a Lisfranc is done, as if the scaphoid alone is removed the foot turns inward, with loss of function. If the external cuneiform is removed the foot turns outward and function is lost, with painful scars as a result. The same thing applies with the metatarsals if more than one is removed. When you remove the lower ends of the tibia and fibula always remove the astragalus so as not to leave the square ends of the tibia and fibula in contact with the articular surface of the astragalus. As a matter of fact, if you do it will slide off the articulation and give deformity and pain. The bones of the anterior line of the tarsus may be removed and still give a useful foot except for ankylosis.

REMARKS ON PRIMARY SUTURE

This case had a retarded primary suture. His wound was received the other day and he was admitted in 14 hours. The wound was of the left shoulder and scapula, and was a large one. It was fully excised. The man shows some temperature, but Professor Leriche states that temperature up to 38° for the first day or two is not important; spontaneous pain in the wound is much more important. A slightly suspicious spot in the interior of the wound at the time of operation caused him not to complete the closure at that time. Another wound was closed systematically.

Case 2.—A large wound of the left gluteal region. This case shows an iodine burn due to the presence of a hematoma which predisposes to iodine burns, but it was closed nevertheless by primary suture.

Case 3.—This man came in 1½ months ago. The musculospiral was cut in two places and he grafted it with the nerve of a young rabbit. The patient is commencing to get nerve restoration.

The following cases were shown just before they were discharged on leave previous to joining their organizations:

Case 1.—Fracture of ulna. Primary suture. Returned to duty with excellent results.

Case 2.—Fracture of right femur—primary suture.

Case 3.—Fracture of the tibia. Removal of two splinters of bone.

Case 4.—Fracture of right radius and right tibia—primary suture.

Case 5.—Fracture of left femur and humerus.

Case 6.—Fracture of first phalanx, with involvement of joint.

Case 7.—Fracture of right femur—primary suture.

Case 8.—Fracture of right tibia near the patellar tendon—primary suture.

Case 9.—Fracture of the left tibia, with division of the posterior tibial artery—delayed primary suture.

Case 10.—Fracture of right shoulder joint.

Case 11.—Fracture of outer third of clavicle.

Case 12.—Piece of shell in the head of the radius in 1915. Returned for operation in 1917. Projectile removed and anaerobic bacteria were found alive in the bone.

Case 13.—Fracture of left elbow.

Army Sanitary School No. 97.

CLINICAL DEMONSTRATIONS, FOURTH SESSION, ARMY SANITARY SCHOOL

By Professor Lemaitre, at his operating group

His boxes of ordinary instruments for operations on the soft parts contain: 4 towel clips; 6 Péan's forceps; 6 Kocher forceps; 1 rugine; 1 eurette; 2 retractors; 1 pedicle forceps; 2 rat-tooth thumb forceps; and 1 director.

There are 3 of these boxes per table, 1 in the sterilizer, 1 being prepared, and 1 in use.

In addition each table had a separate one for Reverdin needles, another for scalpels, another for 6 pairs of blunt, straight scissors, another for 4 pairs of curved scissors.

He gave us quite a talk on the care of instruments and stated that he sterilizes his at 50° in a hot-air sterilizer for from 25 to 30 minutes; that the instruments must be perfectly clean, and that a coffee spoonful (5 gm.) of formaldehyde powder is placed in the bottom of the pan, covered over with gauze, upon which rest the instruments to be sterilized. It takes one attendant alone to look out for these sterilizers, and he devotes all of his time to it. Trioxymethylene is precipitated on the knives if overheating occurs. You need one hot-air sterilizer per two tables.

Although there is a central sterilizing plant at this hospital, Lemaitre prefers to sterilize his own sponges, which he makes of cotton covered with gauze, and they are small. He also sterilizes his own gloves and all instruments and his own operating gown, so that he can always be sure to have them. The water used in the operating group is sterilized outside. There was an ingenious pedal arrangement for washing the hands, the right foot turning on the soap solution, the left foot the water. Wash in sterilized water and soap, then alcohol, then dry with sterile towel; then put on gloves. Lemaitre states that he is not very fond of operating under X rays. He generally makes his assistant use the bonnet or has the radiologist in the room. He says there is too much tendency, operating under X rays, for a man to go straight to the projectile, instead of getting to it through the tract, with proper excision of the devitalized parts of the wound en route.

He prefers not to give ether by the closed method, as it cyanoses the patient, and thus influences the color of muscles to an extent as to confuse him in judging whether a muscle is alive or not. For these reasons he prefers the open method.

He does not believe that teams should operate longer than eight hours. During the first four hours they do excellent work, but he says he would not care to be operated on by the same team after that time.

Lemaitre says that he believes that the primary suture is going to reduce considerably the neurites of war.

He does not believe in antiseptics, but he does believe in early mobilization of joints.

Professor Lemaitre has in his operating group 8 tables—2 for fractures, 2 for injuries of the splanchnic system, and 4 for wounds of soft parts. Four are in one operating room and the others are in two's. Eight teams serve those tables in eight-hour shifts, and patients are prepared in a preoperating room with two preoperating tables to each operating table. These preoperating tables are simply litters with removable horizontal boards in the place of canvas and are placed on trestles. He always has the radiologist mark the position of the missile with nitrate of silver. Lemaitre considers that one X ray and fluoroscopic table will supply the data for three operating tables.

Professor Lemaitre took the class all through his wards, which were pretty nearly emptied of their patients in expectation of a big offensive. He nevertheless showed us 10 cases which demonstrated most of the phases in the technic of the primary suture. The first case was particularly interesting, inasmuch as it was a wound which was continually being opened and which nevertheless healed without suppuration.

Case I.—Multiple wounds with great shock—one penetrating the forearm, a wound transfixing the left thigh, a wound penetrating the right leg, and one in the axilla. In the last the projectile had entered the posterior fold of the axilla and had lodged in the pectoral muscles. It was removed by an incision from the front, débridement was done to the brachial plexus from front and rear openings, and the wound was closed. In a short while, however, there were evidences of injury to the median nerve and an incision was made into

the axilla with a view of examining the plexus at that point. Here the injury was discovered, remedied, and the wound closed; but on the eleventh day attention was again attracted to the wound by pain and a large hematoma near the wound in the rear. This was now opened and the posterior scapula artery was found bleeding. This was tied, the hematoma removed, the wound was closed, and the healing was complete by first intention.

Case II.—Demonstrated excellent results which might be obtained in dirty wounds involving the tendons of the hand. In this case the wound was caused by a shell which had destroyed the second and third metacarpal bones, severing the extensor tendons of the fingers corresponding. It was a primary delayed suture on account of shock; but the bones were removed and the tendons sutured; after 15 days this man had movement in his fingers.

Look out for spontaneous pain 8 to 10 hours after operation. In this case examine your wound right away.

Case III.—Wound of right ankle involving the outer malleolus, with lodging of projectile. Primary suture in eight hours and good result.

Case IV.—Three wounds on left thigh of leg due to grenade; primary suture and perfect result.

Case V.—Wound of right thigh; primary suture; infected; has to have secondary.

Case VI.—Extensive wound of the left thigh, perforating; secondary suture; result good.

Case VII.—Wound of right thigh; clothing carried in; gas bacillus. Immediate suture gave perfect result.

Case VIII.—Missile entered the back of the inner malleolus, cutting the nerve; primitive suture; perfect result.

Case IX.—Tangential wounds of the cranium in which the man was trephined to determine his actual condition. The dura was not injured and the wound healed by first intention.

Case X.—This was a perforating wound of the left thigh in which primitive suture was done, followed by abscess. This was due to the fact that the bacteriologist reported streptococcus and the wound was not opened in time.

Case XI.—This man came in seven hours after being wounded. One of the missiles had produced a star-shaped fracture in the trochanter. A primitive suture was done but a drain left.

CLINICAL DEMONSTRATIONS, FOURTH SESSION, ARMY SANITARY SCHOOL, BY PROFESSOR LERICHE, AT HIS OPERATING GROUP

A true bone injury is always much worse than the X-ray picture demonstrates.

He does not advise the curetting of bone for slight wounds, but uses the bone scissors. It is better to resect than to attempt to close a cavity in a joint surface where the pressure will afterwards fall.

In the after treatment of joints, make your patient use his own muscles; never permit passive motion.

After primary closure of joints you are apt to have an excess of synovial fluid. If there is much fluid, aspirate.

McEwen's scissors are used for trimming off infected splinters. If it is merely a slight abrasion of the bone it may be curetted and the wound sewn up. One of the greatest difficulties with a wound of bone within a joint is that these bones bleed a great deal.

Intestinal bacteria are the chief cause of infection in war wounds. Clothing is carried right into the spongy parts of bone. He demonstrated this to us in some pathologic specimens. Hence, the necessity for removing the contaminated parts of bone inasmuch as we have seen small pieces buried deep in the cancellous tissue. There is another point of view to be considered still, in the small macroscopic pieces of clothing, or exceedingly minute pieces that would escape ordinary detection with the naked eye. These are foci for future gas gangrene or tetanus, given a cause that will awake them from their latency.

When you are told that bacteria begin to multiply in a fresh wound after a certain time, remember that this time is relative. In his experience no considerable multiplication takes place until after the twelfth hour, but some go 18 to 24 hours without marked increase.

Leriche makes a great point of using retractors to expose a wound well, especially when one looks into a joint to search for foreign bodies. Wounds of bone are not often revealed by the radiologist, so when you open up the joint you can expect to find anything from a fracture to a small chipping of bone or cartilage. If there is a wound of bone and cartilage on an articular surface sufficiently extensive to compromise a condyle, then consider a resection. If an important condyle, as in a knee, is condemned by the injury to the bone and articular surface, rather than take it away, which would destroy the statics of the joint, resect the joint and fix the lower end of the femur into the head of the tibia by iron staples.

In the fifth class of joint wounds, in which the epiphysis and diaphysis are fractured, it may be possible that the joint has not been entered at all by the missile; in such a case do not open the joint but treat the wound of entrance.

Many surgeons believe that resections give bad results, but the reason for the bad results they quote is because bad methods are employed. His method of doing a resection of the elbow joint is to merely remove the cartilage and absolutely free fragments of bone; all other fragments are left. The synovial membrane is closed and the muscles and skin later by retarded primary suture. He immobilizes 10 to 14 days and then makes the patient move his own joint, movement which is kept up until after the second month. At this time there seems to be a retrograde process, which continues until after the sixth month. At the beginning of this retrograde process it is well to immobilize the joint for a while. It comes from overproduction of bone.

CASES

He showed a case with complete removal of the head, neck, and great trochanter of the left femur, seen here in January at the second session of this school. At that time it looked as if he were going to die. Ollier's subperiosteal method was here employed and there has been considerable regeneration, as can be seen from the X-ray plate; the man is walking with a cane and is pretty spry and healthy looking.

Ninety-eight per cent of long-distance bullets cause wounds which heal by first intention.

Army Sanitary School No. 98.

MALINGERING

By Maj. John H. W. Rhein

The importance of the study of malingering will be at once apparent when it is realized that it is recognized as one of the most active factors contributing to the depletion of forces and to inefficiency in war (Munson).

It is connected with the administration of the sanitary service in all its problems—primarily, as Munson has shown, in relation to insuring the retention of effectives, and relieving the fighting forces of noneffectives.

Munson in his paper shows how easy it is for a malinger, first, to get on sick report, then to a base hospital, thus separating himself from his regiment and, if transferred to the rear, from his division. Each transfer strengthens his position, as passing through a number of medical officers without a positive diagnosis being made, he has practically obtained repeated and official confirmation of his claims. Then he comes in contact with civilian relief societies who are swayed by the sentimental, and this adds to the apparent plausibility of his allegations. The next move is to secure a sick furlough, his last object to be accomplished, the "escape from any direct military oversight and control whatsoever." Finally, the last step is to get a discharge for disability with a pension, which at this stage is often not difficult with the long hospital records to show to the Government agent who is sent to examine him.

The study of malingering dates from time immemorial. In fact we may recognize in the mimicry or protective disguise of vegetables, plants and seeds, insects and birds, and animal life an analogy, and which Jones and Llewellyn have described as a reversion to a primitive biologic instinct.

The partridge trails a wing to deceive the approaching hound, and it is well known that certain animals feign death to escape danger. In all times, and among all social grades, instances of malingering or dissimulation are on record.

In biblical history you are all familiar with the acts of David who feigned senile dementia to evade Achish, King of Gath. "He scrabbled upon the gates and let his spittal fall from his beard."

Ulysses, in order to avoid leaving the arms of his bride, pretended to be insane. He harnessed an ox and an ass to a plow and scattered salt as though it were seed. His deception was unearthed with the soil he plowed, when Palamedes placed his son Telemachus in the path of the plow.

Self-mutilation was practiced by Pisistratus for the purpose of achieving a military end. He claimed that his self-inflicted wounds were received from the enemy outside the city gates of Athens and as a result of this deception he was given a bodyguard which he employed as a nucleus for developing troops with which he afterwards overcame the city.

Feigning illness was employed by the Greeks for the purpose of avoiding military duty, the penalty for which was death. The practice also existed with the ancient Romans, who cut off their fingers and thumbs to evade military service.

Aristophanes, so Plato informs us, feigned an attack of illness to escape replying to embarrassing questions, and the pupils of Plato padded their shoulders in imitation of his deformity, while Aristotle's pupils affected the lisp of their master.

In the sixteenth century the feigning of deafness, dumbness, and blindness by beggars was reported by Ambroise Paré.

In the medical literature, while Hippocrates mentions it, it was Galen who perhaps was the first to describe with care this condition. Its significance was recognized in the eighteenth century from a medico-legal standpoint, and the British military surgeons were familiar with its importance in the same century. In more recent years we find references to it in the works of Sir John Collie, who discussed the subject in relation to injury and McKendrick in relation to disease.

By the term pure malingering is meant the simulation of a disease which does not actually exist; the willful contracting of a disease by artificial means, or false allegations of symptoms not observed by the examiner. But there should be included in this discussion other conditions related and of much more frequent occurrence, for true or pure malingering, it is generally conceded, is of rare occurrence.

Allied to malingering and really of greater importance is simulation which includes the conscious and intentional exaggeration or prolongation of a real disorder (Ballet). This is by far the most common form of malingering. Roussy and Lhermitte subdivide malingering into that by (1) assumption, illustrations of which are the jaundice produced by pierie acid, dermatitis by vesicants and conjunctivitis by tobacco; (2) by invention, in which an objective disease, an abnormal attitude, a motor or trophic nervous complaint is created or there is complaint of subjective conditions such as pain; (3) by exaggeration, in which actual disorders, organic or functional, are elaborated; and, finally, (4) by prolongation, the persistence of conditions such as attitudes or symptoms the results of actual lesion after these are cured. The term malingering by fixation, for the latter two divisions, has been suggested by Sicard and Cantalaube. It has been aptly said by Joanny and Roux that malingering is intentional simulation, in contradistinction to hysteria, which is unconscious simulation.

Some observers have incorrectly believed that any morbid phenomenon in the realm of the nervous system when not organic signifies malingering. The importance of this phase of the discussion will become more apparent when it is realized that it is generally conceded that simulation can give rise to any condition which is seen in hysteria, for, as Babinski says, "Anything which is impossible for simulation is also impossible for hysteria."

It seems to be a matter of common experience that pure malingering is rare. Oppenheim found only 4 per cent among his cases of traumatic neuroses, and he believed that those who found it a common manifestation were lacking in knowledge of nervous diseases. Apropos of this, Kuhn stated that "the number of feigned lunatics seen by a physician is usually in inverse ratio to his psychiatric knowledge."

MOTIVES

Primarily self-preservation is the motive for malingering in war times. A study of malingering in the American drafted Army by Pearce Bailey showed that the motives of malingering are (1) to evade service; (2) to avoid duty; (3) to obtain service; (4) to obtain exemption from punishment; and (5) to obtain transfers.

(1) Malingering was not frequently seen in the National Guard nor in the Regular Army, in which enlistment was voluntary, and was more frequent in the drafted Army for obvious reasons.

The surgeon of the Columbus Barracks recruit depot classified the malingerers into, (a) those who applied honestly, primarily, but subsequently changing their minds either from homesickness or a belief that service might present hardships that they did not anticipate, and in which the deception was crude and easily detected; (b) and those applying with the deliberate purpose of being physically rejected. They thus could pose as decent men when they were really slackers and could use this to evade subsequent draft by showing physical disability. Such men are selfish and lacking in physical courage.

(2) Drug addicts and fake drug users employ this means to avoid duty.

(3) To obtain service, men falsify their ages. Epileptics, chronic alcoholics, and drug users conceal their disability in the hope of obtaining a livelihood which they can not obtain outside of the service.

(4) Often the malingerer will claim mental disease to avoid punishment when held for a general court-martial.

(5) In order to obtain transfer, some made complaints of their feet with the view of being transferred to the Quartermaster Corps, and timid men requested transfer to the Medical Department.

Suggestion which has been shown by Bailey plays an important rôle in the spread of certain types of symptoms. For example, flat feet are seen in companies. Lectures on disease have created complaints of the disease described by the lecturer.

Recruits from certain communities show a similarity of complaints:

Visits of special boards were followed by the appearance of certain symptoms, such as tremors after neurological boards, or flat feet after orthopedic boards. The past experiences of recruits color their complaints, such as visits to museums, quack advertisements, old wives' tales, misdirected sympathy of patients, statements of unscrupulous physicians (Bailey).

In civil affairs malingering is also practiced to gain money. This is illustrated in the beggar who affects disability in protean forms, and the industrial worker who claims damages for injury. Fear and timidity are shown by the conscientious objector.

Motives of personal advantage can often be traced, for example, cases in which malingerers who have claims pending for injuries received in civil life are on record.

Ignorance is the source in many instances. Many miners, mountaineers, and farmers of the Northwestern and Southern States are reported as not knowing why the United States is at war, or against whom. A number of the drafted Army are Germans or Austrians, or their parents are. The largest proportion are naturally timid, expressing themselves in evasion of responsibilities in civil life, among whom are the truants or runaway, or those who give up jobs when irksome, or those who are vagrants or who give illness as an excuse for avoiding their duty. Farmers are prone to become malingerers. In Quebec the provost marshal general reports as a result of the selective service draft law among the French that 12 in every 100 registrants from the agricultural districts filed claims, and that only 2 in every 100 drafted nonagricultural registrants filed claims. In our own mobilization, those of foreign birth were more apt to practice deception and those from the central and eastern parts of Europe more frequently than from the western parts. The ratio was: Jews, foreign, 5; Jews, native, 3; other (Italians, foreigners notably,) 2; Armenians, 1.

Among the northern negro, malingering is rare, to escape service. When present it usually vanishes when the recruit puts on his uniform, after which he appears to evade duty.

Nostalgia is an important element in the development of malingering. It was responsible for 5,266 during the Civil War. The depression acted as a fertile soil for the exaggeration of trifling ailments in the large proportion of the cases applying for treatment.

Malingering depleted the forces tremendously during the Civil War. President Lincoln said that to keep the forces at the front recruited up was "like trying to shovel fleas across a river."

A word as to the frequency of malingering. True malingering is rare. This is a matter of general experience. In 14 years in the German Army only 43 cases were reported, while in the French Army in 37 years there were only 308 cases. In the National Army camps the number has never exceeded 1 per cent of the command (Bailey).

Type of the individual.—Malingers may be divided into three groups: (1) Those of normal mentality; (2) the degenerate; (3) the hysterical (Dufestel); and (4) the weak-minded or insane (Jones and Llewellyn).

The malingerer of normal mentality is really a liar and cheat and is apt to be clumsy and unskillful in the presentation of his alleged disabilities, while the degenerate malingerer, usually of the criminal type, beggar or tramp, is more skillful.

The hysterical malingerer is, according to Babinski and Strumpell, a rank simulator.

Finally, the weak-minded or insane malingerer is usually of the criminal type who simulates insanity to escape punishment for his crimes.

Gleck's studies of malingering in relation to the criminal departments of insane hospitals lead him to the conclusion that when malingering is found it does not necessarily exclude the presence of insanity. They are often present in the same individual.

Malingering, being a form of mental reaction in an individual with the object of getting out of a difficult or stressful situation, is found in persons who are on the whole psychopaths, hysterics, and insane. Malingering is not always conscious behavior, but results from motives hidden in the subconscious mental life and affects, therefore, the individual's responsibilities for his acts.

Pearce Bailey described the simulators as being hypochondriacal or constitutionally inferior, who throughout their lives have never been able to meet disagreeable situations without complaint and ruse, deceit and evasion. The country malingerer is foolish, clumsy, grotesque, coming to camp with green spectacles, trusses, and alleging variocoele and hydrocele to be ruptures; pains in the back which he attributes to kidney disease; a sprain of the leg or a back sprain which he describes as paralysis.

Age.—Cases are on record in which children of 6 or 7 years of age have simulated diseases. Dufestel reported 76 cases in which the age was less than 16 years. The mature are more prone to malingering, however, and it is probably more frequent in women than men. It is not peculiar to any social class and is not more common in soldiers than among civilians.

Detection and disease simulated.—In diagnosing the condition one must study the appearance of the individual. The city malingerer is less apt to make his complaints specific and is cleverer at deception. The malingerer is disconcerted at intense scrutiny and if he suspects detection, blushes or tries to hide his confusion by turning his face, or averting his gaze. His manner may be brusque or blunt in an effort to be simple and honest, and he is inconsistent, he overacts, is given to generalities, pain of which he complains is always severe and is uninfluenced by treatment. He is cunning, crafty, and talkative. His complaints are not concrete, are vague, rarely localized, and always severe. He exaggerates and affects symptoms which are inconsistent with the disease he imitates. Objective signs are wanting and nutrition is undisturbed.

To detect a malingerer requires, beside accuracy in diagnosis, an understanding of human nature and character.

The usual tests employed in diagnosis of disease are usually sufficient to unearth the deception except in cases of deafness and blindness, when special tests are required. A brief stay in a hospital usually suffices to clear up the situation.

In studying the type of the individual one should familiarize himself with the condition in the community from which the recruit comes, for his motives are usually linked closely to his domestic environment. Study the family relations; the school record, the industrial career, why he chose his vocation, what his economic history is, his social adjustability, whether he has ever deserted women dependent on him, if for him the world is a good place to live in and, if not, why not, and finally his views as to war, the rights of the individual (Bailey).

Motives must therefore be searched for. One must examine into whether the condition presented as to suffering and disability is consistent with the result of the examination. Are the feet calloused when pain in the leg is alleged, or is the palm of the hand when it is claimed that paralysis of the arm is present?

Appeals to manliness should be made, references to fraudulent enlistments, threats of court-martial or of a disagreeable duty; and statements that the complaint is not a disqualification should be resorted to (Bailey).

Surprise, ridicule, irony, satire, and efforts to induce shame or fear may be employed. The attitude of the medical expert should be friendly for the most part and aimed to obtain confidence. In the examinations, look for suspicious features in the relation of the story, such as excessive anxiety, remarks to sidetrack objection, inconsistencies, and vagueness.

Sometimes Bruns's method of suggestion may be useful; i. e., to give the impression that the examiner suspects or knows that deception is practiced and then prescribes in an oracular manner a remedy, whereupon the malingerer usually confesses.

Hysteria.—Since the malingerer frequently simulates conditions in common with hysteria, it will be useful to discuss this in some detail. Hysteria in a malingerer who does not lie (Bonnal). The hysteric is an involuntary malingerer (Mereier). The manifestation of malingering and hysteria are alike in many instances (Babinski).

The old conception of hysteria is that it is manifested by (1) stigmata and transient disorders. Among the first are anesthesia of the pharynx, hemianesthesia, unilateral diminution of the acuity of special senses, such as concentric diminution of the visual field, diplopia or monocular polyopia and dyschromatopsia; and finally areas of sensitiveness to pressure.

The second includes convulsive phenomena, paralysis, spasms, mutism, glossolabial hemipasm (Chareot, Brissaud, and Marie) Astasia-Abasia (Chareot, Rieher, and Bloq) rhythmic chorea, erythema, vesicles, bulle, hemorrhages, ulcerations and gangrene of the skin, subcutaneous edema, laryngeal paralysis, spasms and edema of the glottis, pulmonary congestion and hemoptysis, gastric ulcer, hematemesis and melena, anuria, hematuria, albuminuria, angina pectoris, tachycardia or bradycardia and high fever.

Suggestion auto and hetero, but more especially emotion are the principal factors which prepared the soil and were able to give rise to hysterical manifestations without the intervention of consciousness or the interference of will. The modern conception of hysteria, on the other hand, as formulated by Babinski ascribes the fundamental characteristic of the hysterical manifestation to the curability by persuasion, and he suggests the name "pithiatism," which means "I persuade to be cured."

Hysteria is a pathological state manifested by disorders which it is possible to reproduce exactly by suggestions in certain subjects and can be made to disappear by the influence of persuasion alone (Babinski).

He admits that physical commotion and moral shock may diminish the personality, weaken the critical sense, and increase the suggestibility and thus play an important part in the development of pithiatic disorders. Emotion can not cause pithiatic symptoms itself. A suggested idea is required though supported by systematized affective states. This is a brief outline of Babinski's presentation of the so-called modern view of hysteria.

The old conception credits hysteria with any form of nervous disease, but Babinski concludes that it can not reproduce certain characteristic phenomena of organic paralysis. Vesicles, ulcerations, cutaneous hemorrhage, and the like are "nothing more than a legend."

Certain tests to differentiate between organic and hysterical diseases will be found to be useful in detecting simulation. The contractures or paralysis of hysteria are variable, modified from moment to moment, or day to day, and the resistance is intermittent. With blindfolded subjects presenting contractures of the hand, for example, repeated synchronous movements with both hands vary in amplitude and form, which is untrue of organic contractures. Transitory disappearances of symptoms is characteristic of hysteria. A paralyzed limb of organic origin drops lifeless, while in hysteria the limb is sometimes retained in the position placed by the examiner before it is relaxed. In lifting an organically paralyzed limb there is always the sense of weight given, while in hysteria it will be liable to variations and may for some time disappear entirely.

In contractures, the tendon can be seen to stand out as the examiner approaches and disappears as he leaves. When an unexpected examination is made of a limb the abnormal position is sometimes reduced without using any force. Babinski's diagnostic signs to distinguish between hysterical and organic paralysis are well worth reviewing.

In hysterical hemiplegia the paralysis is not apt to be limited to one side, is sometimes systematic; does not affect the unconscious voluntary movements; the platysma sign and combined flexion of the thigh and trunk are absent, the tongue is often deviated in a pronounced manner or to the opposite side of the paralysis, there is no muscular hypotonus,

facial asymmetry being due to spasm; the sign of exaggerated flexion of the arm and the sign of pronation are absent, the tendon and bone reflexes show no change; and there is no ankle clonus; the cutaneous reflexes are not affected, the abdominal and cremasteric reflexes are normal; Babinski phenomenon is absent; the reflexes of defense are not exaggerated; the form of contracture may be reproduced by a voluntary contraction of the muscles. The course is capricious; the paralysis may remain flaccid indefinitely or may be spastic from the first; symptoms subside and grow worse suddenly; they modify their intensity and form and present transitory remissions.

Reflex contractures and paralysis.—These are distinguished from organic monoplegias, in that, in the former the paralysis involves usually the fingers or foot and rarely the whole limb, remain usually flaccid for a long time, and are frequently associated with contractures, the hypertonus and the hypotonus occupying different muscular groups. In contractures the appearances are of the type described as *main d'accoucheur*, holy water vessel hand, and crowded fingers. In the leg the patient never circumducts, the leg is walking. The reflexes are not usually exaggerated, the cutaneous reflex, however, may be lost, but it reappears after the foot has been warmed. The Babinski phenomenon is never present. Atrophy never reaches that of neuritis and no reactions of degeneration occur.

Reflex contractures are characterized, in contradiction to hysteria, by resistance to treatment, absence of any natural attitude in hypertonic form, amyotrophy marked and rapid in development, marked vasomotor and thermal disturbances, marked hyperidrosis, exaggerated tendon reflexes, marked hypotonus, mechanical muscular hyperexcitability often accompanied by slowness of the contractions, rapid development of fibro-tendinous and trophic bone, hair, and skin disorders.

The symptoms in favor of organic disease, and never present in hysteria in the ocular sphere, are (1) lesion of ocular nerves, nystagmus, pupillary disturbances, persistent hemianopsia; (2) in the motor sphere, degenerative changes of muscles, single nerve palsies, and atrophies (facial or peroneal); (3) in the sensory sphere, anesthesia in the area of the distribution of nerve trunks; and (4) in the reflex sphere, absent knee jerks, ankle clonus, and persistent incontinence of urine and feces (Babinski, Oppenheim, and Leri).

One should be familiar with Sachs and Freund's test for deltoid paralysis. When the individual lies prone on a table so that the arm hangs down by side, he is then asked to raise the arm to his hip and then he is told to remove his arm from his hip. If he can not do this he is a malingerer, for if left to itself the arm would automatically, by the effect of gravity, drop to the vertical.

Malingering as to pain.—The behavior of the individual suffering from actual pain should be studied. Pain when present, if paroxysmal, causes the eyes to stare wildly, the brows to knit, the nostril to dilate, the teeth to clench, sweat to appear on the face, a modification of the pulse rate and respiration. If prolonged there is depression or prostration, pallor, fainting, insomnia, anorexia, and effects on the general health are manifested.

Flat-foot pain disappears when lying, and pain from varicose veins, worse when standing, is helped by rapid walking. Syphilitic pains in bones are worse at night. Look for defensive attitudes in joint diseases or as seen in torticollis, scoliosis, sciatica, and the psoas abscesses.

Search for objective manifestations such as heat, redness, and atrophy in joint cases or functional derangement of an organ when disordered functions are claimed.

Eliminate the possibilities of actual disease. Is the pain along nerve distribution; are there tender areas along the nerve; is the location vague? Does the pulse increase when pressure over alleged painful spots is made (Mannkopf-Rumpf sign), or do the pupils dilate, the face flush, and the pulse and respiration quicken (Bechterew's sign)?

Pain in the back is usually referred to the lumbar or lumbo-sacral region. It is necessary to eliminate the presence of movable kidney, renal calculus, prostatic disease, osteomyelitis, and spondylitis. Search for a history of possible strain to the psoas or anterior spinal ligaments, rupture or strain of the lumbar or gluteal muscles, the posterior spinal muscles or ligaments, or finally strain of the sacro-iliac ligaments. Resort also to skiagraphy in these cases.

Make various tests for mobility of the parts. Is there rigidity, does the individual bend forward without leaning to one or the other side? Does he walk cautiously and grope, or does he sit down carefully, and support his body on his thigh in rising?

In simulated scoliosis, the curve is in the dorso-lumbar region, is single, and lacks compensatory deviation; both sides of the thorax are equal; there is no deviation of the sternum; there is no torsion of the vertebra, and the curvature disappears during sleep.

Pain in the leg.—It is essential here to eliminate sciatica, sacro-iliac strain, flat foot, intermittent claudication, femoral thrombosis, syphilitic periostitis, and malignant disease of the bone. When pain is referred to the joints, search for stiffness, weakness, and limitation of mobility. The most puzzling cases are those which show no objective disturbances. Is the stiffness a voluntary restriction of movement? If the restriction is in some particular direction, or if the resistance to movement is continuous from the beginning and does not intermit and involves the whole limb, we have the picture presented by simulation.

Examine for atrophy, changes in electrical reactions, and reflexes, the presence of callosities, and make bilateral comparisons of strength.

In strenuous movement of the proximal joints against resistance, the distal joint or joints are fixed, so when this is absent one knows that the person is not using all his strength and therefore his weakness is simulated.

In moving the arm upward in abduction the malingerer raises the arms in a backward direction which is opposed to what happens in actual painful conditions where the arm is raised in a forward position.

If he claims not to be able to lift his arms above his head, let him place his arms on a chair lightly in front of him, at the same time bending the trunk forward. Then under guise of examining the back, gradually draw him away from the chair and the malingerer will allow the arms to remain over his head and thus his deception is unmasked.

Test for tremors.—Fuchs's test is based on the fact that it is impossible for an individual to make two simultaneous movements which counteract each other with the right and left arm or with an arm and a leg except after long practice. If the arm or hand is outstretched and the other traces crosses, letters, or circles in the air, the tremors become interrupted in the other arm by the voluntary movement, in the case of the malingerer.

Sciatic pain may be due to malingering or sciatic neuritis or neuralgia. In neuralgia of the sciatic nerve, the pain is dull, more or less constant over the distribution of the nerve, with occasional paroxysms; movement increases; habitual flexion of the knee and hip is present to relax the nerve; there is a compensatory scoliosis; and tender spots are present over the lumbar spine, posterior iliac spine, sciatic notch, popliteal space, peroneal nerves below the head of the fibula and behind the malleoli.

In neuritis the sensation is blunted, there may be electrical changes, muscular atrophy, lowered temperature, and diminished ankle jerk. Laseque's sign is positive, consisting of pain on flexion of the thigh and extension of the leg.

In Neri's sign, when the trunk is bent forward the knee is flexed. In Bonnet's sign, there is pain when the thigh is adducted.

Anesthesia.—In normal sensation, if two parts of the body are touched and pricked at the same time, only the prick is felt. In true analgesia only the touch is felt if the anesthetic area is used for the prick, while the simulator does not feel the touch.

One should be familiar with the Weber's test for sensation. He has pointed out that in health in the mid-sacral region the compass points are recognized at 1.5 inches apart, in the mid-lumbar region 2 inches, and in the mid-dorsal region 2.5 inches apart.

In testing painful or anesthetic areas, sensation should be tested first with eyes open and the area marked and then with eyes closed, remarking. If great variations are found, simulation is inferred.

The zigzag test as suggested by Captain Cuplin, R. A. M. C., is useful. After testing the upper limits of the anesthesia, start again approaching the line in a zigzag manner, when in fake anesthetics the level will be found to change. This is based on the confusion which is created in the mind of the individual by this test.

Also with the eye closed, test by starting on a sensitive area and ask the individual to indicate when the anesthetic area has been reached. Anesthetic areas may be also localized by drawing a pin over the surface, beginning over the anesthetic area and passing beyond to the sensitive area with the eyes closed, observing when the defense reflex occurs. At the moment the pin point is passed over to the sensitive area the patient winces.

Cardiac disease.—In testing for simulated syncope, it is merely necessary to review the symptoms of true syncope. These are: (1) Period of faintness preceding unconsciousness; a period of insensibility; a period of recovery; (2) feeble pulse and suspended respiration; (3) unconsciousness, rarely total accompanied by reflex loss; (4) short duration; and (5) subsequent pallor and sweating.

Palpitation or arrhythmia may be simulated by the excessive use of coffee and tobacco.

Rhinitis has been simulated. For example, there are on record cases in which ozena has been simulated by introducing into the nostrils a piece of sponge saturated with offensive smelling substances.

Epistaxis has been caused by introducing blades of straw or a piece of lead pencil into the nostril or injuring the mucous membrane with the finger nail.

Hoarseness and cough has been simulated.

Tuberculosis has been simulated by substituting tuberculosis sputum from other patients, or faking the presence of blood in the sputa.

When pleural pain is complained of, the absence of the physical signs and fever will clear the diagnosis.

Pneumonia has been induced in some cases. Sand cites a case of a soldier who enveloped his neck and chest for two nights with linen saturated with ice water, provoking thereby an attack of pneumonia from which he died.

Simulated dysphagia may be discovered by the introduction of a bougie, and observing the absence of disturbance of nutrition. In cases of vomiting, search for the presence of gastric ulcer, nutritional disturbances, and hysterical manifestation.

Hematomesis is commonly simulated to obtain discharge from service and is faked by swallowing animal blood or by blood from self-inflicted wounds of the nose or limbs. A study of the nutritional condition is helpful in such cases.

Tympanites is produced by swallowing air. Military boards describe instances of swallowing chalk and vinegar to bring this about.

Diarrhea has been simulated by taking cathartics.

In intestinal pain simulation, diagnostic measures should be exhausted to eliminate actual diseases.

In alleged incontinence of feces, test the sphincter, which should contract on the finger in the absence of actual disease.

Hemorrhoids are frequently faked by cavalrymen, who insert into the rectum bladders of rats or intestines of sheep. (Ambroise Paré and Fallot.)

There is on record instances of simulation of ascites in the British Army. Forty troops were admitted to the King's Infirmary said to be suffering from dropsy and intermittent fever who presented arching spine and who maintained the distention by short respiration. Actual injection of water into the peritoneal cavity was done by French conscripts.

Epidemics of jaundice are reported among the French troops which puzzled the medical officers until it was discovered that yellow pigmentation of the skin could be produced by the ingestion of picric acid. Chemical tests disclose its presence in the urine and clinically an absence of the typical colorless stools. The slowness of the pulse and itching associated with jaundice and the urine which does not contain bile pigment are the methods employed to detect this species of fraud. White of egg has been mixed with urine or even injected into the bladder. Imitators overstep the mark by introducing quantities incompatible with the state of health presented by the subject. Sometimes the subject has a little egg albumen in his pocket into which he dips his finger and smears the meatus with it, so that when he urinates, the urine washes off the albumen into the collecting vessel.

Edema is simulated by injecting water beneath the skin. Paraffin or turpentine causing fixation abscesses, usually situated on the inner aspect of the lower limb, have been employed by simulators, the complaint being phlebitis.

Hydrarthrosis of the knee joint has been simulated by placing a potato in the popliteal space and flexing the joint for a few hours forcibly, and swelling of the feet can be brought about by tying the puttees too tight.

Dumez, technical assistant of the Hygienic Laboratory, United States Public Health Service, reported a list of the drugs, chemicals, and septic materials used to simulate disease. Skin diseases such as erythema was simulated by nettles, poison ivy, squills; eczema, by croton oil, sulphur, acids, oil of cade, ointments of mercury or mezerium bark; impetigo, by cantharides or ointment of tartar emetic; other eruptive diseases by iodides, bromides, arsenic, or mercury taken internally and the use of phenol, cantharides, mustard seeds, or croton oil externally.

Ulcers have been simulated by potash or soda lye, sulphuric acid, or a strong solution of zinc chloride externally.

Abscesses are commonly produced by inserting beneath the skin a thread smeared with tartar from the teeth, saliva, or fecal matter.

Phlegmons have been caused by gasoline, kerosene, oil of turpentine, or a solution of chloride of lime injected hypodermically.

Lipoma has been simulated by the injection of paraffin.

Edema of the hands and feet has been caused by friction between the fingers or toes with a stalk of a species of horsetail (*Equisetum arvense*).

Simulation of diseases of the eye.—Inflammatory conditions have been induced by placing under the eyelid, ipecac, castor-oil seed, cantharides, lime, silver nitrate, red mercuric oxide, copper sulphate, acid lotions, urine, fecal matter, and putrid matter.

Mydriasis is brought about by the use of belladonna, hyoseyamus, and stramonium preparations.

Myosis has been simulated by the use of lobeline.

Diseases of the ear.—Otitis has been caused by inserting into the auditory canal, urine, feces, and chemicals.

Tonsillitis has been simulated by using irritating gargles, and hemoptysis by coloring the sputum with earmine or beef juice.

Gastric disturbances have been faked by swallowing oil and tobacco mixed together.

Diarrhea has been simulated by taking purgatives, by diluting the feces with urine or water, or adding pieces of meat or pork fat to simulate dysentery.

Icterus is imitated by liquid preparations of curcuma applied externally or picric acid internally as mentioned above.

Disease of the circulatory system.—Rapid heart has been induced by chewing cordite, which is a mixture of guncotton and vaseline.

Disease of the kidneys.—Sodium chloride and milk consumed in large quantities is used to cause albuminuria, and albumen has been injected into the bladder for the same purpose.

Disease of metabolism.—Diabetes has been simulated by taking phloridzin or ammonium oxalate or injecting glucose into the bladder.

Fever has been induced by inserting into the anus a peeled tooth of garlic and allowing it to remain 24 hours, or by the same crushed and rubbed into the axilla.

Hernia has been simulated by paraffin injected into the scrotum.

My experience in Camp Travis, where about 40,000 men were examined or surveyed and where, as a member of the special board of medical examiners, I was able to see all the cases of Malingering, the most common type consisted of those whose complaints were exaggerations or perseveration of symptoms which originated in an injury more or less severe some months or years previously which gave rise to habitual attitudes or limps similar to those described as occurring after so-called shell shock and now described by Babinski as reflex disorders or physiopathic disorders.

The limps were of very common occurrence. Some walked on the outside of the foot, due to a contraction of the anterior tibial muscle; or on the inside of the foot, due to contraction of the extensors and peroneal muscles; or on the toes, a flexor contracture; or some walked with bent knee with a list to the same side. Complaints of rheumatic joints were common, claiming restriction in the movements of the joint which were palpably exaggerated.

Fake sciatic cases were frequent, as were also contractures of the trapezius muscle, the sterno-cleido-mastoid, or all of the posterior group of neck muscles. The bent back, the camptocormia or plicature of the French was occasionally observed, also contractures

of the arm, hand, and wrist. In fact, an observation which I was able to make as a result of my studies in camp, in the French hospitals, and in the British "shell shock" hospitals, as well as among our own soldiers subjected to shell fire, is that many of the nervous manifestations are presented by the drafted men in training camps, though in a minor degree, as is observed in the soldier on the firing line who has been under shell fire and who presents disorders referable to the nervous system. In other words, the phenomenon of war neuroses observed among the French and English soldiers and seen in the American forces correspond in a miniature form to those nervous phenomena seen in training camps among drafted men upon their admission to camp or after they have been under training a short time.

Army Sanitary School No. 99.

NOTES ON THE H. O. E. WHICH WAS THE HEADQUARTERS OF THE FRENCH FIELD SERVICE SCHOOL FOR MEDICAL OFFICERS, MADE ON OCCASION OF THE SECOND SESSION, ARMY SANITARY SCHOOL

This hospital is situated in a broad valley near a large château and on the edge of a forest, about 12 km. from the line. It is reached by a spur of railroad from the station about a mile and a half away. There are no military works of any kind in the immediate vicinity of this H. O. E. and there should be absolutely no excuse for bombing it. It has nevertheless been bombed in a most destructive way, for which there is not an atom of excuse.

The plan of the hospital is a poor one, but this is by no means the fault of any of the medical staff nor even of the French Medical Department, as the hospital has been thrown together hastily and from military necessity its plans had been several times changed during the course of its construction. When it was first built a large hospital was not contemplated, and the extension of the buildings was made hastily and cheaply. Less than a year ago it had only 30 buildings. It is by no means poor, but it can not be taken as a model, or even as a type, of institution of the French Medical Department, as it is surrounded in every direction by hospitals of similar size and scope which are infinitely better.

In many ways the institution is a great credit (1) to the medical officers who administer it, and (2) to the French Medical Department, for a success has been made where it seemed impossible; the hospital is not only provided with the most advanced medical and surgical necessities but it is well administered in spite of its manifest defects.

It fronts on a wood and is approached by a semicircular drive near the center of the hospital grounds. All of this open space in front is parked and filled with flowers in summer. Here is the main office of administration, in front of which are three flagstaves—one for the Red Cross, another for the French, and another for the American flag. To one side of the building is the triage, a group of four buildings, described elsewhere.

The patients in this hospital are sent from three main points: 1, —; 2, —; and 3, —. In all, the hospital comprises 140 buildings, with accommodations for over 3,000 patients; this could be expanded to 4,000. They were Adrienne huts. Lack of funds has prevented the building of hard roads, and the walks are of duck board. As the site was very muddy, intercommunication was difficult—in fact, the terrain itself is damp and cold.

On the edge of the woods near by are kept from 18 to 30 motor ambulances; the number is not fixed, as they are sent here according to necessity. They are of the usual Fiat type, capable of handling five litter cases; they have solid metal wheels and solid tires, with an extra wheel in case of accident. The rear wheels are doubled. They showed evidence of hard usage at the time of this visit. The hoods of engines are kept covered by woven straw mats to prevent freezing. While rapid and seemingly efficient, their complete boxing in has been responsible for cases of CO poisoning. In fact, some of our party experienced the ill effects of this gas—not to a serious extent, however. There is no center aisle; it is taken up by an iron rack on whose bars run pulleys for the adaptation of litters. This ambulance is far too contracted and can not be said to be a model for our Army.

Behind the administration building is a long walk running the length of the hospital, connecting its two extremities, and along this walk are placed the administrative offices of the school, some of the lecture halls, some of the dormitories, and at the far end, to the left, the officers' dining room and library; beyond, on the right, are the two operating groups, one of Leriche and the other of Lemaitre. In the center are the nurses' quarters and, to the left,

evacuation wards, and still farther back are the evacuation wards, another lecture hall, and two enormous Bessonneau hangars. One is used as a theater and the other for wounded to be evacuated from Leriche's and Lemaître's operating groups. Just beyond this is the spur of the railroad, already referred to. The following buildings can be specially noted: Administration buildings, four buildings for triage, dormitories for visiting medical officers.

The two operating groups connected by covered ways with their wards, described elsewhere.

A building devoted to offices for the commandant and professors of the French school.

Two very well-equipped laboratories, one bacteriological and the other pathological.

The dormitories for visiting officers connect with a large lecture room in the same building. The commandant of our school and the instructors accompanying him were quartered very comfortably in this building, each room having a small stove, comfortable iron bunk, abundance of bed linen and cover, writing table, and electric light. The entire hospital is well lighted by electricity from a central plant.

Both of the laboratories are conducted by personnel of the Institute Pasteur, and the character of the work done is in accord with the international reputation of that institution.

The wards for hospitalization connected with the operating groups are served, each two, by one female nurse, and each ward contains but one type of injury. There is a service for injuries of the soft parts, one for chest wounds, one for genito-urinary surgery, etc., and each service is presided over by a chief who has upon his staff some excellently trained assistants as ward surgeons.

All parts of the hospital grounds are connected by a narrow-gauge railway which is used chiefly for delivering supplies.

The inherent defects of the hospital, lack of hard roads, mud, and hasty construction, together with lack of adequate supplies and a natural desire to spend more on more perfected hospitals, has made it most difficult to compete with the excellent, well-situated, well-supplied hospitals in its vicinity.

Histories are apparently complete; charts are hung at the foot of beds. In quiet times surgeons from the field ambulance and regimental organizations at the front are sent here as students and are not only allowed but required to do operative work as part of the course of their instruction, under the chief of the service to which they are assigned.

This hospital does not at this time receive head injuries, gassed, mental, or venereal cases. The abdominal cases are held, usually, at more advanced organizations for operation; the others are sent back to ——— or institutions in its immediate vicinity.

The nurses here are volunteers; they have received their instruction during the war and are not graduates. Anyone who has watched their work could see what a waste of valuable personnel it would be to exclude such a nurse, trained in time of war in an institution like this under the highest type of professional men, from exercising all of the duties and from having all of the perquisites of her profession simply because she has not previously received a diploma.

Antiseptics have practically vanished from this hospital, and all the time we were there we did not see a single case being treated by the Carrel-Dakin method. They consistently believe that such treatment is not necessary, preferring, exclusively, surgical prophylaxis. There was a ward set aside for cases of streptococcus infection and we were shown one case of six weeks' duration that had never had an antiseptic dressing (gunshot wound of the leg). Aseptic dressings are applied here on the theory that all infections are self-limited and the only weapon we have against the existence or the progress of such infection is auto-vaccination, which should usually occur in from 3 to 21 days. The streptococcus is the only microbe they fear; and as no safe antiseptic has any action upon this, none was used.

Another peculiarity of this hospital is that Thomas splints are not used while patients are under treatment here, as it is claimed that the pressure of the ring causes a great deal of pain and discomfort. They use several other forms of splints and plaster. We saw several put up in Delbet ambulatory apparatus. Lemaître made the statement that there had only been three cases of streptococcus infection in his six months' service in this hospital, and all were due to the fact that owing to the condition of the patient the wounds had not been sufficiently inspected at the time of the operation. All wounds are radiologically and bacteriologically handled before operation.

It is proper to especially mention that the buildings in the operating group are pleasant, cheerful, clean, warm, and well lighted. To heat them, a special central heating apparatus is provided. The operating rooms are painted with white enamel paint. They are large and very simple and all contain tables for operating under the X ray. Professor Lemaitre has also a large electric vibrator for the determination of the presence and position of magnetic foreign bodies. These radiologic units on hand in connection with the operating groups are merely for localization, the central radiologic and radiographic plant under M. Nogier, an eminent physicist of the faculty of medicine of Lyon, is one of the best-equipped centers we have ever seen and is in another part of the compound. Clean gowns are provided for all visitors to the operating rooms. Ethyl chloride and ether are the anesthetics of preference—neither chloroform nor spinal anesthesia is employed. The anesthetist keeps notes on the operations.

A feature of this hospital is that every wound is voluminously dressed—to our mind unnecessarily so.

The evacuation department has been amply described elsewhere. In addition to the storeroom for regular hospital equipment a special storeroom for Red Cross supplies of American origin is kept, and as a matter of fact it is believed that this is a prominent source of the comforts enjoyed in this hospital. There is also a community store and a sort of post exchange for the men. There are bathrooms for men and officers and in the center of the compound, on one side of a square, buildings for female nurses, and buildings for male nurses on the other. The enlisted personnel of the hospital are quartered in barracks. The pharmacy is large and well equipped.

The kitchen.—This consists of a long building with stoves arranged in a row, each one presided over by a cook and one or two assistants. Food is dispensed by a sergeant at a desk before an open window. The ward orderlies line up before this window and give the sergeant the necessary information. He in his turn notes the information on a slip which each orderly presents, with his respective ward number and number of patients. The sergeant then calls off from each card the order for the food and the cooks handed it out as the orderlies passed by. Several thousand men are fed without friction or overcrowding and with surprising rapidity.

The laundries.—There are 12 to 18 in a group across the track from the hospital. They are of the portable variety.

The grounds.—In general these are laid out and have been well spaded for flowers and crops. There are several large red crosses in the grounds in conspicuous places, made of boards painted red and laid in the shape of a cross on whitewashed rocks. The water is piped to all parts of the grounds from a spring about 500 meters south and is said to be of good quality. The result is that there is running water in all buildings. The hospital is lighted by electricity from the town and from a local generator. They are changing the red cross at this hospital for a black one, which is noticed better by airplanes. No provision is made for the revetment of huts in this hospital, except some few which had sandbag protection from splinters. There is a cinema show given twice weekly. Usually the pictures are of scenes laid far from the war and war subjects. At these shows the orchestra furnishes music. This orchestra is recruited from among the patients and at times artists in comedy, drama, and song are brought here from Paris to vary these programs.

The quarters which were prepared for our students merit the kindest record. They have literally made over an entire barrack for 25 officers. They have waterproofed it with tar paper, painted it inside and whitewashed it out, and have partitioned it off into separate rooms. Each room contains one or two beds and is fitted out with linen and covers, stool table, washstand, wash basin, pitcher, and slop pail. The building is heated with three French stoves—not too hot.

Army Sanitary School No. 100.

MEMORANDUM No. 136

HEADQUARTERS 42d DIVISION,
OFFICE OF THE SURGEON, A. E. F.*To Surgeons of All Organizations:*

I. The following list of emergency surgical dressings, appliances, and gas-defense supplies has been prepared for the purpose of establishing in this division a uniform minimum equipment for regimental and battalion aid stations, advance aid posts, dressing stations, and ambulances, while the respective commands to which they are attached are serving in the line of the advance.

Surgeons of organizations will be held responsible for having on hand at all times at least the amount of such supplies as given below, and frequent checking shall be made and shortages requisitioned for at once.

Surgical dressings and appliances	Distribution

NOTE.—This is special surgical equipment and not intended to replace battalion combat equipment, par. 866, Manual for the Medical Department, but will be in addition to it, except as noted in remarks.

¹ Distribution at discretion of medical officer.

² Par. 866, Manual for the Medical Department.

³ 1 snowshoe, 2 ordinary; par. 866, Manual for the Medical Department.

⁴ When needed.

⁵ Provided when needed.

⁶ Equip. Greeley units, tablets in chest, M. and S.

⁷ 5 per cent strength of personnel extra.

J. W. GRISSINGER,
Lieutenant Colonel, Medical Corps, United States Army,
Division Surgeon.

MEMORANDUM No. 142

HEADQUARTERS 42D DIVISION,
OFFICE OF THE SURGEON, A. E. F.,
June 10, 1918.

To Surgeons of All Organizations:

1. The following additions are made to Memorandum No. 136, Headquarters 42d Division, office of the surgeon, dated June 4, 1918, as gas defense equipment for an ambulance:

Ammonia ampules.....	boxes.....	10
Catheters, rubber.....	number.....	4
Coats, gas.....	do.....	2
Masks, French.....	do.....	4
Mittens, gas.....	do.....	2
Oxygen tanks and connections (small tanks for ambulances).....	do.....	4

2. The surgeons will make the necessary entries, in the appropriate column, on Memorandum No. 136 mentioned above.

3. A copy of this memorandum to be furnished all medical officers in your command.

J. W. GRISSINGER,
Lieutenant Colonel, Medical Corps, United States Army,
Division Surgeon.

NOTE.—These memoranda have been considered of such importance that they are included in the literature of the Army Sanitary School.

Army Sanitary School No. 101.

ADDRESS OF MAJOR GOLDTHWAITE, DIVISION OF ORTHOPEDIC SURGERY, A. E. F.

Gentlemen, the orthopedic branch of medicine has been made very much more conspicuous in the war game, of course, than it has been in civil life, and it has led to a good deal of study. In the United States Army we have tried to profit by the experiences of the French and the British and adopt the best which they have worked out, so we are starting practically where they are in the best part of their organizations to-day, not where they were at the beginning of the war. For that which they have worked out we do not deserve any credit at all—except for having common sense enough to profit by their experience. The things which we are doing represent the best French and British organization.

The work of the division of orthopedic surgery divides itself at once into two parts: (1) That which has to do with reconstruction work, and (2) the classification of soldiers into classes A, B, C, and D, based upon their physical fitness for the Army.

“Reconstruction” is a term which has been used a great deal in connection with orthopedic work. The term used here means the reconstruction of the men in the precombat period. In other words, one of the most important parts of this work is that which has to do with making the men fit so they will be able to stand the stress and strain of combat. The need of this in our country is probably much greater than among the French or the Italians, and is greater than the need among the British, although among the latter it is greater than in the others mentioned. The reason for this necessity so prominent in our country is that we have been a nonmilitary people and we have allowed our youth to grow up without sufficient attention being paid to the physical education or the physical training of the body.

The posture which we have allowed our young people to develop and which we ourselves are assuming is just as much a stamp of ignorance as it would be if that same individual were to use some ungrammatical expression. Some day our country is going to see that the thing that we are struggling with to-day has been overcome by our educational system at home. You know perfectly well that the common attitude of our college boy to-day is this sort of thing (slouching). It is this swagger which the college man of our country prides himself on. The stoop and the slouch are perfectly definite types to-day and the little kid gets it in the preparatory school and it's the same way on up. If his father tells him to stand up straight he says “the old man is a bug”; the girls, of course, have copied it on their part in the “Gaby slouch” and other poses. It is one of the most serious things which our Nation has before it to-day. Now the question of posture has come straight home. Those types of postures mean weak men; they mean weak women; and the coming generations are going to be of the same type if we don't succeed in ousting these unhealthful poses. The problem that confronts us is to make men of these weaklings.

Now, a lot of men are here in France to-day, not by tens and hundreds, but by thousands; and if you take them out on a 10-mile hike you bring them in ready for the scrap heap; and if you scrap all of these men it means a loss of a large proportion of your forces, which will make it pretty difficult to supply your replacements. It means that your transports back with the men that you have to eliminate will be pretty nearly as full as when they came over. When we first undertook this work Colonel Bevans made the remark that at least 15 per cent of the troops would come in with defects which we are trying to correct.

There are two types of weakness: The most common is flat foot. Now, get out of your heads at once that flat foot is a disease. Men with flat feet should not be admitted to sick report. Flat foot is a weakness, and the soldier ought to be just as much ashamed of that weakness as he would be of any other.

The other condition is weak back.

These two elements, weak feet and weak back, are, of course, the most common weaknesses of the body for anatomical reasons. You will find a great number of instances of weak backs, lumbago, muscle strains, and that sort of thing, and these are the conditions that account for the largest number of unfit in a training period. Now, the question comes up, What are you going to do with them?

Recognizing that that condition was a weakness, not a disease, the experiment was tried of taking those men off sick report at once and assigning them to special duty with the idea of overcoming that weakness. That it was a weakness rather than a disease at once became obvious after you had studied the men. The day this was started we had about 25 or 30 men who had been sent in to get a certificate of discharge on account of permanent disability. There they were. All standing this way [illustrating]. Here are some tracings of these men [showing]. These are tracings of the men they are sending over here—a part of the fighting force of the United States Army. Now, I don't think you would hesitate to go up against that sort of a man? These types here are certainly not types that you would pick out as those of a very vigorous manhood. A man standing that way will inevitably have symptoms in the two parts of the body that are weak. He will have flat feet, of course; and he will have a weak back. That type of man will have a weak back in a short time after he is used hard physically. He will also have flat feet, because the moment you let yourself down thus [illustrating] the weight is thrown entirely upon the heels. Now, no ligament has ever been created that will stand strain long without stretching. Try it yourselves and see the way it lets the weight off your body at once. I am on my heels. No man living can stand that way for long without the feet getting tired. Now, pull yourselves up in the position of a soldier. You at once pull yourself over on the ball of the foot. You have the spring and the stretch under you, and no man standing that way will ever get flat feet. If you train a man to use his body rightly you can cure almost any case of flat foot. We have recommended that no man with flat feet be discharged from the Army. Some one said that undoubtedly in the next draft flat feet would not be considered an excuse for being exempted from service; such men would be put into a special training battalion, an experiment which has been proved feasible. You can see what it is to reduce flat foot and weak back to these terms. Such men should not be allowed on sick report and should be made to realize that they have a weakness and not a disease; that medicine is not used in that case and that it is up to him to get strong. Since it is a matter of reeducation, what we have to do with our men is to teach them how to use their feet, just as in the primary schools you show the child how to shape the letters. One is not more difficult than the other; it is a question entirely of muscle training. As a matter of fact, when you take these men and show them how to stand and how to walk and make them do it day after day, after a while it becomes absolutely automatic. It is not at all unreasonable to expect that man to use his body correctly after that. It becomes automatic with the individual. There is no question about that at all.

Now, individuals vary and the types of posture you see that lead to these things of course also vary very much. You can tell at once the type by looking at the man. What I want you to understand is that you don't have to ask a man if he has a lame back or wonder if he is going to have weak feet when he goes on a 10-mile hike. You can tell before he starts. I saw a training battalion at ———, with which Major Jones here had so much to do. We took Colonel Craig there one day; there were 1,500 men lined up in that battalion at the time. We said as we walked past them "There is a type. This man is no good. That man is nearly finished." You don't have to be a medical man to do it. Colonel Craig could have picked out the men just as we did. You can even tell if that man is trying to get out to the front, instead of trying to stay away; you can see some men won't be any good when they get there. Our work does not consist in just relieving a man of weak feet for a day. That does no real good. It means getting these men's feet so that when they go back with your stamp of fitness on them they will stay put and be men fit for combat. In those divisions that are

arriving in France to-day the situation is no better than in this battalion. In some cases the conditions are worse. Understand me clearly and remember that if a man stands this way [illustrating] he will have symptoms of these defects. The symptoms differ. You can tell them in a minute. Just walk down the line and pick them out.

In the 26th Division a scheme was worked out, largely by the medical department of that division, backed up by proper authority, whereby these men were collected and put in a special military unit. They were not on sick report; they were assigned for duty in that special battalion. It was a military unit, in command of a line officer. A schedule of activity was planned which had to do chiefly with what "the school of the soldier" stands for. In the first place you should take the men and talk to them. You should tell them there is only one way to use the feet and that is the way military posture is prescribed. Now, you can't get your chest filled out without pulling your chin in. Try pulling your chin in and see what happens. You can't pull your chin in without throwing out your chest, and you can't fill your chest with your chin forward. Try it yourself. In yawning, of course, we do it reflexly. You can not yawn with your head forward. Nothing happens until you pull your chin in. You can not sigh unless you pull your chin in. We say to a man: "Pull your chin in. Pull your chest up and get a good big place for breathing." Next, we get them to stand right, on the balls of the feet. Then they get bayonet drill, marching, parading, bomb throwing, all the things the men should get in their training for combat. In marching, for instance, the step is speeded up to 140 to 160 a minute, quick, snappy movements; not sloppy, half-hearted ones. Drill every bit of the schedule, whether 10 minutes or half an hour, this to depend on what you mean to do. Keep them busy all the time, but rest the muscles every little while. Make the men remember that their trouble is a weakness and that they ought to be ashamed of it. Tell them, "If you have trouble with your feet, stand up straighter and you won't have weak feet."

In walking, we show the men the proper way, and if they walk that way they won't have weak feet. We don't give them a lecture on weak back; that would be a positive suggestion. We say: "Use your body this way and you needn't worry about your feet and about your back."

All this means that you reclaim the men with these conditions in a comparatively short time and you can send them back to their commands, not as convalescents from hospitals but as good soldiers. The schedule for the first week is prescribed. At the end of the week the orthopedic surgeon in charge examines the men. If they are sufficiently improved they are promoted to another company, the second class, which has more work. They have a schedule of military work under line officers, and the men for the second week are drilled on a more severe schedule. Everything is speeded up. At the end of that week these same men are examined again. If a man has improved enough he is promoted to the next company. At the end of another week he is examined again and if he is coming along all right he is moved up to the top company, and that means he is pretty nearly ready to go back to his command. The top company has a schedule which is almost up to a combat training schedule. He is expected to march 10 miles every morning or afternoon with a full pack and to train pretty much as a combat man would. If he can stand that you can easily see that he is all right. All you have to do is to walk up and down the line. The man should have the springy step, using the front of the foot to get the spring of the arch, not striking the heels as he goes along. When you get these men in shape they can march better than they ever marched before. You don't need to worry about their breaking down again. They will stay put.

Now this is the part of the work of the division of orthopedic surgery, keeping the men fit in this sense, relieving the medical officers of an enormous amount of bother which such soldiers cause in the command, and making them fit for campaign.

At present in the Army, as you know, men are graded into classes A, B, C, and D. It is recognized that some men can not be brought to fitness for combat, generally, because of underlying pathological conditions which were overlooked when they got into the Army. Why we overlooked them, I don't know. There are a number of things that make it impossible to bring a man to the point of fitness for combat. We saw one case among the marines. Every time this man fired his rifle he was laid up with a lame shoulder. When we examined

the man he had absolutely no muscle padding in his shoulder. He had had infantile paralysis when very young. When he fired he hit the great tuberosity of the humerus. You can not make that man over so that he can fire a rifle; you have to assign him to some other job, don't you see? In your special training battalions you have time to assign a man like this. Such a man would be a perfect machine gunner, for instance, or he could do many other things—clerical work, work in a labor battalion, or take one of a great many other jobs in the Army which are open. So you have in such a center a place for studying and classifying men who are not going to be of full combat fitness, and you have them long enough to determine the stuff that is in them.

That is a part of the work of the orthopedic surgeon, and you will realize it the deeper you get into this game. Those of you who haven't already been serving as battalion surgeons realize that there is a great deal of this work. Of course, it isn't done at the front; it should be done farther back, as it is going to be done; but you have in the advanced zone to-day a number of men who are a nuisance to their organizations. There we should have men who can be depended upon to go over the top.

These organizations of reconstruction are called special training battalions. The place in which they are cantoned isn't even called a convalescent camp. There is no special sick call. It is a military unit like all others. They have Army discipline. In fact the whole atmosphere is that of a military camp.

Now this is the solution of the problem, as I see it. Flat foot is a thing that you needn't bother your head about; that will take care of itself. Remember, please, such things don't go in the Army any more. These special training battalions will get them fit and do it quickly and efficiently. And remember once you get a man fit he will never lose that military bearing and appearance. To show that this is not a too hopeful view, let me tell you a story: A number of years ago a British retired lieutenant general came to see me in my office. We had at that time a kind of doorman we had picked up in one of the clinics. He was down and out. We had him under our care for a couple of years and then gave him a job in the office as an extra man around the place. This man opened the door for the general as he came in and indicated to the general the room in which he would find me. The general came in my office and said: "Where did you get that fellow? He has been in our Army." I said: "I don't believe he has, General; he has been in this country for 13 or 14 years." But the general repeated: "He has been in our Army." When he went out John opened the door for him, and the general said: "What regiment were you in?" John came to attention and told him. I asked the general how he knew. He looked at me with an expression of infinite pity. "Why," he said, "Doctor, once a man has been in our Army he never forgets it." Now, there was a man who had been in our country for 13 or 14 years; had knocked around hospitals for a couple of years; was all in, down and out, but yet he carried something with him that made that general interested to know what regiment he had been in. He recognized something that couldn't be taken out of him. It is not unreasonable when you stop to think what it means.

As to the organization of the division of orthopedic surgery:

The chief surgeon has a director of the division of orthopedic surgery. Then there are assistant directors who are given responsibility for certain parts of the work. In the divisions and in each of the brigades are men who are held responsible by the division surgeon for the proper splinting of fractures, for instance, as well as for the proper shoeing of the men. If a man gets trench foot this designated officer is held responsible and expected to report to the division surgeon. In the combat divisions these special medical officers are placed well forward and are given the responsibility of seeing that the splints, which are made to standard, are placed in regimental aid stations, etc.; not only that the splints are there, but that the stretcher bearers and ambulance men know how to use them and do it well in every case. Thus the division surgeon has some one whom he can hold responsible for that specific thing. We have juniors in each brigade under them, all the way along. In the replacement divisions we have our own officers whipping men into shape. All this force is supervised by assistant directors whose duty it is to go forward into the dug-outs and see that everyone is doing his special work. If organizations are having too much trench foot, or something else bearing on our work, the division surgeon is informed of it.

In this way things can be checked up before they get by. These men also have the responsibility for proper transportation of orthopedic cases, not only from the front line to hospitals but also on hospital trains.

Of course, there are surgical problems involved in this, and Major Finney has probably told you about them. The work, of course, is largely joint surgery; and since there are a great many mechanical problems connected with this, Major Finney worked out a scheme by which we place orthopedic surgeons in the evacuation hospitals who know the work. On the hospital trains, at the request of Colonel Stark, we have put an orthopedic surgeon because he says he wants some one there who will be responsible for the joints and bones in transit. In the zone of the interior the work is divided up between the general surgeons and orthopedic surgeons. These things are of more importance probably than a good many of you imagine. A man may lose his leg not because of a bullet wound or smashed femur—the injury may not be the main thing that makes him lose his leg; the transportation of the man may be what causes it. For that reason the splinting is being done just as far forward as we can get the splints—even to No Man's Land. You want to get them on as soon as you can so that the work later to be done on that man will not be obstructed by any damage to the part en route.

Army Sanitary School No. 102.

VISIT TO THE TRENCHES, LEFT SECTOR, OF STUDENT OFFICERS, ARMY SANITARY SCHOOL,
SECOND SESSION

GROUP UNDER COLONEL ASHFORD

The left sector was the scene of a violent engagement which was one of the most historic of this war. We reached the headquarters of the division surgeon, M. Thoris, in the early morning and set out for our visit to the trenches. We reached a canal by motor and left it to walk along the opposite bank to a small relay station of the G. B. D. in the reverse side of the bank, right near the bridge crossing the river. It was a point of embarkation of patients on motor barges holding 20 patients, for a second relay farther down, the point of debarkation from which these patients were forwarded over a motor road by ambulances to the main G. B. D. This was necessary, not only on account of the distance, but because the canal here was extremely dangerous, the banks being lined with artillery. In fact, as the barges were shelled by the enemy, transfer was usually made at night. The dugout here had one room, well heated and well protected from splinters. At this point we crossed the river. This was a famous crossing. Cæsar remarks in his commentaries on the great difficulties of this terrain, but here defeated the Germans after a hard-fought battle. The bridge was a military one, well camouflaged but in full view of the Germans, who gave it their most careful attention as we saw and later experienced. It was very frequently wrecked. After leaving a planked road built to cross the marshes, we came to the opening of the communicating trench, but the morning was a little misty, and the division surgeon stated that he believed it a propitious day to visit the abandoned tanks used in a recent battle. To do this we struck out in the open at a brisk walk with 50 yards distance between each two men. It is the only way to appreciate the difficulties of terrain plowed up by shells, and the completeness of artillery preparation will never be understood until one has had this experience. There was not a vestige of vegetation, and the shell holes touched they were so thick. We made a good inspection of these tanks, and then walked across country to the communicating trench leading to a battalion support aid station, reaching it just as the mist cleared away. The trenches here had no duck boards, but were wide, well built, and entirely suited for a narrow wheel litter.

The battalion aid post was in an old German dugout, with a narrow steep entrance requiring one to descend backwards. It was not commodious, but there were several galleries. It had electric lights, telephone, and stoves. The ventilation was poor and, while fairly well supplied, it was not a very good station. It was, however, clean and well white-washed, and its weak points were in construction, not neatness. Folding litter racks lined the galleries for recumbent cases.

The next battalion aid station was in a complete trench system captured from the Germans and was not only interesting but very well organized. The men were lined up for dinner and we had to squeeze past them to get on. The whole battalion here suddenly disappeared underground into a series of electric-lighted tunnels. The battalion commander showed us the Dutch furniture of the officer's messes, with signs in every direction that this or that was "verboden." It was especially "verboden" to enter certain galleries where officers were quartered. They had managed to drag up here a lot of furniture, and yet the whole system was much less roomy than the French or British, and damp and musty in addition. In this system was found the battalion aid station.

We now visited the regimental aid station, a plan of which is seen in M. Collin's treatise on "Organization and operation of aid stations in army corps and litter bearer groups." It was the very best regimental aid station ever shown a class of the Army Sanitary School. The descent was gradual, by good steps, but there was no vestibule for resting the litter while the first gas curtain was being closed behind. The gas curtains were also of doubtful efficacy, as they were two overlapping weighted curtains which were supposed to fall into place as one passed through; as a matter of fact they took four minutes to adjust them in a demonstration. The main gallery was wide and provided with litter rests against the wall. The room of the medical officer was almost luxurious, with its full-sized bed, mattress, sheets and pillow, easy chair, walls papered with a pretty design, etc.

Across the gallery was the kitchenette and dining room, which was just as comfortable. We were served hot coffee here in fancy cups, with saucers and silver-plated spoons, on a table with a clean tablecloth. In fact they made a great specialty of not only hot drinks but of hot food for hungry wounded.

A step or two farther was an office, and farther on an operating room which was well supplied with instruments, dressing, etc., and could easily handle major cases. There was a ward for 20 stretcher cases. Near the kitchen was a well, 30 feet deep, and the water is chlorinated before drinking. The men were clean, well shaven, and spry. This station was really capable of handling serious surgical emergencies—abdominal hemorrhages, chest cases, etc. The sterilizing outfit was good—there were even operating gowns. This dugout was a full 6 m. underground and was absolutely clean and neat. Every wall was whitewashed and everything in its place. This station would easily hold 100 cases sitting and lying, and had a good shock room for heating patients and performing blood transfusion. We saw one Thomas splint here. They had acetylene lights in case the electricity failed them, and the ventilation was excellent. No Medical Department enlisted personnel was quartered here, nor were they allowed to use it as a lounging place. These men had their dugout "next door." We were told here that the elaborateness of this station was all the more necessary as it took three hours to get a man this far after he was wounded and, as after leaving here there was a long distance to traverse before the G. B. D. was reached it was necessary to have some independent surgical resources. In fact this is a very bad sector indeed. The terrain is flat and in full view of the Germans, and as they held this position a long time themselves they know it. Besides withdrawal of wounded is limited to a single route, and a river has to be crossed as well as a canal traversed and the sector is very deep. Barrages fall with great regularity here and there, and men are thus held up on their way back. For these reasons relay stations of the G. B. D. are found every 1,000 yards on the route to the rear.

On our way back, we visited one of these, a very complete one where, as at the regimental aid station, not only hot drinks but hot foods were provided. Here we were given a demonstration of the Peugeot wheel litter modified by Colonel Thoris so that the wheels were under the litter in such wise as not to project beyond the sides of the litter. It was possible to use this vehicle all the way back to the bridge by the communicating trench which had been set apart for the medical department and so labeled. It was in excellent condition, and was kept up by the litter bearers of the division and appropriately labeled. Here also the personnel of the relay station turned out with Tissot masks and with full mustard gas clothing and mittens, the trousers having no fly and tape being provided for trousers' legs at ankles, waist, neck, and wrists, rubber boots were worn. Each man carried a bundle of sticks painted yellow to mark points contaminated by mustard gas shells and a Vermorel sprayer to treat same.

We had considerable difficulty in returning owing to shell and machine-gun fire, particularly machine gun at a second bridge over the river. On reaching the canal a hostile plane over us drew a lively fire, which ended in the opening up of batteries along the canal. We split up into two's and crossed the open ground to a ruined town where the ambulance head was in a dugout in the side of a hill.

Here we took the motor ambulance and proceeded to a group of three field ambulances, where we had a cordial reception from the officers who had prepared us a luncheon. To our great surprise, M. Chas. Richet, member of the academy, was staying here with them. This very active old gentleman has never been able to keep away from the front since the war began. He returns to Paris every now and then, but he is usually to be found with the men. His frank admiration of our country and soldiers, it was easy to see, was very genuine.

This hospital was a rival of the one seen yesterday and is certainly a close second in neatness, efficiency, and completeness. It was M. Okinezye's operating unit. It was well in range, and a shell not long ago burst in one of the buildings and killed five surgeons, although the place is isolated from all dumps and was plainly marked with a Red Cross. The grounds were beautifully kept and were the park of an old château, which was the administration building. In this building were also rooms for sick and wounded officers. The hospital accommodations were furnished by Bessonneau tents and Adrian barracks, which were revetted against avion attacks.

The same general arrangements were made here as at the twin group seen yesterday. There was an operating group, with its *groupe complémentaire de chirurgie* (portable radiologic equipment), a hospitalization section, a triage, and an evacuation section. The shock room apparatus here was elaborate, the hood had a window out of which a man's arms could be thrust while he was being heated, facilitating pulse taking, transfusion, etc. The hoods were of canvas heated by electric light bulbs. The head was always left outside. We were told that the temperature can be raised this way to 55° C. and that if a kerosene lamp with a stove pipe is substituted it can be raised to 35° C., an alcohol lamp will raise it to 30° C. The radiographic and operating rooms were clean and comfortable, besides being exceedingly well equipped. The latter rooms were fairly glistening with white enamel paint. The hospital was lighted by the portable radiologic group.

The commanding officer of this ambulance isolated all of his streptococcus cases in one ward, a Bessonneau tent well removed from the others. We saw a good pathological and bacteriological laboratory here, and it was evident that keen liaison with the surgeons was being carried out. All wounds are carefully cultured. In quiet times they keep all patients they can and, in fact, it was an evacuation hospital of the first echelon. It was at the time pretty well filled with serious cases. Some of these were remarkable, especially the chest and abdominal ones. There was an X-ray operating table in this operating group, with a fluoroscopic bonnet for multiple lodged fragments. The sterilization plant was perfect. The personnel, except the officers, was billeted in the near-by village. The triage was as usual, reception room (in a Bessonneau tent), preoperating room, shock room, then the two operating rooms, with sterilizing room and X-ray room (referred to as the operating group), all connected by heated covered passages. Everything about this place was neat, tidy, and clean. The floors were sanded. The triage had thorough arrangements for giving incoming patients for evacuation a square meal or at least hot drinks. The kitchen was in a wing of the château, and the food was excellent in quantity and quality. In this hospital, as at the one seen yesterday, great pains had been taken to make it ornate and pleasing to the eye. Here a remarkable frieze was seen and murals painted by a noted artist who was for some time a patient. The especially notable feature in both of these hospitals was the excellent spirit of the medical officers toward their patients. They worked hard, had no complaints, made the most of what they had, and got splendid results. The men had perfect confidence in them and seemed proud of their wounds. Fine spirit of cooperation and confidence in scientific work.

After leaving here we visited another ambulance group in a cantonment area for gassed and slightly wounded. The gas station was being completed. It was on the general plan already described. The triage here was very elaborate. It was for the slightly wounded and they were passed after this triage directly into a large Bessonneau hangar prepared mainly for "sitters." In connection with this was a complete operating group—operating

rooms, sterilizing room, radiologic room, as well as shock and preoperating rooms. In this town, which was a divisional rest cantonment, was a divisional bath station, the section d'hygiene corporelle, described elsewhere. The dirty underclothing is sent to a near-by town for laundering. This tent bath station was near a small stream on the outskirts of town and is the first place visited by troops returning from the trenches to rest. The floor was of cement. The outer clothing when it comes out of the sterilizer is warm, but not wet. They say they can take care of 2,000 men in 24 hours. The French soldier needs no bulky barrack bag with its extra suits of underwear, stockings, and shoes. He comes to look at the bathing station as his surplus kit. Moreover, torn and damaged clothing can often be repaired here. There is a barber shop connected with this bathing station. The whole station can be set up or taken down in 12 hours by 8 men.

GROUP UNDER COLONEL PORTER

The ground was covered by Colonel Ashford; report preceding, as this group made the same trip, but on another day, January 29. Only additional notes will be made:

G. B. D. relay for embarkation on canal.—The room for receiving patients was furnished with 16 bunks, heating apparatus for shock, and was prepared to dress wounds. It was lighted by acetylene lamps. It also had another passage capable of holding 30 more patients. Near by was a set of dugouts for the divisional stretcher bearers (144). They were within 1½ miles of the front line at this point.

Medical department trench for evacuation of wounded from advanced relay of G. B. D.—It was a model of condition and convenience and was wide and drained on the side. The wheeled litter used here could get men to the rear in this trench on the run, as it was well sprung; the wheels, being underneath, could not knock against anything, and it was light. The signs pointing the way were well painted and in relief so that they could be felt with the hand on a dark night.

Regimental aid station.—There was a separate mess room and sleeping quarters for non-commissioned officers.

Second battalion aid post, described as being in a tunnel very thoroughly equipped with roomy beds, litter rests, warming apparatus, and could accommodate 100 patients. It was lighted by electricity. There was a small operating room apart from the dressing room. This aid station was connected by a gallery with the kitchen and dugouts for quartering and feeding the Medical Department enlisted personnel, who were never allowed to take up their quarters in the station itself, M. Thoris's rule in this sector (and a mighty good one, too). A straddle trench latrine screened by burlap was seen here.

The last G. B. D. advanced post was a sandbagged shelter in the side of a hill—not really a station. It was near an artillery position and was directly exposed to shell fire. We walked from here one-half to three-fourths mile farther back to the nearest point to which ambulances were permitted to come in the day.

Field ambulance group of M. Okinczyk (capacity 800 beds).—Many donors kept here for blood transfusion. All division motor ambulances held here in the courtyard. We saw an American ambulance section here.

Ambulance group for gassed and slightly wounded (capacity 600 beds).—Siek also kept here. Buildings were of frame except administration building, which was a house, as it was in a town.

Remark of one of the student officers.—"It was very evident that the working out of the method of evacuation as laid down for the French Army is departed from in practice. There was a great deal of individualism in the manner of conducting these posts. Good officers had good posts and bad officers had bad posts. The matter of more direct evacuation was more or less freely discussed with French surgeons, and it was fairly generally conceded that more direct evacuation to a definite place of treatment would be an improvement." This division surgeon stated that he secured everything he wanted because he never promised anything to anyone without making good.

Army Sanitary School No. 103.

TRIP TO TRENCHES, LEFT SECTOR

UNDER MAJOR M'DONALD, MAY 11, 1918

Members of group: Major Neer, Captains Smith, Chase, McCalman, and Aldrich.

Left at 4.30 a. m. and met the division surgeon and the regimental surgeon of the Nth Regiment of Infantry at a small deserted village 5 km. in the rear of the first line. After a short explanation of the disposal of the Medical Department services in this sector and a demonstration of the map presented by the division surgeon, the party started for the trenches, having as their objective a battalion aid station of the second line. The weather was cloudy and misty and visibility low; therefore we were able to approach within 500 yards of this battalion aid station before entering the communicating trench.

After passing through about 500 yards of well-constructed communicating trench, we came to the battalion aid station in question. This was in a dugout with 10 to 12 meters of overhead cover. There were two entrances, with a 30° slope straight down. Over each entrance was, crossed, a French flag and a Red Cross flag, a gas-alarm bell, and a Klaxon horn. Each entrance was protected from gas by two curtains placed far enough apart for a recumbent patient between, and, in addition, behind each curtain was a swinging door of wooden frame and canvas filling.

In the receiving room there were folding bracket litter supports attached to the wall on either side, there being three such, one above the other. There were also benches for sitting wounded. On the right of this entrance was the dressing room, in which was a table, a large supply of surgical dressings and antiseptics, and an oxygen-administering apparatus. There was also a 3 per cent solution of bicarbonate of soda for the eyes and mouth in vesicant gas cases. Ipecac was also noted among the drugs for the treatment of such cases. The oxygen was stored in 300-liter tanks. There was a Vermorel spray for the spraying of walls and cleaning the floors of the dugout in case of gassing. This, however, was very little used, as the regimental surgeon stated that he preferred fires and gas fans. There were also 300 masks here as a battalion reserve. Draeger apparatus was used for CO, and a Tissot mask was also seen. In the large entrance hall there was a supply of rubber boots and gas-proof clothing, with mittens, for the men who handled Yperited cases, as well as a supply of ordinary clothing for patients; 20 to 25 cases could be accommodated in this dugout. The operating room was 15 by 18 feet, and porch-curtaining material was used for splinting of small bones. There were 4 men seen on duty, 1 medical officer and 1 auxiliary medical officer who had been a medical student only two years. Four litters were seen here, and one was set up on a trestle in the dressing room. This station was especially neat and orderly; the walls were well whitewashed, and the floors, walls, and ceiling were wood. About 50 yards from the entrance of this station there was a small bomb-proof shelter used as a bathroom for vesicant gas cases, it being necessary to free these men from vesicant gas before they were taken into the aid station. The personnel of the station slept in near-by dugouts and not in the station itself.

Leaving here, we followed the route of evacuation of wounded to the rear through the communicating trench. At night wounded were received by motor ambulances directly, but during the day it was necessary to carry them on litters a distance of 2 km. to the nearest post principal of the G. B. D. This entire distance was covered in the trenches on clear days, but on days of low visibility by wheeled litters on certain paths. About halfway from the aid station to the G. B. D. post was found a small post of the G. B. D. acting as a stretcher relay station. This was quartered in the ruins of an old mill once used by the boche. Litter bearers from the aid station carry to this relay and return, and the patient is forwarded by the relay to the G. B. D., which is about a thousand yards away. The principal G. B. D. station corresponded to our ambulance dressing station. To it the wounded were brought on the standard litter or hammock, through the communicating trench; when conditions permitted, they were brought on wheeled litters from the relay post mentioned before. This post was established in a large cellar in the ruins of a small village; there was room for 18 recumbent wounded and three or four times that many sitting. The entire division had two of these ambulance posts, both of which were ambulance heads. This one had a cave for

men who were temporarily unable to proceed farther. A second cave led down from the first and was proof against all save heavy bombardment. The station had hot-water bottles, dressings, and medical supplies. There was a dressing room; also a small room fitted up with warming devices for combating shock. One or two motor ambulances were kept stationed in the immediate vicinity of this dressing station, but the wounded were not delayed at this station if in condition to be transported farther to the rear. Only emergency surgery and treatment for shock was provided for here. The village in which the G. B. D. is accommodated is in ruins.

From this point the wounded were evacuated by motor ambulance to a field ambulance 7 or 8 km. to the rear.

From this point we returned to near the point we had first left to visit the regimental aid station of the Nth Infantry Regiment. This was in an old château 4 km. in the rear of the first line. Owing to its location and distance from the front it was not being used for wounded, but served as a rest station for slightly sick who could be treated for two or three days at that place. There was a ward with eight improvised beds, a gas room containing solutions and medicines, clothing, etc., for gas cases, and a main ward room. It was located in the cellar; both entrances were gas-proofed with curtains, and a revetment wall was placed in front of the main entrance to protect it from shell fire. There were several small chambers in this cellar in addition to the large ward room. In a small room were noted supplies of dressings, clothing, etc. There were no patients here, as this sector is very quiet, although battalions were in battle formation expecting trouble. As a matter of fact the regimental aid station is acting here as a sort of field hospital.

COLONEL ASHFORD'S GROUP, MAY 12

Left at 4.30 a. m.; arrived at the town described by Major McDonald, where we were met by a lieutenant colonel, a division surgeon of an English division, who was there with his adjutant, a captain, to take over from the French. We had met before at the British front. He accompanied us in our inspection. This was in charge of the retiring French officer, who represented the division surgeon, Colonel Thoris, away on leave at the time. We walked directly to the battalion post of the second line visited by Major McDonald's party. This post was protected by a low ridge, but it was in plain view of an observation balloon. The day, however, was cloudy. The battalion aid station was stationed behind the main road from ——— to ———, and was at the junction of two communicating trenches. It was known as the battalion aid station of St. Georges, and was a model, as are all the stations with which M. Thoris is connected. The road was camouflaged and the post was very deep. The medical officer in command gave us a most excellent talk on battalion aid station work. The criticism of this dugout was that there was no horizontal landing between gas curtains for a litter, but a second gas curtain was interposed on the way downstairs. There were several Tissot masks for all attendants. The dressing room had a good supply of drugs, and sutures and ligatures for tying arteries. There were 300 made dressings on shelves, a supply of medicines, antitetanic serum, a box of general operating instruments, an amputating set, and a tracheotomy set. The battalion surgeon stated that he never did an amputation unless the limb was dangling; but if this place is cut off by a barrage they can perform necessary emergency operations. He stated that there is one dentist to each regiment, but that he is left in the rear in the rest station when the regiment is in the line.

The Thomas splint here was a modified Blake with a sliding foot piece, which is of no account. At this station the fêche or diagnosis tag only is made out. The tourniquets used were the Esmarch, but a large rubber tube was preferred. The latrines were outside of the dug-out in a communicating trench. A reserve tank of water was in a trench leading off from a traverse.

A modification of gas mask M² for giving oxygen consisted in piercing it and introducing a catheter, which was connected up with the source of oxygen. For chlorine cases they give hypodermically one two-hundred-and-fortieth of a grain of atropine, or ether or camphorated oil hypodermically, or emetine in one-sixth of a grain doses. If there is edema of the lungs they use wet cups. The treatment of the mustard-gas cases is thorough and includes

washing the eyes with bicarbonate and the body with alkaline soap. Such cases have their clothing changed in a separate dugout nearby. These cases can usually walk at first, but are transported as sitting cases if constitutional symptoms come on. In periods of calm, sick call is held here and the men are brought in in a body. A sick man could even be left here a day or two, as there is usually plenty of room. If they do not get better they are then sent back to the regimental hospital, with a capacity of 40 beds, where they may stay 15 days. During a push, if they need to be evacuated, they are sent to the rear to the divisional rest station. There were 12 full sets of mustard-gas clothing with boots for the men. Shell holes are disimpregnated of mustard gas with the Vermorel apparatus.

At the battalion aid station, St. Georges, antitetanic serum is given, always. We noticed two 300-liter and one 600-liter oxygen tanks. The personnel of this station is 3 medical officers, 1 chemist, 1 sergeant, and 28 men, of which 16 are kept in the line with the troops and 12 here. All of the heavy material at this station is considered as trench supplies that can not be moved. They have the exchange system in this sector; what is taken away is replaced by the organization replacing it. The Draeger apparatus is furnished at the rate of four per battalion. They last half an hour and are nothing more or less than small oxygen tanks, used especially in artillery saps where CO gas is so deadly.

At the town of ———, which was entirely in ruins, we saw the C. B. D., which was an advanced post in echelon and next to the last in the series, the last being the main one. There were 1 noncommissioned officer and 20 men on duty, and at this place were kept two ambulances. The cellars in which this post was accommodated were proof against 6-inch shells. It had folding gas doors and provisions were made for deshoeking patients and for emergency operations. Hot drinks were furnished, and there was a receiving ward for gassed cases. Dressings, litters, etc., were abundant, and we noticed a modified Peugeot wheeled litter. There was a separate room for sitting wounded. This post was being taken over by the British at the time and their ambulances were there.

From this place we proceeded to the main G. B. D. post, the last of the echelon. This would serve as a model for any ambulance dressing station. It was on a height, but in an excavation which hid it and prevented a sky-line view by the enemy. As a matter of fact it looked like a fort, and every entrance had its parados of sandbags. It was clean, well white-washed, and had 30° slopes to its entrances, which were straight. There was plenty of room for 60 or 70 patients and all matériel necessary for emergency treatment. The matériel included an elaborate plant for treating gassed cases, and an equally elaborate canteen for hot drinks and food for wounded. Two ambulances were always kept on duty here.

VISIT TO RIGHT SECTOR MAY 11, 1918

Breakfast at 4.45 a. m. Left Bouleuse at 5 a. m. Arrived at destination in about half an hour by motor. This was the headquarters of the division surgeon. The G. B. D. had three subposts; one for gassed cases, one for slightly wounded, and one surgical station, in connection therewith. At this place triage was accomplished. There was accommodation for 80 patients in the cellar of a bombproof house. There was a dressing station and shock room and a reception room.

We now visited the regimental poste de secours at Rome. This station opened directly into the regimental commander's headquarters and was commodious and ventilated through a broad gallery. To give an idea of its comfort, the medical officer's living room had upholstered furniture in it. There were accommodations for 25 lying and 40 sitting cases; the sitting cases being provided for on sheets folding against the wall; the lying, on litter racks which let down from the wall. Hot sandbags were provided; extra clothing for mustard-gas cases, and Thomas splints. It was lighted by miners' lamps.

We now visited the regimental post and special surgical advance post at ———. This was a dugout like the rest, in a pretty well shelled place, but at the time it was fairly quiet; they had occupied a cut in the side of the sunken road at the entrance of the dugout. This open gallery was merely splinter proof, but it offered an airy place for sick call, for slight dressings, and for booking the men. It was an effort to get away from the dugout life, even with a certain amount of risk. The feature of their dugout was a room for intransportable cases and an operating room connected therewith; here serious operations are undertaken on non-

transportable cases, the surgeon being telephoned for to the headquarters of the division surgeon; he ordinarily succeeds in getting here in about 20 minutes. It is perfectly evident, however, that serious operations should not be done here, and that it serves no very useful purpose, save for individuals at the expense of the mass. Here we heard that the saccharate of lime was made by adding 25 gm. of lime and 60 gm. of sugar to 1,000 c. c. of water; they used it extensively for mustard-gas cases with success, and did not use it only for the eyes, nose, and throat, but also bathed the patients with a 10 per cent solution of the mother liquor, as per above prescription.

We now visited a regimental aid post on a main road and under the very guns of a strongly fortified German position. The Medical Department is holding on to this place by its teeth and nails against heavy shelling, but it will have to be given up, as it is exposed to view and therefore invites fire. After all it is not a strong post and only the most urgent dressing can be done in it, but it was convenient and avoided a long detour.

From this place we walked through the trenches to the battalion aid post known as "la Marguerite," going out into the open over a path instead of by the devious communicating trench. By this route we had a good view of the strong position referred to. It was not over a thousand yards distant, over a perfectly flat country. The weather was slightly cloudy, or this direct path would have been impossible. There was very little in the battalion post to specially mention. The dressings were not gas proof, nor was there a clothing reserve for mustard cases. There were, however, 24 suits with boots for gangs working in impregnated spots. Three tanks of 150 m. of oxygen were kept here and a reserve of 136 masks. The overhead cover was excellent, there being 14 m. of earth. It was also large and could accommodate 18 lying and 50 sitting.

From here we proceeded to the canal, which was practically the front line of the French and the scene of many a coup-de-main, the earth thrown up on either side of the canal serving as a fortification. In fact they had had one the night before. They were drenched with gas and exposed to constant shell fire most of the time. The battalion aid station which served this sector was known as DeSage. Its capacity was 20 recumbent and 20 sitting. According to the medical officer in command, a very young man and still a medical student, there had never been any time to fix it up on account of the activity of the sector. His post was not whitewashed, there were no gas-proof boxes for dressings or food, and it seemed unusually damp. They had, however, pretty good protection from fire, with 6 m. of earth overhead. He evacuated his patients in hand cars at night over a narrow-gauge road to the G. B. D. advance post.

This was the last place we visited, and it was in a town that was literally shelled to bits. Here, also, was the battalion post of the second line, with a capacity for 32 recumbent and as many more sitting. It had an extra room for bathing gassed cases and changing their clothing. The medical officer in command had made a praiseworthy effort to utilize all the space for lying patients by placing the litters on racks, three tiers with only a half meter between each, but as the shelter was lined with elephant iron the space seemed too small, and once the litters were packed in with difficulty he had even greater difficulty in getting them out.

Army Sanitary School, No. 104.

VISIT TO TRENCHES, TO A FIELD AMBULANCE GROUP, AND TO A LARGE H. O. E., MAY 13, 1918

Left early on a misty morning to meet General Route, chief surgeon of the fourth army, who was to personally take us with his corps surgeon to a sector southeast of ——— in the ——— Valley. This was an interesting sector, inasmuch as it was through here that the medieval and early invasions of the Huns had taken place. Owing to the cloudy day, we were able to go over a road which could not usually be traveled, as it was high up on the edge of the hills defending the south of ———, in full view of the Germans, who lay 3 km. away just below, and we were able to fully make out their positions.

We met the general at ———, where he was waiting for us with his automobile. We changed to British ambulances, and proceeded by the ——— road to ———, where there was a regimental aid station which was at the same time an ambulance head, and from there

to an advance post of the G. B. D. The party had been divided into two groups of 10 each, as it was a fine day, and the ground was flat and observation was good. ——— was the R. A. P. for two battalions, one on the right and one on the left. We went to the right of the sector; the other party to the left. We rode in an ambulance to an advance G. B. D. station and there took the communicating trench, walking about 2 km. to the battalion aid station of the first line, passing several relay stations on the way. The trenches were in very good condition, although recently constructed, as this sector had not been long organized. The battalion aid station which we visited was almost beyond criticism. It was deep, with a good 10 m. protection, and well arranged, with whitewashed interior and two entrances; it had electric light, ample accommodations for 50 men, and was well equipped. It did not differ from the one we saw in Colonel Thoris's division. This battalion aid station was 2 m. wide and 25 m. long. It had a dressing room and separate quarters for sitting and lying. It was divided into four long compartments, each about 20 feet long, one being for gassed cases. Three wounded men were seen here at the time of our visit.

On our return we saw an advance G. B. D. post on the firing line side of a bridge over the canal. It had been established there owing to frequent shelling of the bridge and consequent interruption of evacuation for some hours. General Route said that he was suppressing his regimental aid posts to simplify evacuation. He said that advance surgical hospitals were generally not feasible, and it was better to get wounded back promptly to a hospital well in the rear. The main G. B. D. of this sector takes care of two divisions. They were expecting an attack and are in battle formation, one battalion behind the other.

We now proceeded to a very handsome group of three field ambulances for lunch. This group was really a small evacuation hospital of the first echelon. It was immobilized in barracks and tents. We were met in front of the building, where they had raised an American flag, by the corps commander, who had come down purposely to greet our American officers, and he spoke to us and gave us a very cordial welcome. The commanding officer of the hospital first took us to the triage, where he had his entire personnel of the hospital drawn up, officers and all. The grounds and buildings were in perfect condition and very ornate. A great deal of landscape gardening had been done to make it look attractive with flowers and walks. The site was a particularly good one for this, as it was surrounded by woods.

Particularly noticeable were the shock rooms, which were about the finest we have ever seen. There was no particular difference between this hospital and all the others, except that it was as perfect as one could wish and was considered a model of the first echelon evacuation hospital, although it still preserved its name of "ambulance."

From here we were taken to the large evacuation hospital of the second echelon, ———, 18 km. from the front, with a capacity of 3,000 patients. The feature of this hospital was that as one entered the main road which divided it, on the right-hand side were all of the offices, supply depots, etc., and on the left, beginning from front to rear, were the operating section and the evacuation, and at the rear the hospitalization section. There was a special quarter here for gassed cases, with the usual bathing facilities, etc. Their record is 600 in eight hours. They are separated into the vesicated and the asphyxiated cases, and the latter are housed in a Bessonneau hangar. At this station we were told that for outer clothing impregnated with mustard gas, 10 minutes at 90° in an autoclave is enough if they are aired three hours afterward. They can then be immediately put on without danger. General Route remarked that the Bessonneau tents, small as they were, did not stand the wind as well as the Bessonneau hangars; that he had 80 of them blow down in Salonica and his Bessonneau hangars stayed up. There was a bathing section here for the sick and wounded only. They had had only two cases of spirochetal jaundice in this hospital. They can do 120 major operations a day, which is the same as in the H. O. E. at Mont Notre Dame. There is one operating room set apart for septic cases.

Army Sanitary School No. 105.

WAR SURGERY

By Major Brewer, M. C., U. S. R., April 18, 1918

It is a great source of pleasure and gratification to me to come here to-day and meet you all again. As I said the other day, the first opportunity I had of seeing you, that I am here not as your superior officer, not as one who for any reason claims to be a past master in the art of military surgery, or to know any more about military surgery, or as much, as many of you; but I am here as one who is with you, a student of this problem, and what I want to say to you, is simply to convey to you certain impressions that I have gotten as I have gone along in my work.

It has been my privilege to be here in this country on two occasions. One in 1915, when during that summer I was in charge of a French base hospital near ——. Coming here a second time, about a year ago, I had the privilege of serving with the British at the base and front; and only during the past few months, since the 1st of January, have I had the opportunity of serving with our own people. But during that time I had opportunity to learn a good deal of the differences between the work of a civil practitioner and the work of a military surgeon.

Now, the first duty, as I take it, which should guide everybody who is to practice military surgery is this: His first duty is to seek to restore every wounded man to the line in the shortest possible time. Now, that in itself is entirely different from our conception of civil surgery. Take, for instance, a man who has had a severe injury. He comes to the civil surgeon; he is under him for a long period of time; he may have a painful operation and a painful period of convalescence. After going through that, the civil surgeon feels that his patient ought to have a change—to go to California for a while, or to take a trip to the south of France—that he is certainly entitled to a rest. All this is the last thing a military surgeon must think of. The minute that man is able and fit to be restored to the line, it is his duty to send him back—not before he is fit, but the minute he is fit. We must forget everything else. Why is that man here? He is here to win the war, not by being on a vacation or enjoying a leave of absence but by being on the job the first moment he is able. Therefore, we must neglect, throw aside the humanitarian side, and all idea of giving a man something in the way of repayment for what he has given. Our duty to our Government and to the allied cause is to restore him for front line work just as quickly as possible.

Now, the wounds in this war which are the chief causes of prolonged convalescence or of permanent disability, differ from the wounds of civil life and, indeed, from the wounds of any previous war, in their general character and extent, in their amazing multiplicity, in the shocking and paralyzing effects of high explosives, in the cruel and extensive lacerations of tissue, and in the deadly virulence of the infection which accompany them. The world has never seen such wounds. Surgeons have never before felt the inadequacy of the means which they had and employed in the past to combat septic infection. Now, that's a strong statement, but I believe it is absolutely true. I think anyone who has seen the surgery in the early part of this war, and has seen the able men giving their best effort to combat the type of sepsis which we see here, and saw them fail absolutely, will agree that it was due to the peculiar virulence of the infections which were found, which the world had never seen before. You have seen gas gangrene here, certainly. In civil life I have seen five cases that I personally treated and of these four were fatal. I succeeded in saving one. About once in four or five years I would see a case of gas gangrene. When I first came over here I asked about gangrene. "I can show you as much as you want to see. Pretty fatal; but we have in this hospital 27 at the moment," was the answer. I looked at these 27 cases and I was surprised that they were living. One man had a thigh injury in which the gas gangrene had spread so quickly that the tissues were involved halfway to his thorax. Well, they amputated at the hip joint and the man got well. I never saw a case in civil life that had gone a third that far that had gotten well. We simply cut off the leg and let it alone and the man got well. I think perhaps one of the reasons for this is that the men are in the most superb physical condition. You take a man who has lived all winter in the trenches, who has had plain food, hard exercise, and practically no alcohol; if he survives he is going to be in pretty good physical condition, and that was so with the men I came in contact with that

summer. They had a superb resistance, such as I never saw before. That is the reason they recover from these infections. Out of that 27 cases of gas gangrene only 5 died, and the methods employed were crude. They are not the methods used to-day, but the men had that wonderful resistance. So I say the chief cause of delayed convalescence, prolonged invalidism, or chronic or absolutely permanent disability is infection. Now, I can't give you any statistics, but I simply say that if you consider all the factors associated with battle casualties, including the primary injury, the bone shattering, the hemorrhage, the delayed treatment, and the bad transportation facilities, infection is the thing that does more harm and prevents more men getting well and results in more deaths and disability than everything else put together. It is to a large extent a question of infection. Therefore, how best to prevent and combat infection? To avoid it in the early cases you receive, and to treat it, once it is established, is the biggest problem of the military surgeon; and it is a problem upon which has been devoted more attention than any other factor; and, I am happy to say, with a larger measure of success. I called your attention just the other day to the great difference between the general appearance of the hospitals in 1915 and now. Just to repeat: In those days there was practically no clean surgery. I think that in all the time I was on duty during 1915, I never saw one single wound clean, if we except two or three cases operated on, after the battle casualties had healed entirely, for a secondary condition. I saw one case in which there was an internal appendix which healed kindly. Another case of secondary nerve suture and one in which there was some accidental wound which required but two or three sutures, which healed without infection.

With these exceptions I saw no clean cases until after the wound had passed to the stage of healing granulation. Not one single primary, delayed primary, or secondary closure; and the results were those that led me to believe that the greater proportion of our grave cases would be evacuated as chronic invalids. Now it is absolutely different. The large number of cases that you see in the hospitals to-day show none of the signs of infection exhibited by those two years ago. What has been the reason for this? There are two chief factors. These two factors are, in the first place, the definite, operative treatment of these cases has been transferred from the base hospital to the hospital in the advanced area; and the second reason is the use of new and more efficient antiseptic agents. Now, at the beginning, both the French and the British believed that the best plan was to place their best surgeons in the base hospitals. Have the advanced area men apply the first-aid dressings and send them back to the rear, out of the reach of shells, and to the quiet of base hospitals for their final operative work, and that was the general practice at that time. But it was found that most cases, every case, perhaps, that reached the base hospital was already in the stage of infection. Infection was already established; there was nothing they could apply at the front to prevent infection; therefore, every large flesh wound, every joint wound, every penetrating wound of the chest or abdomen, if they got that far, came down in infected condition, and the base surgeons had to treat not only the battle casualty, but also the superadded infection. The result was exactly as I told you. That was the reason they could not clean up these cases by the methods which had in the past been employed, and the first step—or, rather, there were two steps which were taken almost simultaneously; one was the attempt to clean the wound by new antiseptics and new methods; the other was the gradual moving of their operating centers from the base to the front, so they could operate on these cases in a period which may be said to be the period of contamination but not, necessarily, the period of infection. You know what I mean by the difference. A contaminated wound has a potential infection, but it is not actually infected. In other words, the organisms haven't gotten into the tissues, and if you can remove this contaminated and injured tissue and get a clean wound you can get a primary union. If you wait until the organisms develop in the tissues, the problem is more difficult and you can not clean that wound without removing a large area of tissue, pretty much as you would remove a tumor. These two factors have accomplished much. Carrel and his great work on antiseptics, and radical operation at an early period, have resulted in bringing about a great change in the success of wound treatment.

Now, Major Finney has spoken to you about the men doing their individual work wherever they are stationed, and he spoke to you about the front-area men and how important it was for the front-area men to do first-aid and transportation work, and not operative work.

I can not emphasize that too much. I remember seeing at one time just what that means to the wounded men who were being brought in. I will give you a description, very briefly, of what occurred July 31 at a British casualty clearing station at which I was stationed, just to show you what the problem is like. It is very easy for a surgeon to take care of one or two compound fractures in a day in civil life; we have plenty of time and assistance to do what is necessary, but out here, at times, we get cases so fast that one can't handle them that way, and we have got to use all our energy, and ingenuity, and work as fast as possible, often with insufficient assistance and material to do work that is efficient.

The casualty clearing station of the British, as you know, is a general hospital of about 1,000 beds, on an average, with 3 or 4 teams—surgical teams—and 1 or 2 tables working; but during a period of expected activity they send and get additional teams. This particular hospital had 8 teams and 8 surgical tables running. In ordinary conditions of quiet we would receive an average of about 200 cases a day—some were sick, some were sprains, some were cuts and bruises, and a few battle casualties. But as soon as that battle commenced, we began to get a great many more severe battle casualties. In the first 24 hours after that push began, back of ———, we got 903 battle casualties. We handled all those men with 8 surgical teams and 8 surgical tables. Every man worked 16 hours out of 24, but we couldn't begin to do the work that ought to have been done. These cases were brought up in automobile ambulances as fast as they could be unloaded. The men were brought in on stretchers into the anteroom, where their clothes were taken off, and any case that could by any possibility be sent back to the base was redressed and marked "evacuation lying" or "sitting" and never reached the operating room at all. Only those cases whose condition urgently demanded operation were operated on. These cases were undressed, pajamas put on, wound area cleaned, etc., and laid in stretchers along in a line. Every case that was very badly shocked or wounded had preference. Every table was going just as fast as it could, all day and all night; and it was discouraging to get a compound fracture to which under ordinary conditions one would have devoted an hour and a half or two hours, and feel that you were jeopardizing the life of somebody else if you didn't get through in 15 minutes. I remember one afternoon the chief surgeon was walking up and down, saying "Speed up, speed up; ante-operation ward full and 65 cases lying on the grass outside." I just mention that to illustrate one point, and that is the conditions under which you have to work during a battle. If these men had not been brought back promptly a great number would not have received any treatment at all. It was because they had adequate transportation; the advanced-area men did it so well, that all eventually got back. Many of us doing that work felt that we didn't do our best work; too many cases to give adequate attention, the attention that we felt they deserved.

Now, another point. Just in connection with that I want to speak of the multiple injuries. That forms one of the most extraordinary and distressing things about war surgery—the multiple injuries. Now, if a man has a compound fracture, all right; you can take care of it. If a man has a gunshot wound of the chest, all right. A man may have an abdominal wound; another man may have a head wound. You can take care of those. But supposing one man has all of them, what are you going to do? Any one of them may kill him. It is a serious matter, and at the same time you know you can only operate a certain number of hours or minutes on that man. This is one of the most difficult problems. Just let me tell you of two cases:

At one time we were getting a great many compound fractures from war wounds. A man was put on my table in pretty fair condition; that is, a fair color and a good pulse. He had been badly shot up, but his pulse was pretty good. He had a compound fracture of the left femur, a compound fracture of the right tibia and fibula, a penetrating wound of the left foot, a compound fracture of the humerus, a chest-wall wound, and a very deep wound of the neck. Doing the best we could, it took 45 minutes to get that first femur properly dressed. His whole leg had to be shaved, he had to be disinfected; we had to make a long incision, make a thorough débridement, and put on a Thomas splint. That took a long time. It took 45 minutes, working as fast as I could, to put up that compound fracture properly. Then we tackled the fracture of the leg; that took 25 minutes; then the humerus; and by that time the anesthetist said "I am sorry, Major, but this man is getting pretty

weak and you will have to quit." Still you have got to operate, but you can't operate after he is dead. Therefore, such cases present a great many problems. In these multiple operations we very often go too far and the man dies. Take a bad abdominal case. A man was brought in and sent to the resuscitation ward, where they are subjected to the most advanced methods of stimulating treatment. It took 24 hours before the man had enough of a pulse to warrant an operation. That man had in addition a bad compound fracture and an extensive flesh wound. They brought him in. I knew at the time there wasn't much chance. It would take 35 or 40 minutes for the abdominal operation alone. However, we performed the abdominal operation—worked as hard as we could and got him off the table as quickly as possible. For 48 hours his life hung by a thread. After a while he got better. But if at the time we had attempted the other operation, he would have died. I want you to get some idea of the stress at times at the front, and the work which is done by the British and the French under those conditions. You can not expect brilliant results in these cases. A man is called upon to do many of these almost hopeless cases. One of the great problems is to decide what to do and what to leave undone in these bad cases of multiple injury. They form the worst group. One had to decide promptly. You judge what will kill him first, if the abdomen; take that. Compound fracture next; take that. If you can do both, well and good; if not, operate on one and let the other go until his condition improves. By good judgment, however, many lives can be saved. Now, out of 903 cases, 8 tables can only take care of 150 or 160. What became of the other 740 or 750? Some died, most went to the base, and many of them, probably 400 to 600, with minor wounds. If we could have treated these lightly wounded at once, we might get primary union, and they would go back to the line in a couple of weeks. Others would have taken a much longer time. As it was, all of these men went to the base, and all suppurated. It could not be otherwise, as we had only 8 teams. The best group to treat successfully are the lightly wounded. They ought to have the best opportunity for primary union. Not one of them had it. No criticism of the British at all, because no one feels more kindly toward the British or has a greater feeling of sympathy for their difficulties than I have. They did not have enough surgeons; they couldn't get them; and, therefore, thousands and thousands of men lightly wounded had to be sent to the base and their period of convalescence went into months instead of days and weeks. That we hope to be able to avoid in our Army.

Now, that brings us to the real topic, and that is the surgical consideration of wounds of the soft parts. Lectures on wounds associated with fractures will be given by others, and other departments will be taken up by other men. I want to speak to you about wounds of the soft parts. This has to do with the entire question of the treatment, the aseptic and antiseptic treatment of wounds. Let us first consider the different types of wounds. If I repeat, I am sorry—you may already have had it, but I think it is important to call attention to the difference in these wounds. The wounds made by rifle and machine-gun projectiles, are perhaps the least important, in case they do not strike some vital organ or vessel. Why is it? Because at the present time, the modern, high-velocity rifle or machine-gun projectile strikes with such force and passes through the tissues and separates the fibers, rather than tears them, because it is a sharp-nosed bullet and carries very little with it, and often does very little harm unless it strikes an important organ or vessel. You shoot a man through the chest with a revolver and he is in bad shape; you shoot a man with a high-velocity bullet and it may pass through his lung and give rise to the minimum of trauma. That is because it carries very little with it; it separates the tissues rather than lacerates, and it passes in and out and produces a minimum of harm. That is true also of a machine-gun bullet. If however, you shoot a man at short range, the initial shock does very much harm; it causes destruction of tissue out of all proportion to the size of the bullet, on account of the explosive shock you get at short range. Now, on the other hand, if that projectile is fired from a long range, it begins to slow up, and instead of entering nose first, or point first, it will enter sideways. That gives you laceration, much destruction of tissue, extensive damage to the structures, through which it passes, out of all proportion to the other. The safest length is between the two.

The shrapnel bullet has an entirely different effect. It is never of high velocity—always of low velocity. As the shell explodes—and its theory is to explode above the heads of troops—it spreads in every direction. It is a larger bullet and carries in more clothing and

causes more contamination than the machine-gun bullet. It is not as destructive of bone as the high-velocity projectile. I didn't mention in connection with the rifle or machine-gun bullet that when it does strike a bone it breaks it into numerous pieces. A shrapnel bullet will only make a very small amount of comminution.

Now, next, shell fragments. Shell fragments produce more wounds, I think, than any other projectiles which we encounter in military surgery. At one place, at the hospital at ———, in 1915, we estimated that 80 per cent of our wounds were from shell fragments. We didn't get the very lightly wounded. But we estimated that 80 per cent of our wounds were due to shell fragments or other high-explosive missiles from grenades and trench mortars. They are irregular, sharp pieces of steel or other metal which by the explosion are driven with great force a short distance, but on account of their shape they produce the most extensive laceration of wounds that we come in contact with at all. There is a great amount of mutilation of tissue, and the nearer the victim is to the explosion the greater amount of damage produced by these irregular fragments. Now they vary. They vary from very minute little particles which you sometimes find. The little ones are not important, and by little I mean about a half centimeter in length and very flat. These are pretty common; sometimes you see a man with 100 such wounds. They do little harm in soft parts, but they may penetrate the abdomen and make perforations that one can not see. In one case I could hardly make a diagnosis. The man had abdominal symptoms; he had every possible pathognomonic sign. We said he must have a posterior wound, but he certainly has an abdominal injury. I went right through the rectus muscle and as I turned the abdominal wall over I said "There is no rupture of the peritoneum." At the same time I was saying that, I heard ziss-s-s, and I said "That sounds like gas." I explored him further, and from a piece of intestine that looked perfectly normal, I saw little fine bubbles, three small perforations of the intestine which had evidently been made by minute pieces. I call your attention to this for the reason that you won't see it in the reports or textbooks. Many of the British surgeons had never seen it. Another case occurred that same afternoon. There was a small wound on the anterior abdominal wall. You could see something had passed in there. He had exactly the same symptoms. The only way we could detect the perforation was by the bubbling gas.

Now that is the smallest shell fragment. From there on they increase in size until we get them almost any size. Some, of course, kill immediately, and we don't see them at the casualty clearing station. I have, however, seen them 6 inches across. They make some of the most difficult wounds to treat. I remember one night, three bombs fell back of our hospital and one very close to an officer's tent, and a great big piece of metal hit this officer, went through both buttocks, clear down to the bone. It was an enormous piece of metal. We operated on him and he came out all right. These illustrations show that you may have every conceivable size and shape of projectile from shell fragments, and they produce most vicious wounds of the soft parts and the bone skeleton.

Bayonet or saber wounds—I don't believe you will see many of them. I have seen only one bayonet wound in all my experience. That wasn't a thrust; it was a strike. The man had a bayonet on his gun and he struck his antagonist down. As for a saber wound, I have never seen any. I suppose they occur. Certainly lots of bayonet wounds occur, but I fancy they never get back to the hospital. A bayonet wound is a thrust wound. Of course, that's the reason. You can not run a man through the abdomen and expect to get him back to a base hospital; and unless they are through the extremities you don't see them. I don't know what becomes of them.

Buried injury: When a man is in a trench or dugout and a high-explosive shell bursts near, it is apt to bury him. I have seen a great many men come into stations that were asphyxiated. These fellows had been buried alive and dug out. You must remember that a buried man is a man who has been partially asphyxiated and a mighty poor subject for a general anesthesia. Local anesthetic should be given if you can, but don't give that man a general anesthetic if you can help it. Of course, I don't mean a man who was simply tumbled over in the dirt; I mean a man who was actually buried. Another thing about this question of being buried: They are very often in a state of great apprehension and shock. Buried under a load of earth is a very shocking procedure and it is often fatal. Just the other day we had a lot of men out in the front line and the boche were shelling them pretty severely, and one shell struck the earth near them and buried 20 men. The others began to uncover

them. One man was taken out alive, then 6 dead bodies; then another shell buried them again, and as far as I know only 2 or 3 of the whole lot got out alive. Just remember that fact: They are not good subjects for anesthesia.

Another type of accident—the airplane accident. A great many air men have their planes disabled and come down and hit pretty hard so that they have a good many of ordinary results that you see in civil life. Simple fractures, compound fractures, yes, but most of them simple, and you also get a good many cases of profound shock from the suddenness of the falling, but principally they are cases in which you get simple fractures. You don't get very many of them, but they are very apt to multiply. I remember one case that impressed me very much; not from a surgical standpoint, but from the bravery of the man. The man was brought in and put on the table. He had a compound fracture of the right thigh, lower leg, and arm. He looked badly. Pretty soon he said, "Has my partner come in?" I said, "I don't know." "My observer," said he, "was with me. How is he? Is he still alive?" We got this man off the table. The next lad they brought in had a fractured femur. He said, "Is my pilot here?" I said, "Were you the observer?" and he said he was. I said, "Well, he's all right; he's alive." He said, "That's good; thank God; that's one of God's noblemen." I said, "Why?" He said, "I think he is the bravest man I ever saw." He said, "We were 16,000 feet in the air; we were engaged by two boche planes. The machine was shot two or three times, and finally they shot off half our left wing, also hit our engine and tank. We volplaned down and were able to get about 500 feet over the line. If it hadn't been for that man's marvelous skill we both would have been killed."

Army Sanitary School No. 106.

BLOOD TRANSFUSION

By Captain Hussey

(Lecture and demonstration, fourth session of the Army Sanitary School)

Blood transfusion, like many modern therapeutic measures, is an old idea which has been recently developed into a practical and easily performed method. As a matter of fact an attempt was made at blood transfusion as early as the sixteenth century. During the past 10 years many efforts have been directed toward improving technical methods for this procedure. These have been so successful that now it is quite possible for blood transfusion to be utilized on a broad scale.

In reviewing the many methods of blood transfusion extant for the most practicable one to be used under conditions of war in the hospitals of the zone of activity, a committee appointed by Major Finney, chief consulting surgeon for the American Expeditionary Forces, gave due consideration to the many possibilities. These methods fall into two general classes, namely, the direct and indirect. In the direct methods the blood is allowed to flow from the vessel of the donor into the vessel of the recipient. This is accomplished either by bringing the endothelial lining of the vessels of the two people into apposition, or connecting the vessels by means of an especially devised tube. One can not judge the volume of blood transfused and there are many possible misfortunes for both donor and recipient. Moreover, such procedures entail unusual surgical experience. For many obvious reasons the direct methods were considered quite out of the question, so the matter resolved itself to the consideration of the best indirect procedure. It was thought very necessary to keep in mind that whatever method would ultimately be decided upon, it should be one simple enough to assure the possibility of a large number of men being easily and quickly trained to perform it, one that could be handled by one man, yet one which would give the best results. There are two groups of indirect methods, one in which the unmodified blood is transfused, another which utilizes some anticoagulant, thus disregarding the time element of coagulation. The unmodified blood transfusion methods are performed by the means of especially designed mechanical devices or the use of syringes. Obviously it would be impracticable to expect to supply a large enough number of any special instruments on account of the difficulties of manufacture at the present time, the syringe methods require at least two men for their performance. Furthermore, all these procedures require a certain degree of dexterity in handling them which could not be acquired as quickly as is desired in the present emergency; hence any wide application of blood transfusion would be quite impossible. Obviously, then, some indirect method, using modified blood, had to be decided upon. Experience has shown

that sodium citrate is the best anticoagulant to use for this purpose. Although there has been some controversy about the relative merits of modified and unmodified blood transfusion, the use of the citrate method has been very favorably reported upon, and in the hands of workers who have had opportunities to use both methods the results compare very equally. The citrate method was decided upon and adopted for development to be used among the troops of the American Expeditionary Forces.

AMOUNT OF SODIUM CITRATE

Regarding the amount of sodium citrate one can use, it is necessary, of course, to use a sufficient quantity that will prevent coagulation and at the same time be not of quantity sufficient to be toxic. It is generally accepted that a concentration of 0.2 per cent of this salt will prevent coagulation. Different workers vary from 0.2 to 1 per cent concentration for blood transfusion. We use a solution containing a sufficient quantity of anhydrous sodium citrate to give a concentration of approximately 0.21 per cent. There are three salts of sodium citrate to be obtained from the open market, the anhydrous salt $C_6H_5O_7 \cdot Na_3$, one containing 2 molecules of water of hydration $C_6H_5O_7 \cdot Na_3 + 2H_2O$, another containing 11 molecules of water of hydration $2(C_6H_5O_7 \cdot Na_3) + 11H_2O$. We make a 42 per cent solution of the salt containing 11 molecules of water of hydration; 5 c. e. of such a solution contains 2.10 gm. of the salt, which amount is equivalent to 1.518 gm. of an anhydrous salt. When blood is taken from an individual for transfusion it is received into a bottle containing 100 c. e. of physiological saline to which has been added the 5 c. e. of citrate solution, it is intended that 600 c. e. of blood be taken into this solution, which will bring the total volume to 700 c. e. Then in 700 c. e. of the blood-salt solution mixture we have 1.518 gm. of the anhydrous sodium citrate, enough to give a concentration of approximately 0.21 per cent. If, as is sometimes the case, the full amount of blood desired is not obtained, the concentration will, of course, be higher, but the actual amount of salt of course will remain the same, so after all it is a question of the actual amount of salt that is given rather than just the concentration. The citrate solution is issued in glass ampules; these are prepared by first putting in the solution then sterilizing in the autoclave at 15 pounds pressure for 15 minutes; the ampules are then sealed in the blow flame.

DONORS

A very important consideration in blood transfusion is the selection of individuals for donating blood. First of all such individuals must be free from any communicable disease, such as syphilis and malaria. Beside this, there are certain biologic incompatibility of bloods of different individual members of the same species, so it is quite necessary to determine the compatibility of bloods before an attempt at transfusion is made. The serum of certain individuals contains bodies called agglutinins and hemolysins which cause either the agglutination or hemolysis, or both, of the cells of other individuals. While these are not always coexistent, hemolysins never exist without agglutinins. It has been determined by a number of different workers who have matched the bloods of several thousand different individuals that all persons fall into one of four groups, the percentage of these groups are about as follows: Group I, 5 per cent; Group II, 35 per cent; Group III, 10 per cent; Group IV, 50 per cent. A very convenient way to impress your mind with the possible incompatibilities of these different groups will be to follow this diagram. Assuming that the sera contain bodies we call agglutinins or hemolysins represented as *a* and *b* and, that the cells contain substances we call agglutinogens or hemolysinogens represented as A and B, and that similar bodies act on similar bodies, then assume the distribution of these bodies in the cells and sera of the members of the different groups as follows:

Group	Cells	Serum
I	A, B	-----
II	A	<i>b</i>
III	B	2
IV	-----	<i>a, b</i>

In Group I the cells have the A and B bodies, a serum which will cause agglutination or hemolysis of these cells must have either or both *a* and *b* bodies. It will be seen that all other sera save that of Group I contain such bodies, so the serum of a Group I individual is the only serum which will be compatible with the cells of such an individual; therefore the blood of Group I individual could not be used for transfusion to an individual a member of any other group. Now in Group IV you see the cells have neither A or B bodies, so it will be impossible for these cells to be acted upon by the serum of an individual a member of any of the other groups. So the blood of an individual a member of Group IV can be used for transfusion to anybody. You will notice, however, that the serum of a Group IV individual contains both the *a* and *b* bodies, and one might think in view of this fact that such a blood transfused to an individual whose cells contain A or B, or both, bodies that such cells would be harmed. However, the high dilution that is made as the bloods become mixed renders this fact a negligible one. It might be said, however, that there are two kinds of incompatibility, a clinical and physiological; a clinical incompatibility would be one where the serum of the recipient contains the bodies that will affect the cells of the donor and must not under any circumstances be admitted. The physiological incompatibility would be an instance where the serum of the donor may affect the cells of the recipient in a concentrated suspension, but under the conditions of administration the mechanism will not be affected. In other words the rule to remember is that the cells of the donor must not be hemolyzed by the serum of the recipient. By applying this idea, you will see that it is possible to use the blood of anybody for a Group I individual; for this reason such individuals are spoken of as "universal recipients." Also you will notice that the blood of a Group IV individual may be used for the members of any other group; an individual belonging to this group is called a "universal donor." For Group II individuals it will be possible to use the blood of the same group or of Group IV. For a Group III individual it will be possible to use the blood of the same group, or Group IV.

There are several different methods for matching bloods to make these determinations—the one we have decided upon is a microscopic slide method devised by Doctor Vincent of Boston. In this method the serum of a Group II and a Group III individual are utilized; they have added to them sufficient sodium citrate to give a concentration of 1.5 per cent, also phenol 0.25 per cent. In most of the methods it is necessary to have washed cells and separated serum, the citrate is added to this serum so that whole blood obtained from a prick in the ear or finger can be used and coagulation will be prevented. Although the sodium citrate will interfere with the hemolysis, it will not interfere with agglutination. However, in view of the fact that hemolysins do not exist unless agglutinins do, the group determination can be made on the basis of agglutination alone. We have provided a glass slide which has the Roman numeral II in the upper left-hand corner and the Roman numeral III in the upper right-hand corner. One places a drop of each of the sera on the respective ends of the slide, then takes a small amount of fresh blood of the individual to be grouped and intimately mixes it with the serum on one end, and then another small amount of blood likewise with the serum on the opposite end; within a few seconds on one side or the other he may notice an appearance which resembles fine brick dust; this denotes agglutination. If this appearance occurs in the serum of Group II we know that such cells to agglutinate must contain the A bodies, so the individual whose blood it was could not be a Group II individual but must be a I or III, because it would be impossible for the serum to agglutinate its own cells or the cells of a Group IV, as neither of these contain the A body. If the cells were from a Group I individual, we should expect to find the serum of the Group III causing agglutination also because this serum contains bodies and Group I cells contain both A and B; therefore when both sera cause agglutination the individual being tested is a member of Group I, when the serum of either II or III alone agglutinates the cells the individual belongs to the group where no change takes place. If the cells are not agglutinated by either sera, the individual belongs to Group IV.

METHOD OF TRANSFUSION

The outfit designed to carry out this work consists of two boxes containing the necessary paraphernalia for performing every technical detail of the procedure. A large box containing glassware, rubber tubing, needles, etc., and a smaller box containing the laboratory outfit

for group determination, tags for identifying the individuals of the different groups, the citrate solution in ampules, solution for washing needles, and fluid for making red-cell estimations. When one of these outfits is received at a hospital where it will be used, the contents of the box will be prepared for use by being separated into units, each unit will be wrapped in unbleached muslin and sterilized as other surgical materials are prepared. When a transfusion is to be done, one of these large bottles will be unwrapped, 100 c. c. of sterile physiological saline solution will be poured into the bottle, and the contents of one of the ampules of sodium citrate solution emptied into it and mixed well. One unit marked "donor," consisting of a rubber stopper with two short right-angle glass tubes, one a little longer than the other, is fitted into the bottle, to the shorter of these two tubes a piece of rubber tubing is connected, and to the free end of this rubber tube a glass suction tube is connected. To the longer tube a piece of rubber tubing, about half as long as the rubber tubing just mentioned, is attached; at the free end of this tubing a needle of 25 or 20/10 mm. bore is adjusted, the apparatus is then ready for receiving the blood. The arm of the donor should be cleaned, a tourniquet placed just above the elbow just insufficiently tight to prevent arterial circulation, the veins of the forearm will now be seen to stand out prominently. One of these is selected for puncture, the skin over it is painted with iodine and then a venous puncture made to obtain the desired amount of blood. While the blood is flowing into the bottle one should rotate the bottle so that an intimate mixture of blood and citrate salt solution be effected. Suction through the glass tubing with the mouth will facilitate the flow of blood. The rubber stopper with the glass tubes is now removed and in its place is put the rubber stopper with two tubes from the package marked "recipient." One of these tubes is very much longer than the other, reaching nearly the bottom of the bottle. To the exposed end of this glass tube a long rubber tubing about a meter in length is attached and to the free end of this tube a small piece of glass tubing is attached. To the exposed end of the short tube a piece of rubber tubing of medium length is attached and to its free end a small glass tube containing a pledget of cotton is fitted. A needle of about 13/10 mm. is now selected and attached to a very short piece of rubber tubing. One blows through the tube connected with the short glass tube until the blood mixture reaches the end of the glass tube attached to the long rubber tubing, a clamp is now fixed on the rubber tubing until the needle has been successfully placed in the veins of the forearm of the recipient, the forearm having been previously prepared as in the instance of the donor. The rubber tubing attached to the needle is now connected with the glass tubing of the long rubber tubing, the bottle is elevated, the clamp released, and the blood allowed to flow into the vein of the recipient after the tourniquet has been removed. One should allow from 10 to 15 minutes for this amount of blood to be received by the recipient, or a longer time if conditions seem advisable. It must be remembered that if the blood mixture be allowed to flow too rapidly so much fluid may be taken into the venous circulation in such a short space of time that the right heart may not be able to accommodate it; this will be followed by unfortunate results. Quite frequently, with an individual suffering from shock or hemorrhage, the blood pressure may be so low that it will be quite impossible to get distention of the veins by the use of the tourniquet; in such cases it will be necessary to cut down on the vein and use a cannula; there are two cannulae with each outfit for this purpose.

It might be thought that the needles advised for obtaining the blood from the donor are rather large, but where such a large amount of blood is to be obtained it is quite necessary to use a large needle. There will be no difficulty experienced if the needles are well cared for and kept sharpened; so frequently one encounters a good deal of difficulty in entering veins on account of using dull needles, we have in each outfit sharpening stones to be used by the operators so that they may have no difficulty in having their needles properly sharpened. Very frequently a needle may look perfectly well sharpened, but when it is examined with a low-power lens under the microscope, one will notice it to be very defective. It is, therefore, a wise procedure to resort to this before putting a needle into a tube for sterilization for future use. After each transfusion, the needle should be washed with distilled water, then 95 per cent alcohol and finally with ether; then thoroughly dried, carefully examined, and sterilized with dry heat.

INDICATION FOR BLOOD TRANSFUSION

Blood transfusion is advised in all cases of shock and hemorrhage whether existing alone or in combination. It is particularly desirable that the transfusion be done as early after injury as is possible. The best indication for determining the necessity for transfusion is the blood pressure; in any case where the systolic blood pressure is 80 mm. or below, transfusion should be done immediately. However, in cases where there are severe abdominal injuries or other injuries to other parts of the body where bleeding may commence as soon as the blood pressure is elevated, the transfusion should not be done until the patient is on an operating table where a surgeon will be ready to control such hemorrhage with the greatest facility. Some very interesting work has been accomplished in the study of shock by Maj. W. B. Cannon, M. R. C., and it will be your privilege to hear about this work directly from him in a talk which he is to give you at some later date. Blood transfusion may be said to be only one, but perhaps the best of several methods used for the resuscitation of a wounded man suffering from shock or hemorrhage. It should be practiced as often as it is possible; it should be made possible at all times.

RESUSCITATION WORK FOR THE WOUNDED OF THE AMERICAN EXPEDITIONARY FORCES

In view of the fact that blood transfusion as well as other methods of resuscitation will have wide application among our wounded troops, it has been thought advisable to have men especially trained for carrying out this work. Such men will be selected from the medical men; they will be sent in groups of about six to the central Medical Department laboratory, where they will receive a course of instruction which will familiarize them with the experimental facts which serve as a basis for the application of the various resuscitation methods and the technical procedure for carrying out such methods. Such men will be placed in evacuation hospitals and base hospitals; they will group a large number of possible donors, selected from the healthy individuals of the enlisted personnel who will be willing to donate their blood when it is needed. A record of such men will be kept where it can be referred to at any time. When a convoy of wounded arrive at the hospital, the individuals who apparently may need blood transfusion will be placed in a ward where they can be given the special attention necessary for such cases, shock bed, etc. These individuals will be grouped; blood will then be obtained from some of the donors and transfusion can be done at any time. It is even hoped that we may be able to have men placed in more advanced aid stations where, although blood transfusion is not practicable, other resuscitation methods are, and men who have had training and experience will have acquired a degree of physiological judgment which will enable them to save the life of many a wounded soldier who perhaps would die before reaching an evacuation hospital, or would at least be in such an advanced state of circulatory collapse that his condition would be hopeless and perhaps he would die a short time after reaching the hospital.

CONCLUSION

It is hoped that this work will be met with a great deal of enthusiasm and that each and every member of the Medical Corps will cooperate with those who are making this effort to save many lives that under ordinary conditions would undoubtedly be lost.

Army Sanitary School No. 108.

PYODERMIA OF PARASITIC ORIGIN ^a

By Capts. H. C. Semon and H. W. Barber, R. A. M. C. (T. C.); (furnished by Major McCormick)

It is impossible to work for any length of time at a military hospital for diseases of the skin without being impressed by the large preponderance of pyogenic infection.

Thus, out of a total number of 669 patients admitted under our personal care, between April 1 and May 9, 1917, 631—i. e., 94.3 per cent—were cases of this nature.

^a For the purpose of this article it is proposed to use the word "pyodermia" to indicate the various types of lesions denoted by the terms "impetigo," "furunculosis," and "ecthyma."

Among soldiers, pyoderma of the scalp, face, and neck, is usually associated with the seborrhœic diathesis (Darier's "Kerose"), whereas, when it occurs on the trunk and limbs it is, in our opinion, almost invariably the result of a concomitant or preceding parasitic infection, viz, scabies of pediculosis.

It is the object of this paper to establish the parasitic aetiology of pyoderma of the trunk and limbs, to emphasize the striking differences in the clinical pictures produced by the acarus and the louse, and to describe briefly the therapeutic measures which, in our hands, have yielded the best results.

There is seldom any difficulty in recognizing pyoderma due to scabies, even though there be no active lesions present. The distribution of the eruption, or of what remains of it when the case comes under observation, is highly characteristic.

As it is of paramount importance in the differential diagnosis of the various types of pyoderma, we may be pardoned for briefly recalling the main features of the scabietic eruption.

SCABIES

For descriptive purposes we propose to consider:

- (1) A case of early scabies.
- (2) One in which secondary pyogenic infection has occurred.
- (3) One in which the affection manifests itself in a subject with the seborrhœic diathesis.

(1) To meet with cases of early and uncomplicated scabies in troops fresh from the trenches is exceptional, as pyogenic infection is a rapid and almost constant sequel.

In such, burrows and vesicles, if present, can most easily be demonstrated on the hands, especially along their ulnar borders, and between the fingers; on the flexor aspect of the wrists; on the prepuce and glans penis; and on the ankles and dorsum of the foot.

(2) When secondary infection has occurred, papules and superficial pustules and boils make their appearance, not only in the above situations, but also in the extensor surface of the elbows, the anterior axillary folds (where they are sometimes associated with burrows) round the nipples, and very commonly around the umbilicus, and on the lower half of the buttocks. On the lower extremities the eruption is most evident on the posterior and internal aspects of the thighs, the anterior aspect of the knees, the popliteal space, and behind the malleoli.

It is also worthy of remark that long after all evidence of active infection has subsided, chronic pauciginous papules tend to persist in certain situations, particularly the wrists, the inner surfaces of the thighs, the buttocks, and on the scrotum and penis.

A feature of the scabietic eruption that has helped us in doubtful cases of pruritis and pyoderma—and one, the importance of which we particularly desire to emphasize—is the peculiar goose-like appearance of the affected cutis in general.

On examination with a lens this appearance is found to be due to the erection of the pilo-sebaceous follicles, and in our experience it is an almost constant, though unexplained, phenomenon in scabies.

(3) Where the exudative seborrhœic diathesis exists, infection with scabies is usually associated with a severe and widespread eruption. The acarus is one of the most potent agents in provoking and lighting up an acute seborrhœic dermatitis in persons thus predisposed, which is not infrequently mistaken for the dermatitis excited by the injudicious use of sulphur.

(N. B.—On the other hand, seborrhœic subjects are particularly liable to suffer from sulphur dermatitis.)

The eruption begins as a discrete papulo-follicular eczema confined to the erected pilo-sebaceous follicles already described. Later, confluence takes by the eczemization of the intervening skin, the discrete follicular appearance is lost, and diffuse patches of eczema, which may later coalesce to form large plaques, make their appearance.

These characteristic lesions may be generalized, but tend to be most severe and persistent on the forearms, the inner surface of the upper arms and axillæ between the scapulae, on the lower abdomen, on the inner surface of the thighs, and in the popliteal spaces. In this type of case, seborrhœic eczema of the face and scalp coexists, and is apt to prove a trap to those who have hitherto believed that facial eruptions preclude a diagnosis of scabies.

PEDICULOSIS

The conditions under which our troops have been fighting are responsible for the occurrence of cases of pediculosis, far more severe and extensive than are commonly seen in civil hospital practice. There is no doubt whatever that in this connection the *P. vestimentorum* or *corporis* is the chief offender. It is rare to find *P. pubis* while *P. capitis* is still more uncommon. We will, therefore, confine our remarks to the *P. vestimentorum*. The following description of the main external characteristics of the parasite is taken with acknowledgments from that excellent monograph, *The Louse Problem at the Western Front*, by Lance Sergt. A. D. Peacock:^a

The female is about 4 mm. in length, the male about 3 mm. The head bears one pair of antennæ, and the black eyes. The three thoracic segments are fused and present but little demarkation. There are 3 pairs of strong legs attached to the thorax, each of which terminates in a short powerful spine. There are 8 abdominal segments, the 3 terminal being fused. Posteriorly, the male is pointed, and the penis may sometimes be seen extruded, whereas, in the female, the posterior end is bilobed, and bears a pair of ventral copulatory organs.

It is well known that the female deposits her eggs in clothing of all sorts and in blankets, and most of the prophylactic measures against "lousiness" have been directed to the sterilization of the soldier's kits. It does not appear, however, to have been generally realized that the *Pediculus vestimentorum*, like the *Pediculus pubis*, also almost invariably attaches its eggs to the pubic and perineal hairs, and less commonly to those of the axillæ and other covered hairy regions. In no available textbooks or monographs to which we have had access is this fact referred to, although its importance is at once obvious and far-reaching.

Some months ago one of us (H. S.), in examining seven consecutive cases of ecthyma and furunculosis of the lower extremities, happened to notice in each of them the presence of "nits" on the pubic hairs, and from this time forward we have made a point of carefully examining the pubic and axillary hairs in every patient that has come before us.

(1) In almost every case presenting any or all of the lesions we have learned to associate with pediculosis, "nits" were found either in the pubic, axillary, or perineal hair.

(2) In cases of pediculosis in which new lesions developed while the patients were actually under treatment in hospital, careful search of the above-mentioned hairy regions almost invariably revealed the presence of "nits" which had escaped the attention of the orderly in charge of the case. Removal of these, the application of paraffin, or 1 in 40 carbolic lotion, and a complete change of kit were always successful in preventing the further appearance of fresh pustules.

It may here be said that until we realized the importance of the pubic and axillary hairs as breeding places for lice, our cases of pediculosis were constantly developing new furuncles (i. e., infected bites); now that we insist on the pubic and axillary hair being cropped, and all "nits" removed with paraffin, this no longer occurs. The cases are consequently cured in a very much shorter time.

(3) Although *Pediculus pubis* is occasionally met with, and when present is usually found both on the pubis and in the axillæ, in the vast majority of our cases the eggs in these regions were those of the *Pediculus vestimentorum*.

We were first led to this conclusion owing to the frequency with which live specimens of the *Pediculus vestimentorum* were found crawling among the egg-laden hairs, particularly on the pubis, although *Pediculi pubis* were absent.

We have since succeeded in hatching out young *P. vestimentorum* from hairs removed from the pubis, and kept at body temperature for several days. This experiment conclusively proves that the *Pediculus vestimentorum* habitually lays its eggs on human hair, and this fact should always be carefully considered in undertaking prophylactic measures against louse infection.

We may now consider the different lesions met with in association with pediculosis. Apart from the actual bite of the parasite and superficial scratch marks, there are three main types.

^a *Brit. Med. Jour.*, 1916, i, pp. 745, 784.

- (1) Superficial pustules and boils.
- (2) Circular encrusted lesions of varying depth.
- (3) Very characteristic linear lesions, presumably a sequel to (2) and the superficial scratch marks above mentioned.

Scratch marks are most commonly situated on the shoulders, chest, buttocks, and sacral region, upper parts of thighs, both internal, anterior, and external surfaces, and on the legs. The excoriations correspond in their different situations to the lines along which the patient can most easily scratch himself ("grattage instinctif,"? Dubreuilh). Thus on the buttocks they tend to radiate upward and outward from the anus. On the outer surfaces of the thighs they run vertically upward, on the inner surfaces upward, and outward, and similarly on the sacrum.

At this stage it is interesting to compare the scratch marks of scabies with those caused by the *pediculus*. We have already referred to the erection of the pilo-sebaceous follicles in scabies, and in this disease the scratch marks appear as minute pinpoint blood crusts at the apices of the erected follicles, whereas, in pediculosis, in which no such follicular erection is seen, the scratch marks are merely linear excoriations of the otherwise normal epidermis.

(1) *Pustules (superficial); boils (deep)*.—Our observations would lead us to believe that a superficial or deep pustule is the initiatory stage of the other lesions met with in pediculosis. The sequence of events is as follows:

(a) An indurated irritable bright-red halo arises around the original bite. In the center of this a minute yellowish-white vesicle, rapidly drying to form a crust, makes its appearance.

When pressure is applied to a superficial lesion at this stage, a small quantity of pus is exuded from the central vesicle or crust. In the deep variety (or "boil"), which is often elevated and surrounded by a wide area of induration, similar treatment results in the forcible projection of a considerable quantity of sanguineous pus, from what is evidently a bottle-shaped cavity. In both types of lesion the superficial opening or mouth is very minute and of definitely circular outline, a fact that supports our view that these pustules are originally formed round punctures made by the parasite.

If the pustules are dealt with in this early stage by ordinary antiseptic applications (e. g., tinct. iodi.) they usually involute without progressing further, but, if not interfered with, the lesions tabulated under (2) are apt to result.

(2) *Circular encrusted lesions of varying depth*.—It is not difficult to trace the progressive development of ulcers of varying depth and extent (as may be seen by a reference to the accompanying photographs) from the pustules above described.

(3) *Linear impetigo*.—Superficial linear encrusted lesions result from the exudation of serum along the lines of excoriation due to scratching; they may occur in any pruriginous complaint, and are in no way especially characteristic of pediculosis.^b On the other hand, the variety which is pathognomonic of louse infection is a gutter-shaped ulcer covered by a brownish crust, and of considerable depth. Its outline varies with the stage of its development which, in our opinion, proceeds from the longitudinal digital excavation of one of the circular ulcers above described; and, in fact, in a severe case of pediculosis, all the intermediate stages between the circular and the rectangular gutter-shaped ulcer, so-called "impetigo linearis," can easily be demonstrated (vide photographs).

These circular and linear lesions when healed are invariably replaced by bluish stains and brown pigmentation which persist a long time, or if sufficiently deep, by the formation of actual scar tissue.

DIAGNOSIS

The chief points in the differential diagnosis of the eruptions due to scabies and pediculosis may now be presented in a tabular form.

^b Major MacCormac and Captain Small have recently drawn attention to the fact that superficial "linear impetigo" may be a manifestation of what they aptly term a "war neurosis." It is frequently associated with anesthesia of the palate, altered cutaneous sensibility, and other stigmata of the psychopathic state.

Localization

SCABIES

Hands, wrists, elbows, anterior axillary folds, umbilicus and abdomen, lower triangular area on the buttocks; penis and scrotum; front of knees, ankles, and feet.

PEDICULOSIS

Posterior axillary folds, shoulders, sacral region, and upper part of the buttocks, groins, thighs, and the skin between knees and ankles.

Type of lesions

Burrows, vesicles, small superficial crusts, papules, pustules, and a specific erection of the pilosebaceous follicles with secondary eczematization, especially in seborrhoeic cases. Scratch marks are represented by minute blood crusts at the apices of the erected follicles.

Superficial and deep pustules with a surrounding red and indurated halo. Circular encrusted ulcers of varying depth and size, but on the whole very much larger than those met with in scabies. "Linear impetigo."

It is obvious that since infection with both the parasites is quite common, the two clinical pictures may be superimposed.

PROPHYLAXIS OF PEDICULOSIS

It is beyond the scope of this paper to supplement by other suggestions the measures for the disinfection of blankets and clothing at present in use at all general hospitals and military cleansing depots in France. We would, however, emphasize the extreme importance of simultaneously eradicating the reservoirs and breeding places on the human body itself (as is done in scabies), for which purpose baths, medicated or otherwise, are not sufficient.

If these are overlooked, it is obvious that there is every likelihood of a rapid reinfection of the sterilized garments within a short time of their reissue. We have found the cropping of the pubic hair and the repeated application of paraffin, or 1 in 40 carbolic lotion, to the pubis, perineum, and axillæ quite effective, although there is no doubt that, if it could be supplied, petrol (which is used for this purpose in the French Army) would be the most powerful agent, as it not only kills the adult parasite instantly, but also penetrates the chitinous envelope of the ovum and detaches it from the hair.

An improvement on petrol is the solution of naphthalene 1 per cent and sulphur 1 per cent in benzol or petrol, recommended as of proved efficiency by Capt. J. A. Gunn in the *British Medical Journal*, May 5, 1917.

This solution is not only prophylactic to garments momentarily steeped in it, over several months, but is, as we are informed, and have ourselves proved, instantaneously lethal to both parasites and their eggs.

TREATMENT

In soldiers the routine treatment of scabies has already been exhaustively dealt with in this number of the *Journal* by Maj. H. MacCormac; it is therefore unnecessary to discuss it here.

The most important point to be observed in the treatment of pediculosis is the discovery and elimination of the parasite and its eggs.

The methods found efficient by us have already been described. It now remains to mention briefly our methods of treating the secondary lesions.

If the primary pustule is of small or moderate size, expression of the contained pus and painting the surrounding skin with iodine is almost always sufficient to insure resolution.

When ulceration and crusting have occurred, there is nothing which in our hands has yielded better results than an ointment of the following composition:

Acid salicyl.....	}	aa gr. x.
Sulph. precip.....		
Ung. hyd. ox. flav.....		ad one ounce.

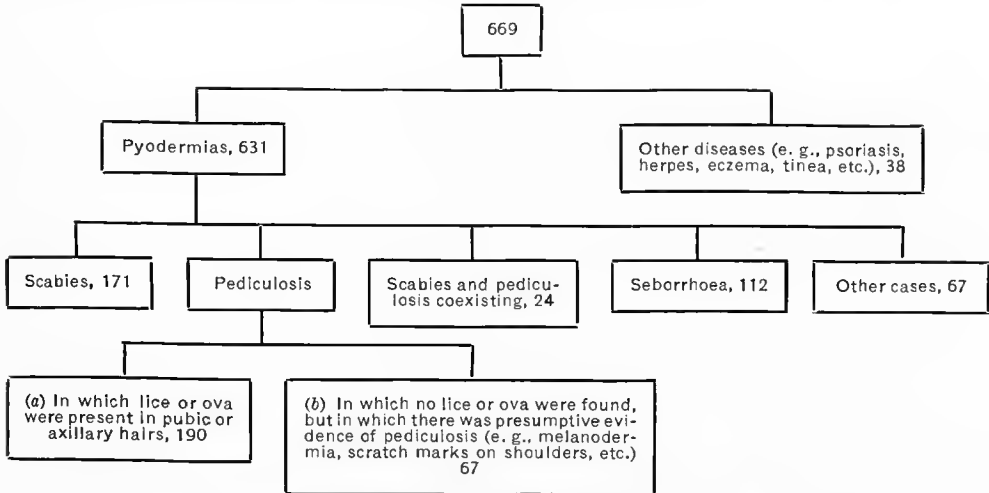

This is kept applied day and night on linen or lint, and in from four days to a week the superficial ulcers will be found, in the majority of cases, to have healed completely. Deep

ulcers of an ecthymatous type also do well under it, especially if the patient is kept in bed with his legs raised. It is only occasionally that we meet with the deeply eroded indolent variety. These have to be treated on general principles with the patient in bed, and will tax the therapeutic resources and skill of the physician to the utmost.

INCIDENCE

The views which we hold on the great importance of the pediculosis as a cause of disability are strongly supported by the figures we submit below.

The results of our analysis may be tabulated as follows:

Total number of cases, 669, were admitted between April 1 and May 9, 1917.

These are the combined results of our independent observations; the individual figures were as follows:

	Scabies	Pediculosis		Scabies and pediculosis	Seborrhoea	Other cases of pyodermia	Other cases	Total
		(a)	(b)					
H. C. S.	101	83	44	11	51	42	14	346
H. W. B.	70	107	23	13	61	24	24	323

Thus the various totals correspond fairly closely under each heading.

It will be seen that out of a total number of 631 cases of pyodermia, 452 were associated with parasitic infection; i. e., 71.6 per cent. Of these latter, 171 (i. e., 37.6 per cent) were consequent on scabies alone; 257 (i. e., 56.9 per cent) were apparently secondary to pediculosis; while in 24 (i. e., 5.5 per cent) the infections were coincident.

The preponderating percentage of the pediculous cases is at once apparent. Of the remaining nonparasitic cases of pyodermia, seborrhoea which is common and of a severe type among our troops—accounts for the majority, whilst in only 67 could no definite cause be assigned. We are therefore justified in assuming that parasites are responsible to a very large extent for the disability induced by skin diseases in this war.

CONCLUSIONS

(1) The disability produced by parasitic infection is very considerable. Of 669 cases admitted in just over five weeks, 442 were directly attributable to scabies and pediculosis.

(2) Of these 442, 171 were due to scabies alone, 24 to the combined infections, and 257 to pediculi.

(3) The *Pediculus vestimentorum* can, and in a considerable majority of cases actually does, lay its eggs in the hair of the pubis and perineum, and sometimes of the axilla.

(4) From this fact there arises the important deduction that measures directed toward sterilization of the clothes can not be efficient, unless the host himself is also disinfected at the same time.

(5) We regard it as extremely probable that the lesions of the pediculosis are initiated in susceptible individuals around the actual bite of the louse.

(6) The severity of the lesions produced, especially in the case of scabies, is very considerably aggravated by the seborrhœic diathesis.

(7) Rapid recovery in pyoderma associated with either scabies or pediculosis is the rule, provided that the respective causes are recognized and dealt with in an efficient manner.*

NOTE.—At this point in the pamphlet is a page containing a print of two photographs denominated "Figure 1" and "Figure 2," taken from the *British Journal of Dermatology and Syphilis*, Volume XXIX, Nos. 7-9, "To illustrate Capt. H. C. Semon and H. W. Barber's article on pyoderma of parasitic origin."

Next appear two photographs (3 and 4) taken from same book and volume as above. Same for Figures 5 and 6.

At page 11 of the pamphlet appears the following:

DESCRIPTION OF FIGURES

Fig. 1.—A case of scabies which demonstrates what is meant by follicular erection. The minute blood crusts on the apices of scratched papillæ are well shown, and there are obvious linear excoriations on the posterior and internal aspects of the left thigh. Most of the secondary infection is limited as can be seen, to the lower half of the buttocks. This picture should be compared with that of "linear impetigo." Note in the latter: The absence of follicular erection; the more scattered and larger size of the lesions; the linear or radiating tendency (*grattage instinctif*).

Fig. 2.—A well-marked example of so-called "linear impetigo"—"*grattage instinctif*." The origin was undoubtedly associated with pediculi, which were present in the pubic region. Note the radiating character of the lesions on buttocks. The crusted lesions, on the left buttock particularly began as boils. Subsequent ulceration of these has taken place, and in the picture can be seen lesions in all stages of transition, from a small ulcer to the linear gutter-shaped excavation with approximately rectilinear outline.

Fig. 3.—The pediculosis lesions are here displayed in several stages. Above the right iliac crest (and somewhat out of focus) is a late stage of the superficial circular ulcer (2 in text). On the right buttock, and in close proximity to the center of the natal cleft, is an abortive example of the type described under 3 in text. The remainder partake of the characters described in detail under the heading of superficial pustules and boils.

Fig. 4.—An absolutely characteristic picture of pediculosis. Note the localization and the appearance of the lesions: (1) An early pustule; i. e., infected bite, with the central yellow vesicle. (2) The central vesicle has become a crust covering a small underlying ulcer. (3) Infection is spreading peripherally along the lymphatics, and the circular ulcer is thus being produced. (4) The circular encrusted ulcer.

Fig. 5.—Two early boils which our experience has taught us to recognize of pediculosis origin. They were situated on the fore and upper arm of a patient with marked evidence of "lousiness" on the rest of his body.

Fig. 6.—Pediculosis boil on the anterior surface of the thigh. A crateriform ulcer is in progress of being formed. The characteristic, circular, crusted lesion would ultimately result.

* We have been asked to explain the fact that whereas about 90 per cent of all troops in the trenches are infected with lice, only a relatively small proportion (the exact figures can not, of course, be given) present the secondary lesions we have described. It can be contended that there is an individual susceptibility in some cases, such as has been proved to exist in the case of flea bites (Boycott) and those of mosquitoes and other insects. In other case the phenomenon of anaphylaxis probably plays a part, so that the susceptibility of the individual, as evidenced by the appearance of the lesions, is at first latent. That some specific toxin is injected by the louse when feeding is supported by the fact that in marked cases of melanoderma associated with pediculosis even the mucous membranes may become pigmented, as in Addison's disease (Thibierge and others). Darier, moreover, points out that it is not rare in such cases to find a marked cachexia with very real asthenia, a fact which we have ourselves observed on more than one occasion. Another factor in the production of the secondary lesion is, in our opinion, the coexistence of the seborrhœic diathesis, which, as we have already pointed out, plays such an important rôle in the severe eruptions primarily due to the *Acarus scabiei*.)

Army Sanitary School No. 109.

SHOCK

By Maj. George W. Crile

I will not dwell very much on the pathology and some of its interesting points and manifestations, but will take up with you, if you please, some of the practical considerations of shock such as one sees in the surgery of war. Now, let me first of all mention some of the salient facts. You will find that shock is quite different under some conditions of battle from shock under other battle conditions. We have always thought of shock as following and being caused entirely by injury; as a matter of fact that is only a part of the shock. We might first of all consider just what shock consists of, the main points in the man himself who is a victim of shock.

A man in shock is self-diagnosed; it is patent to everybody that he is in shock. The outstanding things in his condition that make everybody know he is in shock are these: First, the man is in prostration, and by prostration we mean that he is unable to walk, that he has muscular prostration, and that has loss of mental power as well. He is able to answer questions, give his name, and perhaps talk about very simple things, but unless you make a little more searching inquiry, you will not realize that the man has lost very much of his mental power. A man in shock can not for a moment undertake the solution of a mental problem; if he were the commanding general of a division he could not do much commanding; if he were a mathematician he could not figure out a mathematical problem; he has lost mental as well as muscular power. These are the great outstanding things. The next is that he has also lost the power of producing body temperature. You will find that his temperature steadily falls and keeps falling until death; 1, 2, 3, or even 4 degrees. Very roughly speaking we say that a man in shock is in prostration, and the three great signs are: (1) Loss of muscular power; (2) loss of mental power; and (3) loss of the power of fabricating heat.

Now, we can develop that just a little further: The man that has lost muscular power lies down—he doesn't walk or sit down, he lies prone; and the man who has lost muscular power will exhibit certain signs; for instance, a shrunken face. Have you ever seen a man sleeping heavily; you may not have been sure at first whether he was dying or only sleeping; his face is shrunken and his whole expression changed, and all that is due to the loss of power in the muscles of expression of the face. In the same way a man who is in shock and has a total loss of muscular power has also lost the power of facial expression; and of course the man who has lost muscular power naturally relaxes to a certain extent, and the circulation and the blood pressure tend to fall.

Now, we all know perfectly well, when the muscles are not in use and when the normal muscular tone is lost, from whatever cause, that the individual has by so much lost the power of producing heat. We must bear in mind that in normal times, in quiet periods, 50 per cent of the heat of the body is fabricated by the muscles and that in activity 75 per cent or more is created by them. Therefore, a condition that deprives the muscles of their power of operating ordinarily tends at the same time to deprive the muscles of their power of creating heat. Furthermore, the underlying condition that deprives them of their power to do work or produce heat also interferes with the action of the brain in performing its function. I might go on in this way, but it isn't worth while.

In total shock these functions are practically all suspended; so the three great signs are (1) loss of muscular power, (2) loss of mental power, and (3) loss of power of fabricating heat. These are the three great big outstanding factors; there is loss of many other functions but we do not count them because they are not important.

Starting with these facts, let us see how we can build up our picture. Now, what are the factors which will produce, altogether outside of war, this loss of mental and muscular power and loss of power to produce heat? We know very well that in starvation there is a loss of all these functions, so we may say that loss of food may be one. The loss of drink may produce the same result; you may have all of these things when there is a large hemorrhage in which the circulation of blood is not properly vitalizing the tissues of the body. All these will do it. We know that there is loss of circulation and mental power in an individual who overexerts himself, like a marathon runner, like a swimmer; so that you may exhaust your-

self in such a way that you are not able to do work. The same thing is true in passing through an anesthetic; you have the same loss of power, only more so. There runs through the whole gamut of these things a certain sequence of events, one after another.

Now, we can just as well start our point of attack by considering what it is that a man requires to remove fatigue after running, and you will find—rest. He comes in breathing rapidly and in a state of collapse—you have seen them fall as a result; and that man, that same man, could not solve a mathematical problem, he could not command an army, he could not commit a poem to memory; he is exhausted in every other way except that in his case you don't notice that the temperature falls so low. There is a general agreement that in these states there is created a very decided acidosis. That acidosis is created also by emotion, in animals or men, just the same as from running or from injury, or from a hemorrhage, for in every one of these things you find acidosis.

What do you mean by acidosis? We mean this, and it is a very important factor that concerns us here in our Army work: We, being in a normally balanced state of nutrition, have always a margin of safety between acidity, which causes disease and death, and the proper degree of alkalinity of our blood. It is hard for us to realize that man and animals can only live in an alkaline medium, but we must first of all accept this as true. Every moment that we live the body is producing acids as it transforms blood into energy; to live and perform the functions of the body we are always producing acids. There is thus always a battle going on between life and death, and among other causes, if for any reason the body is not kept neutral, as it were, from the blood all the way through—kept either neutral or alkaline—death takes place in animals and men. Therefore the man who is in the front-line fighting, as you see, is subject to the most common causes of acidosis. There are many factors in the body to prevent acute acids from occurring, but at times it occurs; and whether in shock it is cause or effect doesn't matter; but in the state of shock one of the most fundamental facts is that you have a very marked acidosis—always, always. Now, gentlemen, this is one of the salient facts concerning a man in fatigue from running: Rapid respiration is produced; and in running and in shock and hemorrhage the respiratory rate is governed by the state of acidosis always. It is the acid in the blood which drives the respiratory center to do its work; so when the respiratory rate is increased you know that this is in response to acidosis, or, better stated, to a diminished alkalinity. The striking peculiarity in shock, you see, is an increased respiratory rate, oftentimes very rapid. You have seen that. That is the first diagnostic point.

Then the next thing very striking about the man in shock is the fact that he has a low blood pressure. At the very beginning of the appearance of shock his pulse rate may not be very high; I have seen many with a pulse rate of 80 to 90. But after a while the pulse rate becomes very rapid, and the blood pressure is low. Blood pressure is always lower in shock—always; you do not have shock unless you have a low pressure. Even though the pulse is slow or normal, you will notice without even using an instrument that the blood pressure is low. Oftentimes there is entire failure of circulation and there is no pulse at the wrist at all; circulation fails. The man is nearly always sweating—hands cold, clammy; there is no force to the circulation and the muscular tone is gone; his face is shrunken and pale, sometimes ashen. These are the main things you see.

With this little sketch of some of the manifestations of shock, let us connect it up with our subject. Your soldier, if he is fighting in trench warfare and just happens to get injured, presents one picture; it is a very different thing if that soldier is in a battle, in a tremendously big engagement and a long fight. I want to dwell upon this point because it is the gist of the whole thing. Now in order to do that, just for a minute consider what the man's physical condition is, what the state of his mental activity is, and the state of his nutrition in battle. For example, I happened to have the opportunity of serving in a very active British army behind the lines during the past year, and in that capacity I had the opportunity of seeing a vast number of cases of shock and exhaustion and was given the opportunity of treating them; I also took the opportunity at the same time of finding out what they went through before they were injured. We can not consider this condition intelligently until we appreciate what they went through before being struck, and let me remind you that often you find a very bad case of shock in a man with an extremely light wound. Now, the man who has

gone through what I am about to describe to you may come down with shock from a very small wound, and that is the most dangerous type there is. The man with another type I am going to describe also, will take an enormous injury and hardly have any shock at all. That is the most hopeful type.

I am going to repeat some perfectly patent things to you, but without them I can not build up the picture I want to present. In the first place the enemy sets down a box barrage so that the soldiers are cut off for one day, or two, or three or four from their food supply or drink; they are extremely thirsty and they are not getting sufficient food. That by itself in an animal kills, if it goes on long enough, and before death there is an increased acidosis from fatigue and exhaustion which would be a similar thing to shock, only it takes a longer time. Say a man's resistance represents 100 per cent from his maximum margin of safety to his final collapse. A certain percentage of that would depend entirely upon the fact as to whether or not he got his supplies, whether they were held up by a barrage that cut him off so he didn't get food or drink for one, or two, or three days; a certain percentage of the exhaustion is due to that alone. That's first.

Secondly, we know very well that loss of sleep will kill any man or any animal, usually after the period of five days—loss of sleep alone. We can put a man in this room with all the food and drink he requires, a comfortable bed and perfect quiet, and without being bothered by a lecture or anything else he would die in four or five days from want of sleep. Now, each hour that you are awake beyond the period of time of normal resistance cuts off a little bit from the sum total of the factor of safety you possess; so that if a man is kept awake all night long and the next day and three or four days or so in his tour of duty in the trenches, and so has insufficient sleep, by just so much has that man's factor of safety been lessened, destroyed, and thrown away. Before he receives his injury he must have been reduced to 60 or 70 per cent of his original 100 percentage of resistance by loss of sleep and loss of food. Therefore, if a man, we will just say, has been more or less severely wounded and has had no sleep, that, by itself, would reduce by just one-half the severity of the injury necessary to kill him, and it would take twice that injury to kill him if he had been fresh and well fed; one-half as much injury would produce as much shock here as twice that much would produce in a normal man.

Next type of man: This war has shown the most extraordinary things regarding emotion, the emotional factor that cuts people down. It is all right for us back here to say there is nothing in the emotional factor, but I have talked with all kinds of people who have been through the game, with soldiers and our own officers who have gone over the top with their troops, and I want to say that I have the most profound admiration for the way our men have done their duty. They have said, and I know myself, that the proposition of "going over tops" disturbs them. There is no question about what happens: The mechanism of the body is driven at enormous speed. I have talked with soldiers who have been over here three and a half years and with many that have become accustomed to the front line, and to look at them you would say they didn't mind. But they do mind, and they go over with the most intense feeling of anxiety, and with a rapidly beating heart; they live more life in five minutes than they do in an ordinary day, and you can compress in a short period of time an intense driving of the body organs that mean as much reduction to the factors of safety in five minutes as you would produce by four or five days' loss of sleep, or so much mental exertion. You have added to the man another factor by sending him over the top; for example, it is not at all uncommon to become demented in No Man's Land. Germans have come over to our lines not knowing where they were going in the excitement of battle; they shoot their own comrades, not knowing what they are doing.

Don't get the idea—I don't think you will, in plain justice—that men get used to the front line, get used to going over the top and don't mind it; there is nothing more fallacious, nothing more wrong. So when you think of shock, don't think of just a bullet wound; in that case the bullet may be the smallest part of the whole case. A man who has been kept awake a week at a time in the ditch, without sufficient food or drink, and is then subjected to the tremendous strain and anxiety of battle, may by that time have cut down his reserve and factor of safety to below 50 per cent, and yet he has not yet been touched; it may be as low as 40 per cent.

And then the battle starts and he goes into his last struggle for existence under great difficulties and with the most intense exhaustion; considering these facts you see what tremendous energy they draw upon to use up that last ounce of strength to fight for existence. When that time comes it is like putting a heavy load on an already overloaded machine. And so, in charging a long distance and taking an objective you can readily see that men will be tired out from the physical exhaustion itself, and still the man is not wounded. These things other than the wound are very important, however, and the most common causes of trouble. In the end, after that period of time and stress, suddenly the soldier is wounded. Several things will determine how much of a wound it requires to put that man out. Just remember that loss of sleep will do the same thing as the shell or bullet, and so will muscular exhaustion and emotion.

Finally comes the injury. The man gets a blow. Down he goes. At first there may be very little change in his condition. From the time he gets his blow let us consider the various things that may cause his death—after he gets his injury. His injury isn't the only cause. What I am trying to do is to have you see that there are so many things that are serious besides the injury which is oftentimes the least important factor in the whole case. The injury may consist of a little nick in an artery, but there are added these things we have spoken of. In such a man it doesn't take much to remove the last factor of safety and he may die from loss of blood. Yet if that hemorrhage is arrested and he is brought back with a light wound, is it strange that this man has had a tremendous amount of shock from this small injury? In reality, that injury has had only a little to do with the case. This man who had the hemorrhage didn't die from the traumatic injury, he died from a combination of things, and the hemorrhage finished it up.

A man comes in with a compound fracture of the leg or of the foot and his troops, his company, regiment, are being defeated. We always think of battles as being things we win; well, I expect we will always, but we are not always so sure of it. If he is injured in the leg or foot and he is retreating, what does he do? He goes along and drags that bone or hops along as fast as he can. I have found cases where men walked on a broken foot to get away from the enemy. Each time you step on a compound fracture you can see it get worse; the primary injury did little compared to what he is doing. These are more factors.

The next two factors are those in which we are vitally concerned. The first one of these is movement of the part. Suppose a man gets a fractured femur. Now we know that many deaths have occurred from compound fractures of the femur. In civil life if a patient has a compound fracture of the femur you wouldn't expect him to die of shock; out here they do. In one of the allied armies they had a great deal of shock and death in fractures of the extremities and the whole thing was changed by one thing they did, a perfectly plain thing to do. They carried the Thomas splint way out in the front area; this has been done with our troops. One of the best things that can be done for this injury is to put a Thomas splint over the fracture and handle him back to the rear in the Thomas splint. That was done and there is no better treatment for shock. In the early days—I was here in 1915, and that was not then done by the French—I, myself, have seen compound fractures handled long distances, in which the sharp bones have used up the muscle more than the missile, like a meat chopper, so that the stretcher bearers and those who handled him before he could be relieved did more harm than the enemy. If the methods of transport are good you need never lose these cases by shock from the trauma alone, provided a good splint is put on in the first place. Of course, if the man has only a small amount of resistance left you can knock that out going through the trenches, bumping into things; that will finish the man. Now, it is our duty, as I see it, to take every patient who has a compound fracture and to treat that fracture by extension, thus providing a certain amount of physiological rest at the earliest moment, and it should be kept up until the man reaches the hospital where that rest may be made as complete as possible. There should be no break in physiological rest from the time he is received from the stretcher bearers until he is discharged well.

Now, just right here I want to pause a minute to say a thing I didn't dream of in civil life—I didn't think of it at all, and that is, the enormous extent to which the whole problem of surgery in this war is an administrative one. I could go into that with a lot of detail. If an organization is created to treat shock you should start with the transport people; they

can treat shock better than the doctor. A quick evacuation to the rear means that the stretcher bearers have done what should be done, the men should be handled gently and carefully, and everything should be called on to prevent using up the slender percentage of safety to which we have alluded before. None of this has to do with the wound itself.

Cold.—As a matter of fact, in shock itself, cold is a big factor. I said some time ago at the beginning of this talk that in shock the individual has lost the power of creating heat in himself. You have to supply him with outside heat, a thing that will help to cure him. You see, he has been sweating, his body is moist and he is in a state of exhaustion; and the whole point anyway is that one wants to be sure to have those patients wrapped up very well. Of course we do pack him; we all do. We all know what to put over a man, put round his feet, but what you want to be sure to do is to put something underneath him as he lies on the stretcher. Did you ever lie on a stretcher on a cold day? Usually we think that the man is lying on a stretcher and the stretcher is warm. It isn't so at all; that thin canvas abstracts warmth from a man's body. The thing is to have blankets underneath as well as on top. I needn't go into the subject of warming on the stretchers, and so forth, because that's just a question of supplying heat. The hospitals are being equipped with warmers and all that sort of thing; I won't go into that at all.

We have now finished speaking of the temperature. Now, gentlemen, I don't want to lecture you about these things; but I would like to consider this more of a conference, and I would like to pause before going into the subject of treatment and if you wish to discuss the thing further I would like to do it.

Colonel ASHFORD. Major Crile, we had a very interesting shock conference at Bouleuse, which was visited by us in January, and we had a hundred competent French surgeons and scientists present. The general consensus of opinion tended toward the belief that emotional elements played a very important rôle in shock—

Major CRILE. Oh, yes.

Colonel ASHFORD. What is your position?

Major CRILE. I can tell you something about that. You can frighten the rabbit, and you can produce everything of this sort in a rabbit. Emotion is a most interesting thing. I have rabbits at home, that I have been able to kill by emotion alone. Lots of men are dying from emotion alone when they are not touched. Many of us may not believe it; we don't believe it is true. But if you ever talk to young medical officers—our own—who have gone over the top, they can tell you how real and true it is. In rabbits you can cause high fever or death from emotion as from anything else. If you have emotion you have acidosis, always. I have seen them with red blood cells in their urine. There is just now some research on that point in my laboratory. They put some rabbits in a ditch and fired a thousand shots over them, under much the same conditions as trench warfare. Then they increased the amount and the rabbits went down in exhaustion and died without being hit by anything; they were shocked to death by being frightened. We have always known that was possible ourselves; I think we all have had a "run in" some time or other; I think that sometimes a surgeon gets certain critical responsibilities and knows very well what that means.

Now, about giving a man a dose of morphia; let me tell you something interesting about that. I am going to draw a two-faced picture on the subject of morphia. If you give morphia at first you can't produce any emotion at all. The man who has had a big dose of morphia has neither fear, nor heat, nor cold, nor any emotion, nor with a big dose has he any muscular or mental power; it cuts this all out. You remember the time in the old days here in la belle France, when the aristocrats did not take kindly to being guillotined? Then some one hit upon the idea of giving them morphia first, and after that they did not mind it at all. On the other hand, take an animal that is in shock or emotion; you find their blood has lost its alkalinity and there is acidosis. Then, to my utter surprise, I found if you give these animals half a dose of morphia you can not restore their alkalinity and sometimes they die from acidosis alone.

I was going to make this point later, but I will make it now. Acidosis and shock are much the same thing or the whole thing; at least acidosis is a big factor in shock. Now the way that we overcome acidosis is by oxidizing the acid produced in the cells. What is emotion? It is a burning flame, in exhaustion you turn the flame up higher, but in emotion it

alone burns with great activity. Now morphia cuts down that oxidization altogether, and, therefore, if there is no emotion you get no acidosis, and if there is any acidosis you can not cut it off if you give large doses of morphia. Morphia interferes with the oxidization by means of which the thing is done, as when you have acidosis the only way you can cure it is by oxidization; morphia stops that. It is neutral; it deals with both sides alike. It doesn't allow the emotion to occur and it doesn't allow the cure when emotion has occurred. So up on the line we must be mighty careful in handling these cases. We must remember not to give a large dose of morphia to a man who is in a state of acute acidosis; this cuts off his power of oxidation. It is a very simple thing; be sure of this.

Colonel ASHFORD. I have also heard that Major Cannon, in the First Army, advised cutting down morphia, but that if it should be given there should also be given an intravenous transfusion of sodium bicarbonate or good alkaline drinks.

Major CRILE. Yes.

QUESTION BY A STUDENT. How much would you give, Major?

Major CRILE. That would depend. Now, for example—I will put it this way. If you have quiet trench fighting and a man is hit, it is pretty much like an accident in civil life. He was just living around in the trench and got hit unexpectedly. You can give him much more, but a quarter is all right there, and it may even be repeated. The point is: I would judge a dose of morphia by taking into account a number of circumstances. The first one is this: If you know that the man can not be evacuated without a tremendous amount of injury en route and things have been more or less quiet, go as far as you like with morphia; give a quarter of a grain and repeat that again. On the other hand, if that man has a wound that isn't likely to be very painful and if you know the road and it will be a quiet, easy trip back, then give only a very small dose of morphia. On the other hand, suppose a man came along with an abdominal wound. If it isn't a very slashing wound the best thing he can have is morphia. But if the man has been through all this hard picture I have drawn of battle—I don't know—not more than one-sixth of a grain at any rate. As far as I can see, the man who decides to give or withhold morphia takes a large responsibility. A lot of times a man gets opium and is saved; that is, if he didn't get it he would die. Opium has great effects on human organisms. I wouldn't for a minute say "Don't give opium," because it has done too much good to say that; nor would I be the one to say that you must always give it, because it may do harm.

Major BURNETT. What is your idea about giving alcohol before going over the top?

Major CRILE. I have discussed that thing and have thought of it a great deal and am unable to reach a conclusion. I have talked with the men themselves who have taken it and gone over the top—and I don't know. I understand the enemy uses ether, and according to all stories they certainly do come over sometimes in a very befuddled condition. There is no doubt at all that if a man stands in the trench all night, and knows the zero hour, and knows he is going over, and is chilled to the bone, I think a little rum might help warm him up. On the other hand, can't you see, a lot of men lose so much by being overanxious and over-excited and getting too much of the very thing we have talked about and this thing alcohol creates—I don't know. The armies which have been longest in the field get something alcoholic, but, on the other hand, these people over here have been accustomed to taking more alcohol than the average man in the United States does. The problem is so mixed up—I don't know.

I can tell you another thing that is perfectly amazing to me. I have spoken about how quickly the men may go down under this strain. Many go down with the most surprising resistance. Some fellows stay in shell holes for several days in No Man's Land. I know of one case up the line where two wounded men were out nine days under most extraordinary circumstances, and I would not have believed the story if I had not seen the men and the photographs verifying it. One of the men crawled out to forage in the night and took the rations off the dead. They spread out their raincoats and caught water; the Lord knows there is rain enough where they were. One of these men had a compound fracture of the femur, which united in the shell hole. Finally this man got well enough to crawl in. He had grown long whiskers in the meantime, long hair, and long nails. Compare this with the man who drops in shock before he even leaves the trench.

So there are high lights and shadows of extreme degree, and it is difficult to make rules. Captain Cowell made some very interesting observations: He took a crowd of men in the front area and found that they had a blood pressure 20 points higher than those in more protected places in the immediate rear. You see under firing conditions they are just stoking their engines all the time.

Now, gentlemen, let's go back to the treatment.

Do you know that the real restoration of a man in fatigue takes place only in sleep? Unless he gets sleep he does not restore what he has lost. In all our periods of sleep we have periods of fatigue and periods of restoration in the body, which explains what sleep does. If we knew the remedy which sleep produces we could cure all our cases of shock. We have tried to do it; everybody in the world has tried it; and yet sleep does it and does not try at all. That being the case, I mention it to give you the cue. If you can not imitate what sleep does, then give rest, physiological rest; give all the mental rest, all the physical rest, all the rest against pain, and every type of rest that you can; go as far as you can, and when your patient has pain give morphia to give him rest; there is no objection to it at all if there is no contraindication for it.

Next is warmth. It is highly important to give him warmth; that comes next to rest and, as a matter of fact, the two go together. Now these are two known facts.

And did you ever see a man go through a period of rapid respiration and prostration and notice he was thirsty? Nearly always they are thirsty. The man who has a fever is thirsty; the man who takes an anesthetic is thirsty; the man who has ordinary acidosis is thirsty; the man who is having a hemorrhage is thirsty; and everyone of these has rapid respiration. Thirst is a desire to get water to reduce acidity; that's all this is. Thirst and rapid respiration go hand in hand. Now it is always a good thing to take nature's leads; it is no mistake. You follow nature's lead in sleep and in giving rest. Follow nature's lead again and when men in shock are thirsty give them water. If you can't give water normally by the mouth in severe shock—and as a rule you can not in this war—give water by the rectum. If the rectum is overloaded with feces and you can't do that, give water subcutaneously. Then you have done a great deal.

Now even if all these measures do not fully relieve, would you give saline intravenously? I would say, as fast as you can put it into him if you are going to give it intravenously. But I think there is a better thing than that; I have worked on this problem a great deal at home in my laboratory and clinic. Many times we have given intravenously sodium bicarbonate in 5 per cent solution. It is better than salt solution, but it is not specific; this I was greatly surprised to learn. When we found acidosis we said, that's very simple; we will give sodium bicarbonate to cure him. But to my great disappointment it is not in the least specific, although useful. And perhaps you might think that if you gave it to an animal you could prevent shock altogether; but I have found we could still produce shock in them.

Now, the next question: Here I am venturing a little on uncertain ground. Professor Bayliss and his associates have done a lot of splendid work, and I am hoping that he and Major Yates will make something useful out of it. He has got the idea of taking a kind of solution that would not run out of the blood but would stay in. If it would stay in the circulation that would be the specific thing, and this he accomplished by the use of gum arabic solution, 5 per cent. Well, I tried that a good deal. It does hold up better than salt solution, better than sodium bicarbonate, but, unfortunately, I have had so many patients go and die just the same that I am not enthusiastic. It has not carried me over enough, but I wish it were true.

I think the best thing there is in addition to those we have mentioned heretofore is the direct transfusion of blood, because that is a measure that we know has been tried out a lifetime. It does the thing it is supposed to do and won't run out of the blood vessels. I have sent up a number of men from my unit resuscitation teams and they have done 325 transfusions of blood; they have had all sorts of other things as well, but there were 325 transfusions of blood alone. This is their conclusion: That it is a perfect specific, first, for hemorrhage, and, second, for a man who has had a little wound. But, as described earlier, the men with the small wounds show the greatest number of failures; the deeper the shock and the lighter the wound the more unfavorable is your prognosis—unless the man has a wound so big that his gross anatomical recovery is impossible.

Now morphia: Morphia is a first-class remedy provided you haven't acute acidosis. You may give it for pain in small doses, when the period of acute acidosis is over, when the man is no longer blue—never give a large dose of morphia to a man who is blue; never. We all know of many cases where a man was blue and we gave him morphia and we inducted him into his last sleep. I have done that. But I did that only a few times and then learned better. Have you ever given morphia with anesthesia? The man is blue; he is full of acidosis. Just by accident we discovered in my laboratory that in every case acidosis caused the blue color. I can tell you something about that. [Draws illustration on blackboard.] When you get over that line, that neutral line (a line representing 40 per cent of a man's resistance), death takes place immediately. You know how blue your patient gets—that's acidosis. Morphia comes along and of course does the wrong thing—doesn't it? It is just as plain as can be when you consider it in that light. So I say: Never give morphia in a case of over-anesthesia until the effects of the overanesthesia are past.

Now the anesthetic itself. I won't dwell much upon that, but I will say this. We have a lot of people who urge the use of local anesthetics, and there is this to be said about local anesthetics: If you have to operate on a femur and you can use local anesthesia so it will not reach the brain you get no shock at all; the operation is shock free. But if the blood pressure is low in an animal or man, when you give spinal anesthesia you have a fall of the blood pressure from the effect upon the nerves themselves and also you have a paralysis of all the muscles and that takes away the support of the blood vessels that lets it fall further. If you have any man using spinal anesthesia remember this fact. If, however, you have already a low blood pressure from shock, or from hemorrhage, and then you give spinal anesthesia that man goes right down and out; you should have a good margin of safety before giving spinal anesthesia. We published this several years ago. Give a transfusion of blood first, raise the blood pressure, and then you can give a spinal anesthetic.

But there have been a lot of slips in giving this spinal anesthesia. The British have found that nitrous oxide is best and they use it a great deal. In amputations of the thigh they have a high mortality rate, three deaths to a recovery; when they used nitrous oxide it turned right around the other way—three recoveries to a death. It reaches to the brain cells so they can't work; they haven't got the oxygen—it is turned off. The nitrous oxide leaves a little bit of light burning in the brain—that's all. Now if you give ether anesthetic, I must suggest several things that are important. One is that you watch the anesthetic for impurities, because it has been found that in manufacturing many impurities get in. So I say, look it over. I hope none of you give chloroform over here; I don't believe you will. Chloroform is a nice anesthetic to give and to take; and it is a nice way to get out of this world; but it should not be used in the rough and tumble work we have to do here. I think all experts agree on that.

I have already much exceeded my time, but I would like for a minute, if you wish, to have a discussion on any point you care to bring up.

(Discussion)

QUESTION. Have you ever heard of a case of a man being scared to death from shock?

Major CRILE. Yes; I think so. I believe there have been a few cases. It is pretty hard to say, but many people think there have been quite a number of deaths from that. You can hardly say a man was frightened and died without having something else; there might be the element of rupture of a blood vessel.

QUESTION. What do you think of the combination of chloroform, ethyl chloride, and ether?

Major CRILE. Personally, I am afraid of it, because you don't know what you are dealing with. The British are indorsing nitrous oxide as much as possible; but nobody ought to give nitrous oxide unless he has had careful training. I myself wouldn't for a minute undertake to give nitrous oxide to anybody; it needs technical training. As a matter of fact, the best anesthetists I have seen for nitrous oxide are those who have a very high sense of responsibility and are very keen and wideawake; a woman, as a rule, does very well. The very best anesthetist for nitrous oxide is a splendid woman, with a high sense of responsibility, on the verge of neurasthenia.

Army Sanitary School No. 110.

VISIT TO ADVANCED SURGICAL STATIONS, FIELD AMBULANCES, A MEDICAL CENTER FOR THE ARMY, AND A REST STATION, MAY 14, 1918

Left early in the morning for a trip to the Sixth Army to visit advanced surgical operating stations. The first one was at ———, which is about 10 km. from ———. This was a little town on a hill, in a most attractive wooded country, and the hospital was accommodated in a picturesque château at its highest point. We were met here by General Laznet, chief surgeon of the Sixth Army, who has the reputation of being a remarkably progressive man. He stated in a few words his idea of the advance surgical hospital, which was to the effect that it should be amalgamated with a first echelon hospital; that is to say, with the surgical ambulance of each division. That is what had been done here. All patients are sent to this ambulance for triage, which was underground and constructed of elephant iron; the advanced surgical hospital is in the rear of this, in the cellars of the château, and is entered by simply passing through the ambulance, which was well lighted with electricity. They only had 2½ m. of head protection and were at first only 3 km. from the front. This place was in an extremely exposed position. The only protection it had was its lack of visibility, because it was in the depths of a forest. As a matter of fact it has not been much hurt because the line has been successfully pushed forward by a famous advance of the French, which left it to-day about 7 or 8 km. from the front line. The ambulance had the usual receiving, bathing, and resuscitation rooms, and from there on the advance surgical hospital provided operating facilities and wards. The entire plant was seemingly perfect, whitewashed and painted, well equipped, and provided with attendants who were quick and well uniformed; there was an air of liveliness and thoroughness that was comparable only to what we had seen in Colonel Thoris's sector. The advance surgical hospital had a radiologic room, a small but very hot operating room with two tables, and a sterilization room next to this. There were 55 beds in wards on two floors, communicating by elevator. They had five neat female nurses on duty here, who are said to have accomplished splendid work. It is no exaggeration to say that, from the appearance of things and from the results that we saw they had gotten, few Paris hospitals have any better accommodations. They have a telephone, electric light, good heating, neat ornate wards, and absolute cleanliness and efficiency. It was a wonderful little operating unit, and the one surgeon on duty was the very best they could get. They keep abdominal cases 14 to 15 days. It was perfectly evident from the nearness to the front that the slightest reverse of the French would cause this place to fall bodily into the hands of the Germans.

We now proceeded by machine to ———, which was a G. B. D. triage, but had a field ambulance and also an advanced surgical hospital in connection with it. It was in a hilly country in the ——— region and the medical units were hidden in the ruins of the town, which was 7 km. from the front line. The town must have been very attractive before it was destroyed, but there is not a house now that has not been completely gutted. It is in full range of the German lines, but has hills and forests all around it and is itself down in a hollow. Owing to the severe shelling it still receives, the G. B. D. was underground, although there was a hut for the triage above ground, which is used when possible. The G. B. D. communicates, however, by a tunnel with the hospital, and the galleries were long and well lighted by electricity. It was at this place that an excellent demonstration was had of the way these hospitals were improvised. A village more in ruins could not be imagined, and still in the cellars of many a tumbled-down house was constructed a neat, clean, and even attractive place for wounded, which allowed careful and complete surgical care in the present-day sense. Every convenience had been provided, even an elevator leading down into the cave from the surface G. B. D. There were 15 beds, and some operating was going on when we arrived. It was perfectly safe against everything but a direct hit by a heavy shell.

At this point I was invited to accompany the director, M. Regaud, and the general's representative to what is perhaps one of the most advanced surgical stations in the allied armies—the quarry station of ———, known as Carriere R/1. In order to get to this place, which was distant about 10 km. we had to pass in full view of the German lines. The weather had cleared considerably and a German observation balloon kept the enemy advised of any passing vehicles. The only thing they allowed to pass without firing upon it was the hospital

ambulance. Only those of us who were traveling in a regular ambulance were permitted to visit it; the others of our party went by another road in the rear of the surgical ambulance to ———. Our road ran through the entire district over which the French had advanced, and from what was seen the fighting must have been terrific. Every house had been leveled and the forest destroyed.

When we reached our destination we were on a height overlooking the German position, on which was a stone quarry. At this point was a surgical ambulance, and working in conjunction with it the operating team of the advance surgical unit, the two being housed together. In this case no construction was necessary at all, the quarry furnishing all of the rooms. They had driven the Germans out of it; and, as it was previously used by them as a barrack, the French had a good deal of cleaning to do and a good many dead boches to get rid of. Near it was another enormous quarry capable of holding 20,000 men. This is the real solution for the underground operating plant, and yet these fellows were very unhappy underground. They stated that they get their patients back as soon as possible. It was lighted by electricity and well whitewashed, clean as a pin and equipped with everything that one could want in the good hospitals in large cities. The head cover was 6 to 8 m. This place evacuated for two and a half regiments and had 15 beds for nontransportable, although they could have had any number they wanted to. They had a septic operating room and dressing room apart from the others. It had been occupied by our American troops and they had left a number of large first-aid dressings there. In this place we found a dentist. The entire personnel lives underground in the station, but the kitchen is outside. As long as the line holds they can laugh at the shelling they get, which outside is by no means pleasant.

From here we motored down to a group of field hospitals at ———. This is a place on the heights overlooking ———. It had been occupied by the Germans—had formed a part of their advance line. From here to ———, about a kilometer and a half, they had shelled the city to their heart's content, and on every hand were evidences of their activity. The ambulance itself was practically safe at present (10 km. from the line) as the line had been pushed well away from it. It was in an excavated depression on a height and was neat and well equipped. This ambulance also had a portable surgical group here, and an extensive gas quarter, with elaborate preparations for mustard-gas cases. In the latter there was a ward for heating patients under hoods, a receiving room, a clothing room, etc. The clothing impregnated with mustard gas was not heated here because they had nothing to heat it with, so they dumped it into a tub filled with alkaline solution.

They bathed their patients with an alkaline solution and, after drying powdered them with bicarbonate of soda, magnesia, lime and oxide of zinc, 400 gm. of the first and 200 of each of the others.

This hospital is at present 8 to 10 km. from the line. There is a *groupe complementaire* here to operate on the nontransportable wounded. There was a good sterilizing room and on one side of it an operating room for septic cases. The gas quarter had two Bessonneau tents, with 20 beds each; one for convalescence and one to put men in immediately, which was darkened on account of the severe blepharospasm which this gas produces. There was also a good resuscitation ward. This hospital is specialized to receive the gassed and nontransportable wounded.

The kitchens in this place were in one building; one for the sick and the other for the personnel. Near by was a well of potable water and a washhouse. The pharmacy was rather large; and there was a vestuary for storing clothing, very well stocked. The officers lived in dugouts on the side of the hill.

We now visited a group of field ambulances of the corps. This was at ———. This hospital was extensive and undoubtedly could do a good deal of work. It was just across the stream from the city and here was the consulting surgeon of the corps. The operating rooms were kept pretty hot. This hospital was mainly in four Bessonneau hangars, the triage being accomplished in one of them. It was said to be a very hot hospital in the summer. The wounded were kept in two separate Bessonneau hangars. There are 250 beds for gassed cases and 250 for hospitalization of wounded. This is also an eye and ear depot and a hospital for the slightly sick and slightly wounded; it is now full. One of these hangars was filled with nontransportable.

From here we went into the environments of a town, to a château in the suburb of ———. This was a fine old château in an enormous well-wooded park, laid out with flowers, fountains, and watered by a stream. It also was very picturesque and was built in the seventeenth century. There is one ambulance installed here which is devoted to medical cases. It is a very important center, because here come the sick which are to be distributed to the interior, and here sits the medical board which decides on the degree of incapacity of all sick chronics of the Army. There is a triage for tuberculosis cases here, as before described for a similar medical center, with its radiologic outfit for diagnosis, its laboratory, etc. It came out in conversation that every army has a consulting physician who is also in charge of hygiene, and that our host was filling that rôle. The Sixth Army has six medical centers and they are all placed well in the rear. When a man falls sick in the line he goes to the infirmary of the corps, to the hospital of a division, or a H. O. E. One of the two ambulances of the division takes all the sick which can get well in 15 days. If it appears that they are to be sick longer they are sent to a H. O. E., and from there if they can not get well in four weeks they are sent here. Here, if he has acute trouble, he is kept and given from 10 days to 3 months to recuperate. If, however, his case is incurable within that time he is sent into the interior. If he is a chronic case and does not look as though he is going to get well, they send him before a board and the board recommends where he is to be sent in the interior. This army center can give 10 days' leave of absence. Every such hospital has an infirmary at which men can be treated that come from the troops cantoned in the vicinity.

VENEREAL AND CONTAGIOUS CASES

Really, these should be treated in the division, and normally they are, but there is provision made for a limited number of such cases here. They also may be treated in corps ambulances, or they may go to the special service hospitals created for that purpose alone. There is one such in the city, and it is bombarded constantly. The principle is to never send a man to the rear with venereal disease. There are no separate cutaneous disease centers. They all take venereal diseases, a questionable practice in our opinion.

TUBERCULOSIS CENTER

This is a big question. They are sent here under suspicion, let us say, with chronic bronchitis, and are examined carefully. It seems that the French Army in 1915 made up their minds to look up all the tubercular cases in the army. Since that cleaning-up time there have not been so many. At that time also when the diagnosis was made the place of origin was well disinfected.

NERVOUS CENTER

In this army there is no special neurologic center, but in this hospital there is a good neurologist. There is, however, a psychiatric center provided for, but these centers are only created when there is a large offensive. In the offensive of ——— they had at ——— 100 cases, of which three-fourths were returned to the lines in a week.

PHARMACY

This was the usual thing, plus a very unusual thing—a buffet where men were given hot drinks while they were waiting for prescriptions.

LABORATORY

This was small and devoted simply to clinical work. It is also mobile.

The inscription room for the triage of this center was small. Here there was a clean and attractive barber shop.

The American ward, donated by the American Red Cross, was well equipped, but the ventilation was poor as all windows were closed. There was an interesting feature in this ward which might bear imitation, in the shape of a clothes basket under each bed which could be locked with a Yale lock.

The recreation and reading room was perfect. It was cosy, artistically decorated, well furnished with small tables, each with pens and paper. There was a library also and the windows were curtained; men could be very comfortable here.

ARMY LABORATORY

At this medical center was the central laboratory of the army, divided into a bacteriological and a chemical section. There was also a sublaboratory for surgery. This laboratory was presided over by a very bright young fellow, and he explained that the object of the laboratory was not to examine everything which turned up, but to aid the local laboratories all over the army and do work which they were unable to do. It was very well equipped and fairly well installed; above all, there was a great deal of active work going on there.

The laboratory of hygiene and prophylaxis is a chemical one and, like every one of these chemical laboratories of the French Army, was absolutely clean and above reproach. Moreover, the kind of work that was going on was scientific, and the pharmacist in charge was thoroughly efficient and alive. They examine water, foods, poisons, and make certain chemical analyses coming up in medical and surgical cases. In these laboratories the water is examined both chemically and bacteriologically. If over a hundred colonies are developed in water it is condemned, and we were told that 30 per cent of the water examined had colon bacilli. There was a queer rule that was enunciated very clearly by the bacteriologist. He said if water has up to a hundred bacteria and is chemically good, it is considered potable; but if it only has 10 bacteria and is chemically unsatisfactory, it is condemned. They designate water sources by red, white, and blue signs—white for potable water, blue for water which is considered potable after treatment, and red for water not to be drunk under any circumstances. It is believed that far too much importance is given in the French Army to the chemical analysis of water, which is, however, excellently done. There was a good section for toxicology here. They were actually examining for poisons in tinned food referred to them by the American Army.

We now walked out over these extensive grounds, passed over a wooded ridge and, still within the same grounds, came upon the contagious diseases hospital, which is well separated from the main group of buildings. We had not much time there, but the impression it made was good. We saw two men in the receiving ward raving in the delirium of cerebral spinal meningitis. The cases in the hospital at the time of our visit were as follows: Mumps, 100 cases; cerebrospinal meningitis, 3 cases; German measles, 3 cases; pneumonia, 3 cases; typhoid and paratyphoid, 3 cases; scarlet fever, 15 cases; undiagnosed, probably the majority influenza, 40 cases. There were 26 convalescents and 250 beds, and the contagious diseases of 4 divisions were sent here. Gomenol spray was used in cerebrospinal meningitis, two or three times a day for 10 days. The hospital barracks are divided into segments for different diseases, but there is no special isolation against cross infection noted, but they probably got good results just the same. The sick officers are placed apart. Mumps is the worst infection they have. They have only seen one case of smallpox in three years in the whole army, and that was benign.

On the way home from this place we stopped at one of the most peculiar institutions that it has been our good fortune to see—a combination of trench mortar school and rest station. It was certainly an ideal rest station; loaded with flowers and surrounded by a peaceful farm country, with a fine view in every direction. The station was not a medical unit, but the Artillery officer in command was a practical hygienist and taught sanitation in addition to Artillery practice. He had a separate building devoted especially to cleaning up of men, provided with a barber shop, baths, and a good reading room. He was a warm personal friend of the chief surgeon and had not neglected to prove it. It was a good illustration of cooperation and of the value of having every line officer take sanitation to heart for the purpose not only of preventing disease but of making his men self-respecting and comfortable. We saw one thing there that was really worth while—a real club for officers. It was a well-painted, well-furnished, and well-supplied lounge in a little old-fashioned village house. Near it was a fine post exchange, which was not unlike a large grocery store. It had sold fine wines and all kinds of canned goods, tobacco, etc. In addition a handsome tea house was provided where we were served by some English nurses with chocolate, etc.

Army Sanitary School No. 111.

SECONDARY AND LATE COMPLICATIONS OF BRAIN WOUNDS

By Medecin-Major George Guilan

SUMMARY

Important subject of pathology from the point of view of the neurologist, the general surgeon, and the sociologist.

Our study and conclusions are based on personal documents and information received from all the French neurological centers, crystalizing in a report read before the Interallied Conference of November, 1917. This information covers 6,664 cases.

Subjective symptoms in trephined patients are: Headache, vertigo, psychic disturbances.

General neurological examination and its findings, pathogenesis and treatment of these disorders.

Organic lesions following injury of the brain.

The future of injuries of prefrontal lobes, the Rolandic zone, the pyramidal tract, the parietal lobe, the occipital lobe, and the thalamus.

The grave mental disorders; their scarcity.

The late epileptic attacks, the future of these cases, their treatment.

The late abscesses of the brain; clinical study, diagnosis, and therapeutics.

The late meningitis.

Brain hernia.

Foreign bodies in the brain; what to do.

Cranioplasty; its indications and contraindications.

General remote death rate of trephined cases.

Aptitude of these cases for military duty and work in general.

Conclusions.

His experience comes from a careful examination of 6,664 cases of old injuries involving the brain.

Subjective troubles of old brain injuries.—(1) Headache, worst at the point of lesion. It is like migraine with vomiting and is aggravated by lowering of the head.

(2) Sudden attacks of unconsciousness, lasting a minute or so.

(3) Vertigo, as in Meniere's disease.

(4) Psychic troubles, amnesia, etc.

(5) Asthenia, difficulty in working, in arriving at a decision, etc.; inability to endure emotion, irritability.

Objective signs.—(1) Eye changes—choked disc; changes in the size of the pupils.

(2) Changes in the reflexes—reflexes liable to be exaggerated, including the cutaneous.

(3) Changes due to injury or affection of the semicircular canal, giving uncertain gait, etc.

(4) Babinski's sign.

(5) Thermic instability, with variation in bodily temperature of $1\frac{1}{2}^{\circ}$ C. a day.

(6) Changes in the spinal fluid, increase in albumin content (hyperalbumin and cellular changes).

(7) Neurasthenia. It is possible that some of these cases are merely those of neurasthenia, but it is a fact that old cases after brain operations are mentally inferior to what they once were; they are "diminués."

There is far too much trephining in this war and exploring of brains, and the bad results are seen in these old cases. Such old cases are very apt to be emotionally unstable. Slight causes provoke rage or fear. In fact an old case of brain injury is liable to have neurasthenia. They may even be ataxic.

The labyrinthine troubles account for the vertigo of old brain cases, and such people can not stand looking at a cinematograph show. Later there is a lack of equilibrium and coordination. One of the best tests for this is Babinski's biauricular test. That brings out these lesions well. The chronic headache of very old brain injuries may be due to increased pressure in the cerebrospinal fluid, and we may relieve this by a lumbar puncture once a month. Old brain cases are liable to have flashes of light in the eyes, loss of memory

of recent events, and especially of events connected with the accident. In very rare cases you may have abolition of the deep reflexes, but generally the reflexes are exaggerated. Pupillary congestion of the eye occurs sometimes. The temperature is apt to rise abnormally after exercise.

The moral of all this is: Do not take away so much bone when you operate on the brain; use small trephines and use them less.

The first, second, and third frontal convolutions can be badly involved without sequelæ. The Rolandic convolutions if they are injured give typical reactions. The parietal ascending convolutions of the Rolandic area affect the sensibility as well; that is to say, deep sensibility, the judgment of shape and position in space, the astereognomic sense. The prognosis of injuries to the Rolandic area is at first seemingly very bad because there is absolute paralysis, but usually in a few months the patients can walk and perform other ordinary acts. It is not well, however, to promise anything until a year is elapsed. Focal epilepsy is not always due to injuries of the Rolandic area.

Injuries of the supramarginal convolutions cause anaphasia of the type Wernicke. This is a serious form of injury and brings about a lowered mentality. It is much better for the patient to have a monoplegia. The injuries of the first parietal yield no symptoms and the same can be said of the second and third temporal. But injuries to the posterior portion of the first temporal convolutions cause sensory aphasia. Hearing is not injured by lesion of the temporal lobes. Injuries to the superficial portion of the occipital lobe gives no symptoms, but injuries to the deeper portion give hemiopia and other eye affections, which, however, tend to rapidly disappear. Old injuries to the occipital lobe, internal surface around the calcarine fissure, cause scotoma of which the patient is often ignorant until examined by an oculist. Lesions to the internal capsule from the knee to the posterior limit cause permanent massive, hemiplegia, a permanent spastic paraplegia; never partial. Injuries to the optic thalamus cause thermo-tactile anesthesia, and disturbance of deep sensibility. When one has a painful anesthesia you can assure him that he has an injury of the thalamus.

In general the late effects of the wounds of the brain are by no means as serious as one would expect. Of the 6,664 cases only 10 per cent, or 675, were epileptic, and many of them only partially so. Jacksonian epilepsy points to some local cause of irritation, but some cases developed epilepsy two years after their injury. We should operate in Jacksonian epilepsy only after repeated localized attacks. Trephining for adhesions supposed to be the cause of epilepsy of war wounds is very fallacious and dangerous owing to the fact that there has been penetration and that there is a long cicatricial tract; you never know what part of the tract is causing the irritation which sets up the epilepsy. Besides, apparent Jacksonian epilepsy may turn out to be something else. For instance, it may be the beginning of a brain abscess which is initiated by symptoms like true "mal de epilepsie" with short periods of unconsciousness; these attacks become more frequent one day become generalized, reaching to as many as 40 attacks in a single day. Now a fever of 43 is noted and there is a hyperalbumin and a leucocytosis of the spinal fluid. The answer to all of these is abscess of the brain and not Jacksonian epilepsy.

There is another possibility which complicates the diagnosis: Cases of localized, non-suppurating encephalitis, which one might think were going to turn out to be abscess of the brain. There is also an epilepsy due to hypertension of the cerebral fluid, and this is relieved by lumbar puncture.

The cause of obscure delayed brain trouble may be due to thickening of the dura and adhesions around vessels which cause a diminution in the blood supply.

Acute encephalitis causes a slow and irregular pulse. If it is localized it can be treated by chloride of calcium, $\frac{1}{2}$ to 1 gm. a day, and bromides. A diffuse encephalitis is always fatal.

No cases of general paresis have been observed as having been due to war wounds. Only 47 cases of injuries to the skull of the 6,664 studied have presented insanity of a severe type.

Of 4,262 cases, there were collected 710 hemiplegias, 206 monoplegias, 200 asphasias. Quillain has collected 164 cases in which foreign bodies were lodged and very few gave any trouble. They should not be fooled with unless they cause symptoms. The truth is that fragments of cloth and splinters of bone cause more after-trouble than the projectile.

Delayed abscess.—Of the entire series, there were only 94 cases of delayed or late abscess. These began with headache, vomiting, and bradycardia. You should always send for an ophthalmologist in the presence of these symptoms to examine the fundus of the eye. Whenever in a hemiplegic, due to a war wound, this hemiplegia is exaggerated, look out for abscess in the presence of the above signs. The diagnosis between acute encephalitis and abscess is difficult. The local symptoms are more exaggerated, however, both with irregular and slow pulse. Gordon Holmes says that late abscess of the brain occurs in from $1\frac{1}{2}$ to 2 per cent of all cases. The treatment is to open the abscess, and a bacteriological culture should be always made of the pus at the time and successively thereafter in order to know when to close.

Retarded meningitis.—There are only 32 cases in this series. In this case one should operate if the epilepsy is Jacksonian, but if the epilepsy is general there is no treatment possible.

Cerebral hernia.—This may be due to a deep abscess, and in such case you should not do a lumbar puncture, as pus may be thus drawn into the lateral ventricles or spinal canal and set up meningitis. It is a rare condition and is generally due to deep infection. The treatment, of course, is to open the abscess well. When it comes on late it has the same significance. You need not hesitate at all to cut off the fungoid growth, as the nerve cells therein have long since disappeared.

Cranioplasty.—Many cranioplasties have been done, but correct records of the results are difficult to get. Marie studied 21 cases, with the following results: 6 improved, 12 remained the same, 3 were made worse.

Statistics.—Of 4,983 cases which recovered, 1,267 were permanently discharged from the service, 1,559 were temporarily discharged, 1,802 were made noncombatants, and only 295 returned to the trenches.

By cranioplasty we mean a bone graft or the placing of cartilage or fluids to fill in the defect in the skull. There is a double object in view: First, an esthetic one in which the result is attained; and, second, a curative one for the subjective symptoms, but the results are not good. If the wound is large the plates are not well tolerated, and in small defects they are not needed. You should never do a cranioplasty unless the nervous system is intact, and you should never send a trephined man back to the front, under any circumstances.

Army Sanitary School No. 112.

WOUNDS OF THE ABDOMEN

(Summary of a lecture by M. le Medecin-Major Okinczye)

I. Definition.—Only penetrating wounds will be considered under this heading.

Their gravity is due essentially to the injuries of the viscera, the gravest being the intestinal wounds; then in order those of the liver, the spleen, the bladder, the kidney, and the stomach, and the blood vessels—vena porta and blood vessels of the intestine.

Graver still are associated injuries—pleuro-visceral, thoraco-abdominal, spine, skull.

Necessity of preliminary examination to decide whether to operate or refrain.

II. Indications for operation and contraindications.—The operation is serious, long and difficult—presupposes, therefore, sufficient resistance on the part of the patient.

(a) Immediate and absolute contraindications: Absence of radial pulse—low blood pressure—traumatic shock—association of irremediable injuries.

(b) Relative contraindications: Thoraco-abdominal injuries, grave associated lesions of the limb or skull and time elapsed since injury.

(c) Indications: Signs of active intra-abdominal hemorrhage. Radial pulse below 120.

III. Examination of the patient.—Conditions under which examination is made. Diagnosis of penetration; signs making the diagnosis probable or certain; situation of the wound; muscular defense; percussion; urine; vomiting; digital examination of the rectum; radio-scopy, for finding and locating projectile.

IV. Preparatory treatment.—Treatment of shock—heat, morphine, etc. Duration of this treatment.

V. Operative treatment.—(a) Choice of anesthetic—chloroform, ether, morphine.

(b) Choice of incision.

(c) Exploration—explore before repairing; explore before manipulating. Exploration must be anatomical and methodical. Exteriorization of injuries—simple for the small intestine. Splitting of the fascia to make this possible for the duodenum and large intestine. Particular positions of the patient necessary for the upper and lower abdomen.

(d) Repair of injuries—freshening, suture, and resection of the intestine. Treatment of injuries of liver, spleen, and kidney wounds.

(e) Cleansing of the peritoneal cavity—ether; artificial serum.

(f) Drainage—must one drain? How to drain.

VI. *Postoperative treatment.*—Diet; Fowler's position; Murphy drip.

VII. *Study of a few cases and results.*—The diagnosis of the penetration is made by the appearance of the patient plus the usual signs. Do a laparotomy and examine the intestine, the liver, the spleen, the bladder, the kidney, and the stomach in this order, which is the order of seriousness of the injury. There is a great deal of shock in abdominal cases, and a fall in temperature makes the prognosis much worse in winter than in summer. Wounds of the kidney and stomach seem to be less serious than those of other organs. Of 64 cases seen lately 40 were operated upon, 20 recovered, 20 died, 2 more were benign and had no operation, and the rest were not operated upon on account of the gravity of the case due to shock, and all of these patients died. Operation to be successful in this class of cases needs to be early. In periods of calm the abdomen should be opened as a routine whenever the indication is clear that there has been an injury within and the state of the case permits, but all cases should not be operated upon, of course. The condition of the pulse is the most important indication. As long as that is below 120 one can feel safe in operating. If the wound is a thoraco-abdominal one, operate on the abdomen first, and if the condition of the patient forces you to stop, complete the abdominal operation and repair the thoracic injury later. After 12 hours from the receipt of the injury the chances are not good. Hemorrhage is an indication for immediate operation. Complete absence of radial pulse is a contra-indication to operation. Cases are especially bad that have serious multiple wounds in addition to those of the abdomen. It is a very suspicious sign when you have all the symptoms of shock plus a great deal of pain in the abdomen; colic in shock stands out in intra-abdominal injuries. In badly shocked cases always transfuse your patient before the operation. This is especially so when shock is accompanied by hemorrhage, in which you should operate as long as you can feel the pulse. You can not give more than three-quarters of an hour or an hour to treatment for the relief of shock in abdominal wounds. Then if you are going to operate at all, operate without further delay. Small wounds of the flank, groins, and buttocks are apt to end in intraabdominal injuries, and they should be carefully examined and watched. You should catheterize to avoid overlooking bladder injuries and also make a digital examination of the rectum. It is not safe to continue preparatory treatment of any sort longer than the time we would give to combat shock. Morphine is of great value in this treatment. You may use either chloroform or ether, but ether is preferred. Never use lumbar anesthesia. It should be a dictum that abdominal wounds should have precedence over all others if they are at all serious, as they usually are. In fact, wherever there is any doubt open the abdomen, and such doubt will come in connection with wounds of the lumbar region, wounds of the lower thorax, and wounds in the flanks and buttocks before mentioned. Examination should take place in a warm room, but accurate diagnoses are best made after opening the abdomen. He emphasizes the fact that injuries of the intestinal blood vessels are very dangerous, and that when you operate under these conditions transfusion should be going on at the same time. It is useless to operate on a man who has an injury of the spinal cord. The diagnosis should embrace, always, a careful X-ray examination. The great point is to distinguish between the small wounds and the severe ones. There is no injury of the abdominal contents without rigidity of the abdominal muscles, and it is a most important sign of intraabdominal injury. Fear plays a great part in producing shock in abdominal wounds, and the wounded man should be removed from the front as soon as possible, but it should be borne in mind that rough and cold ambulances are the cause of many deaths in abdominal wounds. Their gravity depends upon their extent and their number. In intraabdominal injury a suspicious sign is the disproportion between the size of the wound and the serious condition of the patient. This is peculiarly suspicious in wounds of the buttocks with an abdominal syndrome where

one would not expect ordinarily to find intraabdominal injury. In operating on these cases we should give a good incision for exploration; that incision should be anatomical and preserve the muscular wall. It is very important to have proper retraction to allow a careful visual inspection before the hands go into the abdomen. Always explore in this way and with the hands before you operate, but in so doing do not eviscerate. Make a routine examination from the stomach downward, through small intestine and colon; use hot compresses. The Trendelenburg position is useful in making a thorough examination of the pelvis. In repairing, freshening, and suturing, if the mesentery is injured, do a resection of the part affected together with removal of the injured mesentery. An end-to-end anastomosis should be done, as it takes less time. If the spleen is more or less severely injured, better remove it than try to sew up a large wound in it, but the kidney should not be removed unless there is a vascular injury. Do not use ether inside the abdomen, but salt solution at 40° C. In going over the intestine you can explore the ascending, the transverse, and the descending colon well, but the flexures are hard to get at. A very good plan in this case is to reach up and free the ligaments holding the flexures to expose them. This can be done, especially on the left side, where the ligament runs from the spleen. As soon as the injured part is found, pull it out and clamp it and go on. With regard to the intestine, small wounds can be sutured or elbows can be formed. Before closing the abdomen go over every part of the intestine with a sponge. A particularly serious combination is a combined wound of the intestine and of the liver. Regarding the after treatment, unless there is an injury to the rectum, the sigmoid, or the descending colon, use the Fowler position or the Murphy drip. Keep on starvation diet for 24 hours. Do not give a laxative for a week. Remember that glass tubes only drain the pouch of Douglas. Remember that the cases that you get within 3½ to 5 hours after the injury have the best prognosis. Consequently, if you can not bring them back within that time to a regular hospital, send up a team to meet the man and operate on him at a field hospital, because it is better to bring the operation to the man than the man to the operation in this case. But if you have good transportation for wounds of the abdomen, send the man back; do not leave him at the ambulance head. In fact, he believes that good roads and good ambulances are the real solution of the problem and time hasn't quite as much to do with it as we used to think. These patients do not die from peritonitis but from shock, hemorrhage, etc.

GUNSHOT WOUNDS OF THE SKULL—THEIR IMMEDIATE TREATMENT

By Medecin-Major Lecene

TRANSLATION OF SUMMARY

The gunshot wounds of the skull (including wounds caused by bullets, shrapnel, and shell splinters) are certainly among the most severe and deadly observed in this war; many of such wounded die in the first few minutes or hours following the injury and remain on the battle field. A second important percentage of mortality occurs among those who are transported to the field hospitals and who are hopelessly wounded (bursting fractures of the skull); these can not be operated upon.

The remaining (about a third) are the only ones of interest for surgical treatment.

It must be emphasized that since the use of the helmet has become a matter of regulation, the gravity of the wounds of the skull is very much lessened. The helmet is chiefly useful for preventing the penetration of shell splinters or shrapnel and the introduction into the wound of dirty fragments of the cap, so often observed at the beginning of the war. The helmet is not so efficacious against bullets. The wounds of the skull are doubly dangerous: (1) Because they injure the bones of the skull (danger of osteitis); (2) because they injure the meninges and the encephalon (encephalo-meningitis), without speaking of the numerous late complications and definitive lesions of the brain (hemiplegia, hemanopsia, aphasia, traumatic epilepsy.)

The skull wound can be separated into two great classes: (1) Nonpenetrating or extradural wounds; (2) penetrating or intradural wounds.

The first class of wounds is certainly more benign; but it must not be forgotten that an extradural wound can be complicated: (1) By osteomyelitis of the bones of the skull; (2) by severe contusion of the brain, even though the dura may be intact.

The special severity of gunshot wounds consists usually: (1) In the more or less contusion of the parts by the missile; (2) in the penetration and implantation in the wound of septic foreign bodies. (The hair of the soldiers must be always cut very short.)

There is a class of penetrating wounds of the skull that is especially dangerous, namely, the wounds penetrating into the brain cavity after passing through the accessory nasal cavities (ethmoid, frontal sinuses).

Wounds of the skull can be anatomically divided into several varieties: (1) The tangential extradural wounds; (2) the tangential intradural wounds; (3) the perforating through and through; (4) the depressed extradural fractures; (5) the depressed penetrating fractures.

The first and fourth varieties are quite analogous to the fractures observed in civil practice.

The second, third, and fifth varieties are certainly more severe than the revolver bullet wounds observed in civil practice, because the war missiles are much more destructive and irregular.

The importance of microtraumatism disseminated in the white substance of the brain must be here emphasized (small foci of localization observed at a long distance from the principal traumatic focus).

The greatest immediate danger for the patient is, naturally, the infection of the meninges and brain tissues. It is evident that another great factor in skull wounds is the damaging of various parts of the encephalon, but it is not possible to treat here this important question.

The primary shock is generally not very severe, according to my observations. The pulse is generally full and the wounded, often unconscious, do not present the dangerous shock of many wounded in the extremities.

I think it is justly the unconsciousness of the wounded which explains the absence of "mental" shock. A practically important consequence of this observation is that the cerebral cases can be transported to a relatively distant hospital without aggravating.

To prevent the infection of the wound must be the principal scope of the military surgeon; the reparation of the possible damage caused to the encephalon by the missile is entirely the work of nature, after infection is done away with.

It must be remembered that wounds of the skull are generally less soiled than wounds of the limbs (helmet; nonpenetration of fragments of clothes).

A very difficult question is that of the missile or bone splinters deeply included in the brain substance. Some surgeons think that every wounded man whose brain has a missile or bone splinter in it is condemned to death sooner or later (delayed abscess of the brain), sometimes one year after the injury. Consequently every missile lodged in the brain must be removed. But it is not at all certain that the remote prognosis of the lodged missile is so irremediable severe; numerous cases of tolerance of missiles by the brain are now known, and certainly the number of those cases will increase if the immediate suturing of the skull wound is more generally practiced. Often the secondary complications take their origin in an osteitis following the "leave open" treatment of the wound. I think that it is chiefly a matter of each individual case. When the missile is not too deeply situated it is certain that it must always be removed, and the sooner the better. But, when the missile is small and deep, I think that the removal of this foreign body is often more dangerous than abstention. The operation, even when it is done several weeks or months after the injury, is always difficult and very damaging for the brain substance. When indicated, this operation should be done only after a careful localization of the missile with special instruments (Hirtz's compass and under the direct control of X rays).

The most frequent immediate complications of the skull wounds are: (1) Diffuse encephalo-meningitis; (2) localized meningitis with superficial brain abscess; (3) deep brain abscess; (4) cerebral hernia.

The surgical treatment of the first is practically nil. The localized meningitis with cortical abscess can be cured by opening and draining. The deep brain abscess is very severe,

and its diagnosis is always difficult. It is rarely multiple and its opening into the ventricles is frequent and always ends fatally. When this deep abscess is solitary and duly recognized, it can be cured by opening and draining like the otitic brain abscess.

Cerebral hernia of moderate size, appearing soon after the injury and chiefly when the wound is left open (a bad method), is generally due to the edema of the brain around the traumatic focus; it can be easily cured by enlarging the opening of the bone perforation and by gentle pressure, as also by lumbar puncture. But cerebral hernia, generally of great size and appearing later, is much more severe. It is generally then produced by a form of suppurating encephalitis beneath the trephine opening. It can be cured only by the opening and draining of this focus; but generally the encephalitis is diffuse, the pus not collected, and the majority of cases end fatally.

All these complications can be generally avoided by the following treatment, which is only a particular application of the general treatment of fresh wounds:

First. Excision of the wound.

Second. Enlarging the opening caused by the missile.

Third. Careful removing of the bone splinters, foreign bodies, and missile (when possible and after X-ray localization).

Fourth. Suturing of the wound with a safety drainage, remaining two days. Naturally this treatment must be applied soon after the injury (on the first day).

With the systematic use of this method for eight months I was able to lower the mortality of penetrating wounds of the skull to 17 per cent from 60 per cent, the death rate observed by me in the first months of the war with the "leave open" treatment.

This lecture was confined to the pathology and treatment of gunshot wounds of the skull. This is the most serious of all war wounds and was the most common cause of death on the battle field in the Russo-Japanese War. All cases are not of particular interest to the operating surgeon; they live to get to the field hospital and that is all; probably two-thirds of men with skull wounds die on the battle field and in the field hospitals.

If the skull is well treated the brain often escapes injury. Extradural wounds are much less fatal, as the dura is quite a barrier to infection; hence you should not open it unless you have to. It should be remembered, however, that severe contusions of the brain occur from a wound not opening the dura; there may be even no fracture to show for it. Of 26 such cases, 3 died. We should remember, also, that tiny pieces of shell with sharp, cutting edges produce effects such as experimental physiologists might produce with a bistoury, giving extremely localized effects. The cavity is usually reached by injuries of the vault. The steel helmet is a protection to the head, but it should not be forgotten that it frequently deforms bullets and causes, therefore, worse injuries when they do penetrate. He believes that men going into battle should have their heads shaved on account of the blowing in of the hair and infection of the brain.

He divides wounds of the skull into five varieties:

First, gutter fractures with the dura intact, although the underlying brain may be badly contused, as above noted.

Second, tangential fractures, where the cranial cavity is infected and the projectile emerges by a larger exit than that of entrance.

Third, perforating wounds of the brain, the most dangerous of all.

Fourth, explosive wounds, which invariably wind up in the cemetery.

What one generally sees as the result of a shell injury is a rough fracture of the skull, as if from a hammer, the depression or craterlike funnel formed of four fragments pressed in. Often a bit of a bomb is lodged in the skull; it sometimes goes no farther than the external table, but on opening we find a piece of the internal table fractured, with extradural hemorrhage.

In another type splinters of bone, with hair and bits of scalp, are blown in, forming a chamber of attrition surrounded by brain tissue, punctuated with petechial hemorrhages. Such hemorrhages may affect a whole hemisphere.

Brain cases are proverbially believed to be in a state of shock, but unless the anatomical injury is going to be fatal they are not. They lie as if in an epileptic coma and not in collapse. They are the antithesis of chest wounds and can be transported from 18 to 30 km. without

damage. As a matter of fact this long transportation is necessary, for they need a good hospital, free from noise and dirt, where they can remain in good hands until they are well.

The treatment.—Prevent infection and complications. This is done by excision of the contaminated, dead, and devitalized tissue. Reparation and return to physiologic condition is in the hands of nature alone. The surgery of the brain in war means very little intervention. For an extradural fracture excise your devitalized tissue, remove foreign material and the missile, if it is near the surface, and close with a filiform drain. In treating wounds involving the brain, suture the skin but do not touch the brain substances. Lecene does not believe in decompression operations. As to lodged projectiles, these do not all cause trouble, but they frequently do cause abscess. Pieces can be removed from the brain substance if they are only 5 to 6 cm. away, but no farther, especially if the missile is rather large. Lecene is bitterly opposed to removing projectiles after the wound is healed. He states that we should evacuate an abscess always.

Meningo-encephalitis is not seen when the excision of the scalp wound is properly done, and as a matter of fact the primary suture has done an enormous amount already in reducing the mortality and the after effects of war wounds of the skull. Local abscesses are easy to treat, but they are easier to prevent by excision of devitalized tissue in primary suture. When a missile or foreign body lodges deep it may set up a localized abscess where it lies, but this is rare compared to what usually happens, which is that the tract of devitalized tissue breaks down from the wound of entrance progressively on to the place where the missile is lodged, and this may extend sidewise as well as directly in.

Traumatic hernia.—First, immediately following the wound. This looks like a mushroom, and the cause is hypertension of the brain and edema of brain tissue. It is generally easy to cure by enlarging the opening and by applying pressure.

Second, late. These hernias appear two weeks after healing of the wound, and are large. They are due to encephalitis and abscess, and the prognosis is extremely grave on account of the cause.

The usual treatment of skull and brain wounds.—First, excision of the wound of entrance. Remove bone and splinters, foreign material, and devitalized tissue as far as possible.

Second, close the wound, as the bacteriology of these wounds shows the cerebral mass to be usually free from infection.

From November, 1914, to June, 1915, he was in the habit of seeing the wounded of the skull and brain from 12 to 48 hours after their wounds were received, usually 24 to 36 hours after, and at that time 12 out of 15 died. This was in a field hospital, and was poor on account of the hospital itself. His last results, with ideal conditions, were 20 out of 24 penetrating wounds cured. He had 26 extradural wounds. Although these lives were saved, he can not speak much of their future as to function.

At the conclusion of this lecture the director of the school, Professor Regaud, protested bitterly against considering these cases intransportable and against keeping them at the front.

Army Sanitary School No. 114.

GUNSHOT WOUNDS OF THE NERVES AND THEIR SURGICAL TREATMENT

By Medecin-Major Lecene

TRANSLATION OF A SUMMARY

The tiny pieces of shell, irregular and sharp as a razor, cut or nip the nerve in this war much more frequently than in previous wars, although complete sections are rather rare. In addition there is a radiant action on the nerves, a molecular stunning not seen in civil life. Lastly, to this must be added infection.

Lecene saw a hugely swollen end of a sectioned nerve (the sciatic) in which a fragment of projectile in its course had buried a bit of periosteum and which "took" as a graft producing ossification of the bulbous end.

In type 4 Form A (referred to in summary below), the axis cylinders pass on either side of the neuroma; in Form B, there is an external neuroma but still within the sheath. These neuromata he calls pseudoneuromata of attrition.

The bulbous ends of a severed nerve the French say are really "keloids," but we would call them formation scar tissue.

In type 1, as a matter of fact, the frayed-out end of the proximal piece of nerve is soon embedded in connective tissue cells. Although the axis cylinder pushes out vinelike shoots into this mass in its vain endeavor to reconstruct the bridge over the gap caused by the missile, these are caught in this scar tissue and crushed to death. Therefore we have to cut off the bulb well back in order to get healthy axis cylinder.

In type 5, the same thing occurs for the part of the nerve affected. In type 4 the neuromata can be enucleated. A diffuse neuroma (type 5) has a variable amount of nerve tissue ensnared and crushed in the neuromatous growth.

If we admit that these so-called "keloids" are impassable, then we should extirpate them, but in certain cases the function is nevertheless reestablished, and right here lies the bone of contention; the surgeons arguing for operation before it is too late and the neurologists arguing for more time to demonstrate the necessity for the operation in the hope that function may be established without it. When there is loss of sensation and motion, loss of muscular sense, trophic changes with reaction of degeneration, and a failure to excite the nerve by the faradic current, or even the galvanic, the evidence seems complete that the nerve is really interrupted. But in other cases, with the syndrome of compression, the decision is difficult. One should not rely too much upon the electric reaction of the nerve, and it should never be depended upon solely. There is a certain conservation of sense of pain on deep pressure in badly compressed nerves which allows one to say, in spite of other discouraging signs, that the nerve is not interrupted. One thing is certain: One should not wait too long to do a secondary operation upon the nerve, as the distal part degenerates entirely.

Owing to the cutting, laceration, and shocking caused by high-explosive shell wounds, lesions of nerves are extraordinarily common now. Lecene believes that with the primary or primary retarded suture there will be much fewer cases of serious and permanent nerve trouble. The neuromata are a source of pain as well as loss and damage of function. Really, the best way to find out about the actual condition of a nerve is to cut down upon it; and if it does not respond to the faradic current, operate.

The most frequent types of nerve injury are seen in types 2 and 5.

The syndrome of irritation of a nerve.—This is a surgical neuritis, follows infection, and is apt to be superadded to a lesion of adjacent vessels. In a case of this kind we get burning (causalgia), dryness, and violent paroxysmal pain. The patient is anxious all the time because he never knows when he is going to get a sharp attack. This pain is indescribably acute. The sufferer from an irritated nerve must always have cold water near by so that if pain and causalgia come on he can plunge the part into it. To these symptoms may be added trophic and sympathetic troubles, generally at the level of the hand or the foot. There may be contractures, cyanosis, anesthesia, hyperesthesia, etc. After all, what interests us is, What shall be done? The causalgia is on our hands and those cases are a terrible responsibility to the surgeon. The question must be answered, Shall we resect, or what?

The prevention in a fresh wound of the type shown in types 1 and 3 is apparently only a simple primary or primary retarded suture. But in types 2, 4, and 5, what are you going to do there surgically with primary suture? In addition to this, you should not rely too much on primary union in a case like those illustrated by types 1 and 3, because the ends are badly shocked and you do not know how far up. Those widespread contusions of the nerve may later end in diffuse neuromata and even if the nerve may not be cut, a block may be constituted by the fibrous tissue which forms between the healthy proximal and distal portions. An exploratory operation is not of itself dangerous, and one can thus decide many important points.

The treatment of the type 1 wounds is clear in a secondary operation—suture. The only difficulty lies in deciding how much of the ends are involved in the keloid process at

the ends of the healthy portions. When there is a considerable interval after all is cut away that should be, to join healthy ends you can not bring them together and make them unite by putting the extremity into all sorts of positions to secure approximation without tension. If you do this you will have ankylosis in a bad position. You should certainly not attempt to bridge over a gap in the way described by so many textbooks of turning down a flap of nerve from above. The best thing to do is to decide on a graft or the autograft. This latter has been successfully done with the sensory nerves of the patient. Often the dead nerve of a young animal can be used, preserved, however, in alcohol, as formalin-preserved nerves are bad.

The great difficulty is in cases such as illustrated by type 2. Professor Marie believes we should not intervene surgically when the continuity of the nerve is preserved. A good way to decide on the condition of a nerve like type 5 is to faradise it after exposure. If there is no response, there is sclerosis. If the current excites a response, then the trouble lies in the binding down of the nerve by adhesions. "Neurolysis" is a term used to describe the surgical liberation of a nerve from those adhesions. It should be done in the case of compression of a nerve, but in a section, partial or complete, of a nerve the keloid must be removed. The musculospiral is a purely motor nerve. The median has sensory fibers and is complex. The result is that when the musculo-spiral is united it gives pretty good results as it has only one function, while suture of the median frequently fails, at least to the extent of bringing incomplete results. Professor Leene has a friend and patient, who was a very brave and stolid man, who had a hematoma pressing on his median nerve trunk in the axilla. The pain was so extreme that he completely went to pieces and threatened to kill himself. Liberation of this nerve and turning out of the clot did away with the causalgia, and he finally became entirely normal. This was purely an irritation of the nerve and the remedy was neurolysis.

For severe pain one could inject alcohol into the sheath of the nerve, but the result can not be controlled and it is better to employ surgical methods. When one sutures a nerve primarily use fine linen thread and only go through the sheath, avoiding coarse needles and tying too tightly. It is well to leave a very small space between the divided ends of the nerve.

Leriche has dissected out the sympathetic plexus from a man's vessel to get rid of the syndrome of compression. It is never wise to suture nerves in a septic wound. The results of grafting the ulnar and median tracts in the brachial plexus and the great sciatic have been bad. It is always well to follow nerve operations by physio-therapy and orthopedic treatment. If you feel reasonably sure that there is danger of paralysis in a bad nerve injury put your extremity in the best possible position and keep it there in anticipation of contracture. Therefore, you hyper-extend the wrist with rubber bands to extend the fingers.

GUNSHOT WOUNDS OF THE NERVES AND THEIR SURGICAL TREATMENT

I can not, in the short time allotted to this conference, study the whole clinical aspect of the question. I will limit my study and describe only: (1) The macro- and microscopical lesions of the wounded nerve; (2) the symptoms of grave lesions of the wounded nerve with the indications for surgical treatment; (3) the technique and result of this surgical treatment.

The frequency and gravity of lesions of the nerves in the present war was unexpectedly great. We did know, however, that lesions of the nerve trunks were produced by bullets in the War of Secession. In that war Mitchell described new types of surgical neuritis following gunshot wounds. After the Russo-Japanese War, a certain number of observations of wounds of the nerves were also detailed. But the extraordinary frequency of wounds of nerves during the present war enabled us to enlarge and perfect our knowledge of these severe wounds.

Wounds of the nerves can be produced by bullets, passing through or near the nerve, and by shell or bomb splinters, sometimes cutting, more often crushing, the nerve. The destructive effects of war missiles on the nerve substance are very much greater than those of the cutting tools which produced the wounds observed in civil practice. I think it is this severe and diffuse bruising of so delicate a substance as a nerve, plus the infection of the wound, that explains the serious prognosis and the unexpected gravity of nerve wounds during the present war.

Anatomically, we can distinguish several types of nerve lesions: Type 1.—Total division of the nerve trunks. This type shows the appearance of a totally sectioned nerve one to two months after receiving the wound. Here the ends are buried in muscles. Fine connective tissue fibers seek to establish reunion, but are functionally of no value. Type 2.—Pseudo-neuroma consecutive upon general bruising of the nerve. This is a contused nerve which at the point of shock has a neuromatous formation. In this fusiform swelling the nerve fibers are mainly replaced by neuroma cells, but a few fibers may still pass and permit a faint conduction of nervous energy. Such fusiform swelling may be from 2 to 4 cm. long. Type 3.—Lateral notching of the nerve. Type 4.—Intra- and extra-neural scar neuroma. Type 5.—Diffuse sclerosis with thickening of the nerve. In this type the main part of the fibrils of the axis cylinders are interrupted and their places are taken by neuroma cells without any fusiform swelling. In this case the nerve is thick and sclerosed.

The first class is rather infrequent; the most frequently observed are the second and the fifth. The relative frequency of simultaneous lesions of the large arteries and corresponding nerves (chiefly in the upper limb, art. axillaris and brachial plexus, art. brachiales and median or ulnar nerves) must be emphasized.

Histologically, the chief lesion observed in all the wounded nerves is sclerosis. This fibrous tissue is very dense (quite analogous to keloid tumors) and causes the degeneration of the nerve fibers included in it, hindering the normal process of regeneration. In the wounds which suppurate, the injured nerves and vessels are always surrounded by the same dense scar tissue formed during the healing process; this scar tissue is the cause of great difficulty in the operative dissection of the nerves.

Clinically, we can describe three great syndromes, whose causes are different. First, those due to physiological interruption of impulses in a nerve; second, those due to compression of the nerve; third, those due to irritation of the nerve.

In the first class, we observe: Complete palsy of the muscles, with loss of the normal tone; loss of cutaneous and deep sensibility; later atrophy of the muscles, trophic disturbances, and electrical R. D. The study of electrical changes in the nerves and muscles is always interesting, but we can not conclude with certainty, after its study, that the nerve is completely or partially divided, or, even, only compressed.

In the second class, the symptoms are very analogous to those of the first class, but deep sensibility is rather often preserved and the electrical R. D. is not always so complete. The prognosis is milder and spontaneous recovery is sometimes possible.

In the third class, painful sensations prevail, causalgia of Weir Mitchell, paroxysms of burning pain, vaso-motor disturbances (cyanotic hand). The motor troubles are very much less severe; but the pain prevents use of the limb. The prognosis is always very serious.

Surgical treatment.—The immediate suturing of a completely or partially divided nerve in a clean wound is evidently the ideal method of treatment. We do not yet know with precision the results of this only recently applied method. But it is certain that the immediate cleaning and suturing of the wounds, as now more and more practiced, will lessen in the future the gravity of prognosis of nerve wounds since the majority have complications which, up to the present, are certainly of infectious origin (suppuration with excessive scar tissue formation).

When the wound is infected and suppurates, it is not wise to try a suture of the nerve; the dangers of septic neuritis are certainly too great. When the wound is healed what ought we to do? The operative indications are somewhat loose and the best neurologists do not entirely agree. But we can affirm that an aseptic exploratory operation is never damaging to the patient. I think, then, that in every case with symptoms of interruption, compression, or irritation, clearly recognized and carefully observed, we ought not to defer surgical treatment. When the wound is opened, the scar tissue dissected away, and the nerve trunk fully exposed, one of several conditions may be observed:

1. When the nerve is quite divided or only united by small bands of scar fibrous tissue, there should be no hesitation. The nerve must be united by a suture; the ends of the separated nerve are lightly trimmed to remove the fibrous scar tissue and these ends are reunited by stitches of very fine catgut passed with fine needles. The stitches ought to be passed only at the periphery of the nerve, through the neurilemma, and it is particularly necessary not to tie them tight. But when a large defect (4 cms. or more) is evident, it will be necessary to bridge this defect between the two ends of the nerve. The only physiological proceeding

is to perform a graft. We know now from the researches of Professor Nageotte that a graft composed of dead nerves of animal (calf) preserved in alcohol is experimentally the best grafting material. When this special material is not at hand, we can make a graft with a fragment of superficial sensory nerve of the patient.

The results of these secondary sutures of nerves, with or without graft, were not till now very successful; nevertheless, favorable cases were published, chiefly for the musculo-spinal and the peroneal branch of the sciatic nerve. The results for the median, ulnar, brachial plexus, and great sciatic nerves are very bad.

2. When the nerve is not interrupted, only notched, or thickened with a larger or smaller neuroma, the opinions of surgeons do not agree. Some, with the authority of Professor Marie, never resect the nerve but only liberate it carefully of the scar tissue (neurolysis); others, with the authority of Professor Deperins, do not hesitate to resect the keloid scar of the nerve and unite it again by suture. It seems very difficult to give a definitive and general rule in such a difficult matter. But I think it is chiefly a question of individual cases.

When the scar neuroma is external to the nerve proper or even internal but enucleable, I think it is safer not to interrupt the continuity of the nerve which has been preserved, but to do only a neurolysis; when hemostasis and asepsis are perfect, this simple neurolysis gives rather often very good results.

But, when the scar neuroma is large and clinically the symptoms of interruption are observed, I think that a resection of the diseased part of the nerve with suture is a logical operation. Some recently published cases agree with this opinion.

When the irritation symptoms are severe, with causalgia, the operation on the nerve alone (neurolysis) is often without results. Some authors advise injecting alcohol into the nerve trunk (Sicard); others, like, Leriche, used to dissect away the sympathetic plexus which surrounds the main artery of the limb, both proceedings have given good results in certain cases.

Finally, it is important to emphasize the always necessary use of orthopedic and physiotherapeutic treatment in cases of nerve wounds.

As soon as possible after the positive diagnosis of interruption of a nerve trunk we ought to give to the patient one of the many prosthetic apparatuses designed to correct vicious positions of a limb (generally it is located in the hand or foot).

Physiotherapy is always useful before and after the operation; it lessens many disturbances presented in the wounded limb (hot air, massage, electricity).

Army Sanitary School No. 115.

CONFERENCE ON TRAUMATIC SHOCK, ARMY SANITARY SCHOOL, FRENCH ARMY, JANUARY 23, 1918

Present: Major General Bechard, jr., chief surgeon of the fifth Army, 75 French surgeons and biologists, and 25 American medical officers.

Presiding: M. Charles Riche, member of the Académie Française.

(Questions appended.)

The conference was opened by M. Leriche, who stated that the object of the conference was not to define shock and we did not know yet, clearly, what it was, but to come to a decision concerning the treatment. He stated that primary shock must be very rare. If so, shock is only secondary to other causes. What are these? Just when does shock appear? There is very little information on this subject.

Does hemorrhage play a rôle? If so, to what extent? He believes that prompt operation often prevents shock, secondary causes of shock are admitted by all: Pain, cold, loss of morale, etc. In septic shock we see improvement and its disappearance in a short time after removing source of sepsis. Leriche states that reflexes are diminished in shock and the pressure of the spinal fluid is very low; the normal being 17, it falls to 6 and 8 in shock. The blood pressure also is low. There is something to be said on the histo-pathology of shock. Are there minute emboli in the brain? There are certainly many cases of shock without injury to the soft parts of bone and consequent liberation of fat; hence fat emboli can not be always the cause of shock. The treatment of shock: Heat is now much used; also transfusion of blood and intravenous injection of salt solution, but nothing as yet is of great enough value to merit the term "specific." Leriche states that spinal anesthesia is dangerous.

M. OKINCZYC (LAPAROTOMIST)

Can not define shock; fear often has a part and the wound is an added cause. There is a great difference between the effect of a wound upon the highly educated man, such as a surgeon, and an ignorant one who has been used to hard labor in the field. In the first the shock is apt to be profound, in the second not so—given the same sort and degree of wound. Shock does not exist in brain cases and it would appear that the loss of consciousness is a preventive of shock. Morphine is absolutely necessary to take away the psychic causes of shock. In fact one should recognize (1) psychic and (2) traumatic shock. Shock must be distinguished from hemorrhage.

M. ROUX-BERGER (CHEST SURGEON, H. O. E.)

All deaths from wounds of the chest can be explained by mechanical respiratory difficulties, by hemorrhage, and by sepsis. He does not believe that shock intervenes in wounds of the chest; hence we should operate immediately and thoroughly. Employ ethyl chloride anesthesia.

M. LEMAITRE (GENERAL SURGEON)

His answers to the eight questions are as follows:

1. "I do not know, but I believe so, although before the war I did not." Never saw a case of shock without injury but believes it exists. The combination of pain, cold, and hemorrhage are additional and all together make "shock."

2. The most important etiological factor is fear; next cold. Psychic influence is marked in shock and pain is a corollary of psychic conditions. Hemorrhage is not necessary to make a picture of shock. Intoxication certainly can produce it, he thinks; shock due to sepsis disappears when source of infection is removed quickly and thoroughly.

Questions 4 and 5 he can not answer.

6. Little, save color of muscles; muscles are brownish red in shock, not healthy red. Cases in shock do not usually bleed very much.

8. Heat is of capital importance. Morphine is good. Normal salt solution is no great value. Has seen good results from subcutaneous injections of oxygen. Don't use chloroform at any price in a military hospital. Advises strongly against lumbar anesthesia.

M. PIOLLET (SURGEON, EPERNAY, AND FORMER ASSISTANT OF CARREL)

The true type of shock is found in multiple wounds, none of which is capable of causing death. The excitement of the attack increases the number of cases of shock due to slight injuries. Fatigue is a potent cause of shock. The higher the development of man the greater the shock. The blacks do not suffer as often or as profoundly from shock as the whites. Long and difficult evacuation of wounded is a cause of shock. Pain is a great cause of shock. There is a low blood pressure in shock (80 to 100 mm. of mercury); when blood pressure reaches down to 40 or 50, death ensues. We must not confuse the effects of hemorrhage with shock. It is dangerous to operate during shock; it does not help—it hurts. But there are some cases in which immediate amputation causes shock to disappear. He believes in the use of morphine and intravenous injection of Loche's serum. He can not see any use in oxygen.

M. LAMBERT (OPERATING SURGEON, CHALONS H. O. E.)

He believes in rapid amputation for severe shock in bad, crushing wounds to the extremities. Has employed spinal anaesthesia, but it had no influence in preventing or increasing shock. If operation is advisable, operate after three-quarters to one and one-half hours in spite of failure of antishock measures.

M. BERTIN (REGIMENTAL DRESSING STATION)

The great point is that there is never any shock to amount to anything seen at the regimental aid station, although pain, cold, and hemorrhage are common. Persistence of these, plus septic intoxication, bring on shock, although pulse may be excellent at first. He had a

case of very slight importance anatomically die of delayed shock at the field hospital, which was not due to unduly long or trying transportation. Some cases of nervous shock are bettered by operation. Heat is the most important antishock treatment. Believes in operating immediately upon all which have but one wound, but antishock treatment is necessary for the cases with multiple wounds. Don't try to find any medicine to correct shock, but prevent it by preventing the causes of shock—cold, etc. Especially important to immobilize fractures and all extremities with bad flesh wounds. Necessary to have better ambulances and a good heating apparatus in them. There are four kinds of shock: (1) Toxic—this may also be due to gas; (2) psychic shock—a primary shock; (3) commotion; (4) emotional shock—use camphor.

M. PIEQUEE (REGIMENTAL SURGEON)

Believes in primary nervous shock, and in amputation to combat shock. He believes in operating on the *mono-blessé* first, and says we should operate in spite of shock, transfusing if necessary later. Transfusion has brought about veritable resurrections. But in the *poly-blessé* you have to treat the shock first before operating.

M. VORVEIUEL (NEUROLOGIST)

There are three different kinds of shock—nervous, toxic, and hemorrhagic. There is commotional and emotional shock. Death can result, due to what is known among the French as "*nevroses' anxieuses mortelles*." The regimental surgeon of the Algerian regiment expressed his belief that emotions have a great deal to do with shock.

M. SANTI (REGIMENTAL SURGEON)

Must remember that shock comes on late, as a rule—not right away.

M. DE LAUNAY (EXPERIMENTAL PHYSIOLOGIST)

Calls attention to tremendous fall of blood pressure after a primary rise, due to exhaustion of the vaso-constrictors. The bombardment will have brought about a great rise in blood pressure at first due to constriction of the arterioles. We should measure the shock of hemorrhage, which causes great fall of pressure, not by the amount of blood lost but by the rapidity with which it is lost.

M. MESTRAEZ (CHEMIST)

Calls attention to the intervention of acidosis as per Cannon's theory in the production of shock.

M. POLICARD (PATHOLOGIST)

Has very little to report as to histological findings in rapid deaths from shock, but in those in which death is retarded he can report loss of lipoid from the nerve cells in the cortical area.

HEMATOLOGIST

In shock there is an absolute and relative mononucleosis.

The discussion was summed up by Professor Charles Richet, member of the Academy of France, and discoverer of anaphylaxis. He began by saying that, as there was no personal question involved in the matter, although there had been considerable animation, he wishes to be permitted to sum up the discussion first and give his own opinion afterward of the little that he knew about shock.

(1) As to primary shock, if it exists, it is at least open to discussion.

(2) Shock must be distinguished from the effects of hemorrhage. In true shock do not depend too much on intravenous injection of salt solution or even on transfusion of blood.

(3) Whatever name you give shock, it is evidenced by a depression of the nervous system, which is the key to the situation. The spirit of man is the key. Depress that spirit and shock comes on. After that comes the effects of cold. In fact, the anxiety before the combat, the fatigue, and, perhaps, cold, all precede shock in many cases and it is thus often initiated. Pain and realization of danger in the intellectual white soldier plays a great part.

(4) The comfort of a man has a great deal to do with the degree of shock. If you want to get your highest degree of prevention, transport rapidly and comfortably. As pain influences the production of shock, morphine should be used. He believes in operating as soon as possible to remove the source of pain, etc., and, therefore, the source of shock. Do not use chloroform; he does not believe in the efficacy of the injection of drugs, but recommends chloralose.

PROGRAM OF THE MEETING OF SURGEONS AND BIOLOGISTS ON THE STUDY OF TRAUMATIC SHOCK

Sanitary Service. Groupment of Surgical and Scientific Services.

Fifth Army, S. P. 223, *January 20, 1918.*

ORDER OF THE DAY

I. Opinion of each surgeon and biologist listed to speak, with observations on subjects mentioned in the following program, or any other points directly concerned in shock.

II. Final general discussion of the principal points taken up by speakers noted.

III. Detailed plan for treating shock in the wounded; suggestions for a continuation of the subject at a later date.

QUESTIONS

1. Does primary shock exist? Leave aside hemorrhage, prolonged pain, chilling of the patient, etc., as well as cerebral or medullary concussion due to an explosion.

2. Secondary shock. Time of appearance. Influences which determine or prepare for its appearance (normal state, pain, cold, hemorrhage).

3. State of the blood in shock, blood counts in pure shock and shock due to hemorrhage; how these may be related and differentiated.

4. Importance of arterial pressure.

5. Nervous symptoms in shock; condition of reflexes and of the spinal fluid.

6. Anatomic, histologic, and physiologic facts in shock.

7. Early operations in shock. Amputation as a means of removing shock by moving the site of the primary lesion. Is there a shock whose source and cause of persistence of symptoms lies entirely in the wound? Septic shock?

8. Efficacy of the different means of treatment, excluding heating of the patient? Morphine; transfusion; injection of artificial serum, serum of Locke and its derivatives, gum arabic, adrenalinized salt solution, etc.; injection of oxygen subcutaneously; emetin.

9. Anesthesia in cases of shock, particularly lumbar anesthesia?

Army Sanitary School No. 116.

ORAL HYGIENE

(Synopsis of a lecture by First Lieut. William H. Potter, D. R. C.)

In order that soldiers may have hygienic mouths they should be taken in hand when children. This is what the German authorities did 12 to 15 years ago when a municipal dental clinic for school children was established in the city of Strasbourg, and later was duplicated in its essential features in many places throughout the Empire. Their soldiers now fighting have the benefit of the care given their teeth in the school clinics and also the accompanying instruction as to the value of teeth and the best methods to preserve them in a healthy condition. School dental clinics have in recent years been established in many parts of the United States and when they become general will exercise an important influence in maintaining oral hygiene in the case of soldiers. The unhygienic mouth conditions found amongst men of the present army are largely due to neglect of the teeth in primary and grammar school days. This neglect may be remedied in the case of soldiers of the future, but we must meet the conditions of the present and the following recommendations are made:

(1) Lectures, illustrated if possible, should be given by a dental surgeon to instruct men as to the value and function of their teeth and to interest them in such care of their mouths

as will lead to oral hygiene. Much of the neglect of the teeth is due to ignorance of their value; what is lightly valued is, as a rule, neglected, and vice versa. Much interest in the teeth can be aroused by a well-planned lecture, which should make clear the following points:

(a) The teeth are necessary for the preparation of food preliminary to its digestion and absorption.

(b) The most important factor in the decay and loss of teeth is the production of lactic acid in the mouth. This attacks the teeth, dissolving their surfaces, forming cavities, and finally bringing about their destruction.

(c) Lactic acid is formed when particles of food composed of starch or sugar are allowed to remain in contact with the teeth.

(d) To prevent decay of the teeth keep them clean.

(e) *Cleaning the teeth.*—Teeth should be cleaned after each meal if possible. If the teeth can be cleaned but once a day, it should be after the last meal, before going to bed. Destructive processes have a better chance at night when the mouth is at rest than during the working hours.

The second most important time to clean the teeth is after breakfast, and the third is after the noontime meal.

(f) *How to clean the teeth.*—Use a moderately stiff brush, and brush as far as possible from the gum tissues onto the crowns of the teeth. A tooth powder helps clean the teeth; if this can not be obtained, use a little soap or a solution of common salt, or even cigarette ashes.

Scraping the top of the tongue helps in oral hygiene. Use a piece of wood about 6 inches long and $\frac{1}{2}$ inch wide, whittled down so that it is very thin and pliable and has a sharp but smooth edge.

(g) *Use of fruit acids.*—It has been shown by accurate experiments that fruit acids are efficient in cleaning the teeth because they break up the adhesive power of mucin causing it to let go its hold on food particles which stick to the teeth. Fruit acids increase the alkalinity of saliva and also its quantity. The saliva has, therefore, greater power to protect the teeth by neutralizing harmful acids and mechanically washing food particles from the teeth.

A practical use of fruit acids can be made by eating an apple or some other fruit at the end of the meal. If an apple is used, the forcing of the teeth into its substance is a mechanical cleansing process and the malic acid of the apple loosens the hold of the food particles on the teeth and increases the quantity and alkalinity of the saliva. While fruit acids produce in the mouth a temporary increase of acidity, it is followed by a prolonged, heightened alkalinity. As a rough and ready way to clean the teeth after a meal, the eating of an apple is recommended to soldiers. It does not make unnecessary the tooth brush, but supplements it and takes the place of the brush when circumstances will not allow its use.

(2) *Prophylactic treatment by the dental surgeon.*—While each man should be taught to clean his own mouth, there are times when he needs help. If tartar or discolorations form they can be removed only with appropriate instruments. Every mouth is improved when its teeth are gone over once in a while by a dentist with polishing sticks or wheels carrying fine pumice. While giving prophylactic treatment the dentist has a good chance to stimulate the interest of his patient in the daily care of his mouth.

(3) *Operative dentistry by the dental surgeon.*—Cavities of decay should be filled, worthless roots removed. Nothing contributes more to an unhygienic condition of the mouth than the presence of cavities of decay which become filled with decomposable food and are favorable growing places for numerous bacteria. Foci of infection about the tips of the roots of the teeth should be carefully sought out and eliminated, either by extraction of teeth and curetting the infected area, or, in certain cases, by cutting off tips of roots in situ, and removing the infected bony socket.

TRENCH MOUTH

This affection demands serious consideration on account of its frequency and disabling results. Its characteristics are those of Vincent's angina and can be thus summarized: Ulcers with irregular outline, covered with whitish gray membrane easily removed. Ulcers are separated by healthy tissue and may penetrate deeply. When the membrane is rubbed off, the surface beneath bleeds readily and is sensitive. Favorite seat of ulcers, near gin-

gival border of mucous membrane, in the region of the second and third molars, especially in the lower jaw. Ulcers may exist on tonsils and pharyngeal tissue. Gums are generally inflamed and sore. Lymph nodes may be swollen and salivation occur. Usually there is a rise of temperature and always a characteristic fetor of the mouth. *Bacillus fusiformis* and Vincent's *spirillum* usually can be found. In some cases the organisms of Vincent's angina are not found, but this may be due to lack of skill or chance. Trench mouth, sometimes called ulcerative stomatitis, is one of the commonest affections among the troops in France. In an examination of the mouths of 1,000 soldiers as reported by F. B. Bowman, M. B., Tor., No. 1 Canadian general laboratory, the conclusion was reached that Vincent's organisms are much more prevalent in mouths that were not cared for than in those which were cared for. The disease in a large percentage of cases is one of unclean mouths. Hence the importance of insisting upon the care of the teeth amongst soldiers.

Treatment: Cleansing the teeth, removal of tartar, filling cavities of decay, extracting worthless roots. The following substances have been used with good results as application to ulcers.

Argenti nitras, 5 to 10 per cent.
 Chromic acid, 5 per cent.
 Cupri sulphas.
 Eusol, Dakin solution.
 Liquor potassii arsenitis.
 Methylene blue, powder.
 Phenol, 5 per cent in glycerine.

Salvarsan, 10 per cent emulsion in glycerine.
 Tincture ferri chloride.
 Trichloroacetic acid.

R Vini ipceaeuanhae	32
Glycerini	4
Liq. potassi arseni-	
tis	16

In addition to making an application to the ulcerated areas, an antiseptic mouth wash should be used frequently during the day. The following can be recommended:

Liquor cresolis comp., 3 to 5 drops in one-half tumbler of water.
 Pot. permangans, 1 to 3,000.
 Dakin solution, 1 in 3 aqua.

The frequent occurrence of trench mouth with men having gonorrhœa and syphilis has been noted by some observers.

Oral hygiene as applied to injured mouth where there are wounds of the face, jaw, and neck.—Such patients are especially liable to secondary hemorrhage and infection of the lungs or general infection. Fatalities from wounds involving the oral cavity are most commonly due to these causes. It is, then, of the greatest importance to so deal with the mouth and associated parts that decomposition and infection be reduced to a minimum. The following régime to be carried out by the dental surgeon is recommended.

All tartar, as far as possible, should be removed from the teeth. They should then be rubbed with a roll of cotton held in dressing pliers and carrying powdered pumice moistened with H_2O_2 . Then the mucous membrane of the mouth and areas about the wounds should be gently gone over in the same way. The tongue should be first scraped with appropriate instruments and then rubbed with pledget of cotton loaded with pumice and H_2O_2 . In this way decomposing and decomposable material is loosened from its position in the mouth, and can be removed by a stream of fluid introduced by a proper syringe or tank douche. If a syringe is used it should have a capacity of at least 1 ounce and a curved nozzle. It is impossible to reach all parts of the mouth with a straight nozzle syringe. If a tank douche is used there should be a curved nozzle glass tube inserted in the rubber tubing. The mouth can not properly be cleaned by simply spraying or washing with a syringe. The preliminary rubbing with pumice and H_2O_2 is necessary to get proper results. When having the mouth washed out it is necessary for the patient to sit up in bed and lean forward in order that no fluid may run backwards and cause strangling.

Various antiseptic mouth washes can be used. It must, however, be recognized that the mechanical action of the fluid is more important than its antiseptic quality. The following can be recommended: Eusol (Dakin sol.) and aqua. a. a.

The treatment here outlined should be carried out every two or three hours during the day in recently injured mouths. Nurses can be trained by the dental surgeon to help in this treatment, but it should not be wholly given up to them during the first 10 days after the injury.

Army Sanitary School No. 117.

LECTURE ON ORDNANCE AND ITS EFFECTS

By Maj. Chester R. Snow, C. A. C. (trench artillery), June 20, 1918.

The term "ordnance" in its broadest sense includes nearly every tool and weapon used in fighting. Thus it embraces everything from the trench knife and war club through machine guns and grenades to the heaviest artillery weapons.

We will consider briefly each of the principal weapons now in use.

Trench knife and war club can not be said to be new weapons, but at least the use of them is new to soldiers of the present generation. Their effect and also that of the bayonet is obvious, so that nothing further need be said of them.

The rifle is the principal weapon in modern warfare. The rifles of the different belligerents differ but slightly in appearance, size, and mechanism and our own .30-caliber Springfield may be taken as typical of all. The bullet is of lead with a cupro-nickel jacket, weighing 150 grains, and has a muzzle velocity of 2,700 foot-seconds. The rifle is sighted for firing up to 2,500 yards, and at 45° elevation it will carry as far as 5,400 yards, or a little over 3 miles. At 200 yards the bullet will penetrate 0.3 inch of steel plate, 60 inches of pine board or greasy clay, about 20 inches of loam, and 9 inches of dry sand. At 600 yards it will penetrate 12 inches of dry sand. This difference in the case of sand is due to the fact that at the shorter range the bullet is deformed by its excessive energy and consequently its penetration is reduced. In all other substances the penetration is greater at the shorter ranges. On account of its great energy, the bullet has great shocking power as well as penetration.

The pistol is a minor weapon in this war. The French officers provide themselves with such pistols as they choose and have calibers ranging from .32 to .45. A German pistol that I have seen was about a .41 caliber. Our Army uses the .45 Colt automatic pistol or Smith & Wesson revolver, using the same cartridge. The bullet is of lead, .45 inch in diameter, the outside being a cupro-nickel jacket. It has a muzzle velocity of 800 foot-seconds, and at ordinary ranges at which a pistol is used it will penetrate 6 inches of pine. A 1-inch penetration of pine is considered the equivalent of a severe wound. This pistol was designed to give a rapid fire and great shock effect. The .38 caliber revolver, which was abandoned for the .45, had a higher muzzle velocity and greater penetration, but not sufficient shock or stopping power. One incident which led to the change to the .45 caliber was the fact that in the Philippines an officer fired six shots from the .38 into a native, who continued his rush and severely injured the officer with a bolo before dropping dead.

The sawed-off shotgun is in use in this war principally for trench cleaners. It is very effective up to 60 yards, and at these ranges is more effective than the rifle on account of the number of shot and their tearing effect.

Grenades may be classified as hand grenades and rifle grenades.

The hand grenades are of two principal types—the defensive and offensive grenades.

The defensive grenade is made with a heavy body checkered with lines of weakness to insure complete fragmentation, and it carries a heavy charge of high explosive. The fragments are killing up to 50 or 75 yards and dangerous up to 100 yards, and hence the person throwing it must take cover in a trench or shell hole to avoid fragments of his own grenade.

The offensive grenade has a body of light tins and contains a large charge of high explosive. Its extreme killing radius is only 8 to 10 yards, the splinters of the light body being very small, and its blast effect is depended upon to do the damage.

Grenades are also filled with smoke compounds, and tear and poisonous gases. These grenades are used by the trench cleaners in clearing dugouts. It is evident that in a dugout a man may take shelter from the fragments of an explosive grenade by going to another compartment or taking cover, but the gas grenades will penetrate to every part, and the

fillers of some are gases which, it is claimed, will penetrate the German gas mask. (British K. J. grenade.)

All modern hand grenades are ignited by a time fuze which lights the powder train as the grenade leaves the hand. The fuses are timed to burst the grenade five seconds later. Grenades may be thrown up to 35 yards, the distance depending upon the strength and skill of the thrower and the weight of the grenade.

Rifle grenades are similar to hand grenades, but are propelled by using a rifle with a suitable attachment for holding the particular grenade. They may be fired by an ordinary cartridge or by a special blank cartridge, according to the particular model. Rifle grenades are filled with the same substances as hand grenades and their effects are the same. The advantage is that their range is greater, being as high as 210 yards. The rifle from which they are fired is usually placed in a special frame so that it may be given any desired elevation. We know that a man in a trench or shell hole can not be reached by a rifle bullet. He can, however, be reached with a grenade which may be dropped into the trench descending at a steep slope. I might add that a grenade is a very dangerous weapon and should be handled only by those who have special training in its use.

Automatic rifles differ from machine guns in being light enough to be easily used by one man. They can be fired by a man advancing, and the rate of fire is up to 60 shots a minute. They use the same cartridge as the regular rifle and consequently their effect is the same.

Machine guns can be fired up to a rate of 400 shots per minute, the rate being governed by the operator by adjusting the gas escape or the special mechanism according to the model. They use the same cartridge as other small arms. In this war indirect fire for machine guns has been developed, and consequently their use in barrage fire. When using indirect fire, the machine guns are placed well to the rear of the target and fire at high angles. Consequently the slopes of fall are very steep and overhead cover is needed for protection against it.

We next come to the weapons of the artilleryman, or what is termed ordnance within the most common meaning of the word.

The artilleryman's weapon consists essentially of the tube or barrel, the carriage on which it is mounted for firing, the explosive used both as a propellant and as a bursting charge for the projectile, and the projectile.

The barrel of the gun is very interesting in itself in the ingenious methods used to make it withstand great internal pressures, but time will not permit us to consider its construction.

The carriage has two purposes: To take up the recoil and to direct the fire. This second purpose only concerns us. We classify fire into three kinds according to its use, namely, direct fire, where the gun is fired at angles up to 15° ; curved fire, when the projectile departs at angles between 15° and 45° and high-angle fire, when the angle of departure is between 45° and 90° . Guns designed especially for curved fire are called howitzers, although in the present war all guns are mounted so that they can be fired at angles up to 45° . Guns designed for high-angle fire are called mortars. The needs for these classes of fire are readily seen. Suppose we have a target which is greater in dimension vertically than horizontally, as the walls of a building. Direct fire is the most useful. Suppose we must fire over a high hill or a woods. Obviously curved fire is called for; while if the target presents greater vulnerability on top than on the sides, as the top of a building or shelter, we need high-angle fire. The kind of carriage provides for this.

The subject of propellants leads us to consider explosives. An explosive is a solid or a liquid which can be readily converted to a gas. An explosive consists essentially of a combustible substance, as carbon, and an oxygen producer, as a nitrate or chlorate.

Explosives are divided into three classes: (1) Powders or propellants, (2) detonating explosives, and (3) detonators.

Powders or propellants burn in the same manner as wood or coal, only, having their oxygen contained within them, they burn at a much greater rate and this rate increases with the temperature and pressure under which combustion takes place. Keep in mind for the moment that it is simple combustion, and then we can contrast them with the second class, or detonating explosives or high explosives. In these we do not have combustion, but rather an instantaneous disruption of the force which binds together the atoms in the molecule, which causes

the atoms to depart from their present comparatively unstable combinations as nitrates or chlorates and form more stable ones as carbon dioxide and nitric oxide, and others according to the composition of the explosives. This class of explosives is used in blasting and as shell fillers.

The next class is the detonating explosive, which is characterized by mercury fulminate. Explosives of this class are not only of a higher order of detonation than those of the second class, but they have the power of initiating detonation, or the disruption of the molecular bond in explosives of the second class. Take, for example, trinitrotoluene, a high explosive and a most common shell filler. If we ignite it with a match in the open it will melt and slowly burn. If we light it when confined it will burn more quickly, but will cause an explosion only as the gases accumulate from the rather rapid combustion. But if we explode some mercury fulminate in contact with it, we immediately obtain a detonation of the whole mass.

High explosives have individual characteristics, and their utilization as shell fillers is governed accordingly. Picric acid, for example, is comparatively insensitive, but very quick and of great disruptive power. It, or some of its compounds, is the almost universal filler for high-velocity shells. The speed of these explosives is such that it tends to disrupt rather than remove material. On the other hand, certain chlorate explosives have 50 per cent more power of removing earth than the picrates. They are used more for the destruction of dug-outs, but their great sensitiveness limits the use to shells of low velocity.

Projectiles, as regards their effect, may be classified as follows:

1. Shrapnel.
2. High-explosive shell.
 - Air or time fuze bursts.
 - Ground or percussion fuze bursts.
 - With instantaneous fuze.
 - With nondelay action fuze.
 - With delay action fuze.

The shrapnel consists of a case with a charge in the base and the rest of the case filled up with balls of lead or iron about an inch in diameter, and the interstices filled with a smoke-producing compound, which is useful to show the point of burst in order that the fire may be adjusted. Shrapnel is used mostly in guns of about 3-inch caliber, as the French 75 and the German 77, and such a shell will contain about 260 of these balls. The head of the shrapnel holds a combination time and percussion fuze, the time fuze being an arrangement by which the interior charge is ignited a certain length of time after the projectile starts, and causes the balls to be projected forward. The percussion element of the combination fuzes detonates upon hitting the ground in case the shrapnel does not burst in the air. The effect of shrapnel is to sweep a cone-shaped area, the area varying in size with the height of the burst, the higher the burst the more area covered and consequently the thinner pattern made by the 260 balls. The penetration of the individual balls is slight, 10 cm. of earth giving protection, and shrapnel is of slight use against troops under cover. However, it may be effectively used against troops in open trenches by enfilading the trench or by bursting the shrapnel at such a point in the trajectory that the cone of dispersion will be directed downward.

High-explosive shells, equipped with a time fuze, are fired from both field guns and howitzers. The field gun is a high-velocity cannon having a flat trajectory. A shell, from the German 77, for example, bursting in the air will give a cone of dispersion of the form shown, the direction given to the fragments being the resultant of the forward movement of the shell and the lateral motion imparted by the bursting charge.

The howitzer uses curved fire and low velocities. Therefore, the air burst of a shell fired from a howitzer, the German 105 for example, will give a somewhat different dispersion of the fragments, throwing some directly downward and to the rear. The rearward motion of the fragments is due in part to the steep slope of fall of the projectile and to its low velocity.

The thing to note in regard to these shells is the fact that while a trench may give cover against the 77 high-explosive shell, overhead cover is essential for protection against the shells fired from howitzers. The fragments from these shells are very numerous and very irregular in shape, and at first are propelled with great speed, which they rapidly lose. The penetration of the fragments is not great except close to the point of burst.

The high-explosive shell with a percussion fuze will give three effects, according to whether an instantaneous, a slight-delay action—say, one twenty-fifth second—or a long-delay—say,

one-sixth second—action fuze is used. The instantaneous fuze, as its name indicates, detonates the projectile the instant it strikes the ground. It makes very little, if any, crater, and the fragments are projected horizontally in all directions, making a very destructive projectile against personnel or wire entanglements. The slight-delay fuze or nondelay fuze makes but a small crater—say, from 6 inches to 1 foot deep—and sends part of its fragments and the material from the crater upward and downward at varying angles depending upon the depth it has penetrated and the strength of the explosion. We may have craters, with the resultant flight of débris and fragments.

The high-explosive shell with the long-delay action fuze is used against shelters and dugouts, the idea being that it shall not detonate until it has penetrated the ground a considerable distance. An ordinary 6-inch shell with delay action in soft soil makes a crater about $1\frac{1}{2}$ m. across the top and about 1 m. deep. A 58-mm. trench mortar bomb will make a crater 2 or 3 m. in diameter and about 2 m. deep.

In some cases a shell will penetrate the ground so far that the explosive contained in it has not sufficient power to raise the earth above it. In this case we have what is called a camuflet. Such a burst near a dugout is very destructive.

One case I have observed is interesting in connection with protection fuze shells. You will notice that most all old soldiers drop very quickly to the ground when a shell is heard approaching. The value of this is proven. A shell dropped 40 feet from a group of men without cover; 6 of them were hit by fragments, 2 being killed instantly and 3 severely wounded, but in no case was one of them hit less than 24 inches above the ground. One man still nearer to the shell heard it coming and dropped to the ground. He was not hit. The evidence shows that had all the men dropped instantly to the ground none would have been hurt. This shell was about 105 mm. caliber. It had a very quick fuze and made a crater only about 9 inches deep and 24 inches in diameter. Some fragments were about 2 cubic inches in size.

So much for the effect of the shells themselves. The destruction done by the shells will be influenced by the way in which they are used, and this has changed in a very marked manner from that of previous wars. These changes may be considered as:

1. The greater proportion of guns of large caliber in use.
2. The greater number of guns of all calibers in use and the consequent prolonged and violent artillery activity.
3. The use of barrage fire, which is made possible by the great number of guns.

The great number of guns and the large assortment of calibers, with ranges varying up to 38,000 m. has enabled the guns to be distributed in depth. Consequently, on a given length of front many more guns may be used than formerly, and targets at a greater distance behind the lines may be reached. The use of a greater number of guns of all calibers has enabled the density of fire to be increased. More enemy guns must be put out of action before one side remains with a marked superiority of artillery. The long ranges of the guns enables them to have a greater choice of positions from which to fire, and consequently more time is required to search them out and neutralize them.

The great density of fire permits the use of the barrage or curtain of fire, which is made by all guns, including machine guns, being directed upon points so that the whole makes an impassable barrier. When a barrage is put down the bulk of the fire is directed at trench junctions, communication trenches, and roads where the enemy would most probably try to pass.

These points of dense fire can be learned by observation, and one can use this information to advantage should it be necessary to attempt a passage through a barrage.

Army Sanitary School N. 118.

DIRECTIONS FOR THE OPERATION OF PERSONAL HYGIENE SECTIONS

(Translation of a French pamphlet)

Personal hygiene sections (P. H. S.) are special organizations of the "service de santé," whose aim is to insure the individual cleanliness of the men, the "disinsectization" and the disinfection of personal belongings and the issuing of clean linen. They contribute, therefore, to preserve the health of the soldier, being at the same time a means of prophylaxis against contagious diseases.

The P. H. S. are army units placed under the authority of the army surgeon, who determines their use according to the indications of the general commanding the army. They work under the control of the directors of the "service de santé" of army corps or of the division surgeons. The order of bathing of troop units (regiments) is regulated conjointly between the command and the "service de santé." The chief surgeons take advantage of the hours of bathing to make an individual inspection of the men in order to detect parasitic and contagious diseases.

PERSONNEL

The personnel of a P. H. S. includes: 1 noncommissioned officer (auxiliary physician or assistant pharmacist, M. C., sergeant, or "top sergeant"), 2 corporals, 3 mechanics, 10 corps men, 1 of them a barber.

This personnel receives practical instruction at the central workshops of the "service de santé"; it forms a special detachment which is, for administrative purposes, attached to the nearest permanent sanitary formation designated by the army surgeon.

It is considered a specialized personnel.

The task of the mechanics is to operate, maintain, and to look over the boiler, the drying place, the pipe system, cocks, valves, and, in general, everything pertaining to the mechanical side of the organization.

Corps men are employed especially in loading and unloading operations and in setting up and striking tents. They insure the working of the different services under the supervision of the section chief.

MATÉRIEL

The matériel is described in the summary appended. It is in charge of the section chief.

OPERATION

Everything being prepared, the rooms are heated or ventilated according to the existing temperature.

The mechanic in charge of the drying room makes sure that the tank is filled and that the thermometer marks the desired degree (40° C. more or less).

Soldiers entitled to use the showers are divided into groups of 40 men. Every group enters first a "tortoise" tent serving as dressing room; each man leaves in a numbered bag (from 1 to 40) his valuables—watch, pocketbook, purse, etc. These bags are placed in a basket provided with a padlock. On delivery of the bag to the attendant, each man is given a wooden tag bearing the corresponding number.

Once relieved of their valuables, the 40 men making up a group step into room A, furnished with benches numbered from 1 to 40; with each numbered seat goes a net, also numbered to correspond.

Each man walks to the place marked with the same number of his tag, undresses, puts his clothes in the net and enters the shower room (room B), carrying his shoes, helmet, and gas mask. He places all these objects, together with his tag, in a cubby-hole of a set of shelves bearing his number, and takes from a special container enough soap for his own use. Underclothes are left on the floor of the dressing room, where they are collected and taken to the soiled linen room by the corps man on duty before the next group of men moves in.

After the men have assembled in the shower room, they are separated in two series; the first, comprising Nos. 1 to 20, and the other, Nos. 21 to 40. The men of the first series are first exposed to a short shower and are immediately thereafter replaced by those of the second series. The men of the first series soap themselves and again take their places under the shower heads and finish their bath. They now dry themselves with a towel provided them by the corps man on duty; get their helmet, shoes, gas mask and tag, and pass to room C, where they take their places on benches according to their tag number.

The men of the second series go through the same maneuver in their turn.

While the men are bathing, the nets containing their clothes are being disinfected and dried in the autoclave. This operation lasts from 25 to 30 minutes, according to the hygro-metric index of clothing; it is the duration of the autoclave that regulates the number of men that can be admitted per day. In room C the men find on each seat bearing a number, one

shirt, one pair of drawers, one flannel undershirt, one pair of socks. These are distributed in advance by the corps man on duty. They are given their outer clothing, disinfected and dried. Before leaving they turn in their tags in the dressing rooms, in exchange for which they get back their valuables.

In order to insure a distribution of linen according to the size of the men, it is advantageous to sort them according to their height, No. 1 being assigned to the tallest.

Before passing the men through the shower, the barber of the section, assisted by the company barbers, shave and trim the hair of each man.

Such is the routine followed by a P. H. S.

ISSUING OF LINEN

Clean linen is issued by the quartermaster upon requisition of the chief of the section. A reserve of 10,000 sets (shirts, drawers, undershirts, socks, towels, handkerchiefs) is constantly kept in store.

Soiled linen is passed through the autoclave in the evening, and thereafter taken to the quartermaster, who is in charge of washing and exchange of worn-out clothing.

APPLIANCES AND ERECTION OF A PERSONAL HYGIENE SECTION

A personal hygiene section includes: One boiler mounted on a two-wheeled cart; 1 autoclave and 1 shower tank, mounted on another two-wheeled cart; 1 portable hut, composed of canvas-filled frames or panels, making up three rooms (undressing, showers, dressing); 3 tents serving, respectively, as vestiary, clean-linen store, and soiled-linen storeroom; accessory fittings and mountings, whose nomenclature is given further on.

All requisitions for new appliances or for important repair work must be made on the central workshop of the "service de santé" by the chief of the section.

BOILER

The boiler is of the "field" type, tubular, vertical, with a heating surface equivalent to 6 sq. m.; it is measured up to 6 kilos pressure and provided with the necessary gauge and safety appliances.

The feeding of the boiler is secured through an injector whose water valve is located in the shower tank so as to obtain pressure and, at the same time, already heated water. The stack for the fire box, made of sheet iron 3 mm. thick and provided with a spark arrester, is set above the boiler and projects 1 m. 50 cm. above it. It can be taken down and easily fastened to the boiler cart for transportation.

The boiler is provided externally with a water gauge set in a metallic bearing box, splinter proof, to avoid danger in case of rupture.

Above the fire box, at a man's height, the boiler has a distributing system of three valves, commanding, respectively, three pipes, leading to (1) the steam distributor for the autoclave; (2) the feeding apparatus of the boiler; (3) the fire-box blower of the boiler.

To start the boiler, the stoker lets in, through a small funnel placed on top, the necessary volume of water. He next fires the furnace and regulates the draft by means of the blower; he endeavors to keep the necessary pressure; that is, 6 kilos to a square centimeter, determined by the manometer (pressure gauge). When the steam is up the shower tank is filled through its ejector system, as explained later on, and the feeding of the boiler is carried out by means of the injector, whose water valve is cast in the shower tank.

The boiler is mounted on a two-wheeled carriage, whose seat and shaft can be easily removed.

This vehicle is drawn by two horses hitched in tandem.

The total weight of the boiler carriage with road equipment is 1,450 kilos.

AUTOCLAVE

The cylindrical autoclave is double doored, measures 1 m. 10 cm. interior diameter by 2 m. 25 cm. in length, measured from the exterior of the convex doors. The doors are kept shut by means of articulate bolts with round screw nuts and handles. The autoclave is fitted inside with sheet iron down to about 10 cm. from the horizontal axle, to prevent

damage to the clothing by direct contact with the water of condensation and steam. A heating battery, consisting either of a steam chamber or of a series of steam pipes, is located in the lower portion of the stove and constitutes a source of heat which lessens the cooling down while the clothes are being introduced and taken out; it also prevents the condensation of steam at the beginning of the operation.

The operations of disinfection and of "disinsectization" are carried out by the use of flowing steam maintained at 750 gm. pressure.

Clothes to be disinfected, as we have seen, have been previously inclosed in netting bags, one complete outfit to a bag (breeches, coat, overcoat and a pair of puttees). Each disinfection takes care of 40 outfits of clothing. It should be announced that all rubber and leather included in the net bag will be completely ruined.

STEAM DISTRIBUTING SYSTEM OF THE AUTOCLAVE

The distributing system on the right side of the autoclave, toward the undressing room, within reach of the autoclave operator who remains in room A, is connected with the boiler by means of a flexible steam pipe. From this distributor spring (1) a pipe extending to the upper part of the autoclave serves to convey the steam for the disinfection; (2) a pipe going to the heating battery of the autoclave; (3) a pipe feeding an ejector destined to force water under pressure into the shower tank; (4) a pipe going to a mixer which makes possible the sending at will of steam into the water of the shower tank, to regulate the temperature within the desired limits (38° to 42°); (5) a pipe leading to an ejector destined to secure drying by creating a partial vacuum (this produces a vacuum by carrying off the steam which is in the chamber and whose place is filled by the vaporization of the moisture in the clothing).

TANKS, SHOWERS, AND ACCESSORIES

The tank containing water used for showers consists in a sheet-iron cylinder, entirely closed, set on top of the autoclave and mounted on the chassis of the same carriage. It is fed through a rubber hose 15 m. in length, ending in a strainer plunged in water, by means of an ejector which receives the steam from one of the distributing valves. The suction pipe for the water carries an air passage served by a stopcock which permits the introduction of compressed air into the water of the tank. Thus it is feasible to obtain a shower force with pressure varying between 100 gm. and 1 kilo. The man in charge of the autoclave regulates the pressure to impart more or less violence to the jet, according to whether it is necessary to rinse after soaping or simply to wet the men.

Pressures over 1 kilo are avoided by a valve cast on the upper part of the tank and regulated for 1 kilo; a metallic manometer gives the pressure of the shower. It should be noted that the pressure thus obtained is absolutely necessary to insure a proper force of the shower, furthermore, it prevents the obstruction of the holes of the sprinkler through small foreign bodies.

A pipe system proceeds from the lower portion of the tank to the shower distributing pipe of the shower heads. It is fitted with a stop cock. There are two of these distributing pipes, each supplied with 10 shower heads; they are fixed to the trusses of the shower room.

That the shower may prove comfortable and adequate from a sanitary standpoint, it is essential that its temperature be regulated to about 38°, summer and winter. The temperature desired for the water is produced, on the one hand, by the working of the ejector feeding the tank, which raises the temperature of the water drawn from the outside about 15°, and, on the other hand, by the mixing, which may be varied in intensity, of the water in the tank with the steam coming from the distributor through a special pipe fitted with a gradually opening valve.

In order to obtain the exact temperature, the admittance of steam to the mixer is regulated according to a thermometer which marks the temperature of the water as it leaves the tank. As a safety measure, when this thermometer shows a temperature of 45°, an electric connection is established which rings a bell. The thermometer, the autoclave manometer, and a clock serving to give exactly the duration of the autoclaving are all fixed on a plate set above the autoclave.

The autoclave and the shower tank are mounted on one two-wheeled carriage drawn by two horses hitched in tandem. The total weight of the autoclave carriage with road equipment is about 2,000 kilos.

HUT

The portable hut for a P. H. S. has three rooms: A, B, C, disposed of as shown on the plan, and provides an undressing, a shower, and a dressing room.

This hut consists of: (1) A floor supported on sills; (2) vertical partitions of canvas panels, interchangeable and double walled; (3) a canvas cover resting on trusses which are laid on top sills resting on the wall panels.

Floor.—The floor is composed of interchangeable sections, adjustable on the sills without being fixed in place. To facilitate its erection the external face of external ground sills are painted green.

In the center of the shower room, gratings are substituted for the painted panels of the same dimensions.

Wall sections.—Wall sections consist of a wooden frame braced with one transverse piece and two ties. This frame is covered on both sides with well-stretched canvas. On the outside awning is used, while for the inside rough cloth is sufficient.

The interior partitions separate the dressing and undressing rooms from the shower baths.

The lower transverse pieces of each section carry two round pegs, 14 mm. in diameter and 35 mm. long, fitting in holes bored in the ground sills.

Furthermore, the fitting of sections one to the other is made solid by a screw-clamp whose two pins fit into holes bored in the panel frames. The fitting of corner sections is accomplished in the same way.

Cover.—Above and on the inside of the longitudinal wall section is affixed a top sill which supports six trusses, designed to sustain the canvas roof. The general appearance of one of these trusses is seen in the plan, which also gives the details for joining the top sill to the tie beam of the truss.

The carpentry work of the roof is completed by rafters supported by the top purlin, the intermediate purlin, and the top sill.

One piece of awning is affixed by means of ropes to the top purlin of the dressing and undressing rooms, covering these two rooms. It is fastened to the gables and to the front panels by means of a side rod.

Another piece of awning is fastened to the top purlin of the shower room, covers this room, and is attached to the lateral sections as in the preceding case.

The interval between the two top purlins is covered with canvas curtains forming roller blinds; these curtains can be reefed so as to allow proper ventilation. For lighting, the roof admits of four sections to each room, made of oiled cloth, 2 by 1 m. in size.

In addition, each room is provided with a velarium of white cloth to isolate a portion of air beneath the awning forming the roof; the air layer thus confined between the velarium and the awning as also the air layer inside the panels, act as heat insulators and permit an even interior temperature of the bathroom even during the severest cold spell. The necessary ventilation to avoid excessive heat in summer and also to insure the removal of over-charged air is secured through the set of curtains covering the interior between the roof purlin of the shower room and those of the dressing and undressing rooms.

Doors.—The wall sections are provided with doors leading outside of the building; there are 5 of them, distributed as follows: 2 in the undressing room, 1 in the shower room, 2 in the dressing room. The inside partitions have two connecting doors; one leading from the undressing to the shower room, the other from the shower to the dressing room.

Opening frames.—There are 2 window frames covered with transparent cloth in each of the 2 dressing rooms and 5 in the shower room.

TENTS

To the hut are annexed several tents for accessory services, viz, one store or supply tent to keep the reserve of clothing outfits; one tent for barbers and chiropodists; one tent serving as a depository for the valuables of the men, turned over before undressing.

The tent serving as clean-stockings store is a Bessonneau of the large type.

The barbers and valuables tent and tent serving as soiled linen store are "tortoise" tents, small type, covering an area of about 15 sq. m.

ACCESSORY APPLIANCES

These appliances include:

- (a) The necessary pipes and distributing pipes for operating the boiler, stove, and showers.
 - (b) Twenty folding benches for the two dressing rooms, of lattice work, of the following dimensions: 1 m. 40 cm. by 60 cm. (each bench for 4 men, 2 on each side).
 - (c) Two sets of portable lockers, comprising each 20 numbered compartments, wherein the men deposit their helmet, shoes, and gas mask. The dimensions of the compartments are 30 by 35 by 40 cm.; each locker covers a space of 60 sq. cm. They are located in the shower room.
 - (d) Three series of 40 nets, numbered the same as the valuable bags and tags. These nets are 40 cm. diameter by 65 cm. in height. They contain the clothes to be disinfected; that is, a complete outfit (breeches, coat, overcoat, and a pair of puttees).
 - (e) Three series of bags 14 cm. in diameter and 20 cm. in height, numbered 1 to 40, to deposit in the valuables (watch, pocketbook, flat purse, knife, etc.).
- These bags are placed, for the duration of the shower period, in locked baskets; after the operation they are returned to the men holding tags corresponding to the numbers of the bags.
- (f) Three series of wooden tags, 7 by 5 by 1 cm., numbered up to 40. These tags are issued to the men together with the bags, the numbers on both corresponding.
 - (g) Three wicker baskets with lid, to contain the valuable bags. They are 1 m. 15 cm. by 72 by 30 cm. in size. These baskets, once closed, remain under guard of the attendant in the tent designed to receive them.
 - (h) The necessary equipment for the barbers.
 - (i) Small implements.
 - (j) Wedges of diverse thicknesses serving to level the ground sills of the hut.

TO SET UP THE BUILDINGS AND TENTS

Selecting and preparing the ground.—The location of a personal hygiene section must, as far as possible, meet the following conditions:

- (1) It must be in immediate proximity (about 15 m.) to a well or source of clear water, such as a river or creek with a minimum delivery of 1 liter per second.
- (2) The ground must be sufficiently even to allow the erection of tents and huts, covering an area of about 500 sq. m.
- (3) It should not be over 3 m. higher than the source of water supply.

On the site thus chosen and on the spot where the gratings for the shower baths are to be placed, a slope or glacis is built with gradient of 3 cm. to the meter, 8 m. 65 by 2 m. 25 cm. revetted with corrugated iron furnished by the engineers, having at its lower point a drain, through which the used water runs into a down gutter. The use of a drainage basin where water becomes stagnant is to be rigidly proscribed.

Setting up the appliances and huts.—The mechanics fix the position of the portable autoclave and boiler and remove seats and shafts; they connect the distributing system of the boiler with the distributor of the autoclave by means of a flexible pipe and the feeding injector of the boiler with the shower tank; they then fill the boiler and start the fire.

The corps men, under the supervision of the noncommissioned officers, are distributed into three groups:

The first group sets up the undressing room; the second group sets up the shower baths; the third group sets up the dressing room.

The ground sills, sorted according to their color, are carefully set in place and leveled with the aid of wedges; this requires more time than any part of the preparation.

After the ground sills are in place, the floors and gratings are adjusted; this operation is greatly facilitated through the use of interchangeable sections. It takes about two hours to finish it.

The principle of the hut lies in the fact that there are no uprights to hold the panels and the woodwork; hence the operation becomes a simple one; the panels are set side by side and held together through the sills and screw clamps; trusses are mounted directly upon the panels and are tied together with purlins; on these the rafters are fixed, which will be covered

with canvas. For transportation purposes this canvas is rolled up parallel to its shortest dimension. To mount it, each roll is hoisted with the aid of ropes sliding over the top purlin. The side rods to fasten the canvas to the panels are only fixed at the end, being careful never to tighten them to the limit. It is important, before laying the roof, to set the four batter posts of the façade opposite the center trusses of the small rooms.

While the corps men are disposing the benches and numbered nets in their places the mechanics adjust the distributing pipes for the shower to the tie beams of the trusses.

The section is now ready for use.

A trained detachment completes this work in about eight hours.

Army Sanitary School No. 119.

HISTOBACTERIOLOGICAL CYTODIAGNOSIS OF WAR WOUNDS

A demonstration by Maj. G. Rosenthal, chief of laboratory at the H. O. E. de ———.

(Translation of summary)

Every recent war wound and every foreign body removed must be subjected to bacteriological examination.

The examination includes two steps:

1. Examination of smears.
2. Making of cultures in order to rapidly determine the nature of the microorganisms.

A. EXAMINATION OF THE SMEARS

Always make two smears on separate slides.

The first one is stained with a carbolic solution of methylene blue or thionine; the second one by the gram method with gentian violet.

Examination of the smears considers:

1. The leucocytes, defensive elements, and distinguishes—
 - (1) Whether poly or mono nuclears predominate.
 - (2) Their relation to the intra and extra cellular organisms.
 - (3) Their state of preservation.

One must consider as favorable: A good coloration of the nucleus; a good contour; a predominating number of cells.

2. The microorganisms, in a recent wound (during the first week)—

- (1) Large bacteria, Gram-positive, with square ends. This is the perfringens group; look out for gas gangrene.
- (2) Cocci in long chains of 12 to 30 elements, all alike in the same chain and Gram-positive. This is probably the true streptococcus; never close such wounds.
- (3) Indifferent organisms—
 - (a) Gram-positive cocci (diplococci with an aureola; enterococcus; bunches of diplococci; staphylococcus; isolated cocci).
 - (b) Gram-negative bacilli (belonging to the *B. coli* group).

Cytodiagnosis to establish three types:

- (1) Defense—innumerable organisms and no leucocytes (attack without defense).
- (2) Victory—two forms:
 - (a) Few organisms, numerous polynuclears in good condition.
 - (b) No organisms; polynuclears in bad condition; watch the general condition of patient.
- (3) Struggle:
 - (a) Danger of gas gangrene if big Gram-positive bacilli.
 - (b) Danger of septicemia if streptococcus (don't close).
 - (c) Favorable type if diplococci and Gram-negative bacilli, with leucocytes in good condition.

B. THE CULTURES

1. Are made in numerous streak inoculations on an ordinary agar culture tube and in broth; indispensable to detect streptococcus.

2. Inoculation with a sealed pipette of milk by the Rosenthal method and in a Veillon gelose tube. Milk is the best medium for *perfringens*.

After 12 hours, examine the cultures.

1. The agar tube may show:

(a) Large colonies of staphylococci (Gram-positive clusters of cocci).

(b) Large colonies of *B. coli* (Gram-negative, groups of small bacilli).

(c) Abundant fine colonies of enterococcus (diplococci in short chains with an aureola).

(d) Fine colonies like tapioca grains, or dewdrops very close together; streptococcus (long Gram-positive chains composed of homogenous elements).

2. The broth tube may show at the end of 8 hours a growth of streptococcus (clear broth with a bread-crumb deposit). Note that the streptococcus grows in long chains in the broth; the smear alone might be misleading.

3. The sealed milk tube reveals *B. perfringens*.

(a) The clot is retracted.

(b) The serum is clear.

(c) The gas collects under the lanoline top layer.

Note that massive coagulation of the milk is of no value.

4. The agar in the Veillon tube is broken up by the gas.

C. POSSIBLE ERRORS AND REMARKS

An indifferent organism may simulate *perfringens*; the error is exceptional, because morphologically similar bacteria appear late in old wounds; the error causes the patient no harm.

Common germs like *proteus*, *subtilis*, and *paracolibacilli* occur late and are of no interest at the front.

Differentiation of the varieties in the *perfringens* group (mobility, character of spore formation, fermentations of *vibrio-septicus*, *B. oedematicus*, *B. bellonensis*, etc.) and differentiation of the cocci in staphylococcus and *micrococcus candidus* are purely of scientific interest. Up to the present they are of no practical value in the clinical control of wounds.

FOR FIXING TISSUES—BOUVIN'S SOLUTION

Formol (40 per cent).....	10
Water.....	30
Acetic acid.....	2

Let rest one to three days. Pass to alcohol without washing in water.

Army Sanitary School No. 120.

ARMY SANITARY SCHOOL,
ARMY SCHOOLS, A. E. F.

The following suggestions have been submitted by Lieutenant Colonel Allison, M. R. C., and are recommended to all student officers of this school as representing the basic principles which this school is teaching.

NOTES ON THE SURGICAL SUPPLIES AND SURGICAL TREATMENT IN A COMBAT DIVISION

1. *Supplies of splintings, dressings, and accessories.*—The division medical supply officer will requisition and obtain from the advance medical supply depot the following list of splints and splint accessories and will distribute this supply in the quantities indicated to the various units of the division. What remains he will hold in his supply depot as a reserve supply.

Division supply of splints and accessories

Distribution	For each						
	Com- pany dugout	Battal- ion aid post	Ambu- lance com- pany	Ambu- lance dress- ing station	Field hos- pital	Non- com- bat unit	Total for di- vision
Thomas half-ring thigh and leg splints (B. K.).....	4	8	60	10	104	4	540
Thomas arm splint, binged (Murray's modification).....	2	4	40	10	10	2	300
Cabot posterior wire leg splint.....	4	8	50	10	20	4	700
Jones humerus traction splint (right and left).....	0	0	0	0	12	0	^a 48
Ladder splints.....	12	24	100	25	25	12	1,725
Thomas traction arm splint.....	0	0	0	0	10	0	40
Wire gauze (rolls).....	5	10	50	15	25	5	600
Light splint wood (3-foot and 4-foot lengths).....	2	4	50	10	10	2	^a 450
Long Liston splints.....	0	0	2	1	2	0	20
Jones cock-up splints.....	0	0	0	0	10	0	50
Litter bars.....	0	6	25	10	25	2	300

Sinclair glue.....	0	0	0	0	^b 1½	0	^b 2

^a Each.^b Kilos.

Additional surgical supplies: In addition to the combat equipments supplied by the Medical Department to the division, the following list of surgical supplies should be obtained and distributed to the various units.

Front dressing packets:

1. Red (small).....	6,000
2. White (medium).....	4,000
3. Blue (large).....	2,000

Total.....	12,000
------------	--------

Blankets (extra).....	1,000
-----------------------	-------

Burners, blue flame, Primus type.....	50
---------------------------------------	----

Hot-water bottles.....	200
------------------------	-----

Acetylene lamps.....	50
----------------------	----

Carbide.....	pounds— 300
--------------	-------------

Tea, chocolate, and sugar.

Oil for blue-flame burners, primus type.

Antitetanic serum (1,500 syringes).....	20,000
---	--------

NOTE.—The above list of supplies is approximate only and is subject to variation according to the military situation.

2. *Details of distribution.*—(A) The battalion aid post, Infantry and Artillery.

The battalion surgeon will establish his post in the rear of his battalion and will so arrange its equipment that it may function as a first-aid station for the treatment of the wounded. He will direct the Medical Corps men and stretcher bearers assigned to his battalion for duty in such a manner that the wounded will receive prompt and efficient attention. He will administer antitetanic serum (A. T. S.) to all wounded (1,500 units). He will properly splint and dress fractures and wounds and treat shock and hemorrhage. His duties require coolness and precision. During quiet times he will instruct and give practice to the Medical Corps personnel under his direction in the proper application of splints, the dressing of wounds, and the necessary measures to combat shock. At the battalion aid post he will maintain the supplies following.

Thomas half-ring thigh and leg splints (B. K.).....	8
Thomas arm splint (hinged), Murray's modification.....	4
Cabot posterior wire leg splint.....	8
Ladder splints.....	24
Wire gauze (rolls).....	10
Light splint wood (3-foot and 4-foot lengths).....	4
Stretcher bars.....	6
Triangular slings.....	48
Cotton (batting-wadding) rolls.....	25
Muslin bandages.....	12
Zinc oxide adhesive plaster:	
Foot and 5-yard rolls.....	2
2-inch rolls.....	6
Straps and buckles (2 sizes).....	24
Trench litters.....	4
<hr/>	
Front dressing packets:	
1. Red (small).....	120
2. White (medium).....	100
3. Blue (large).....	30
Total.....	250
Blankets.....	25
Hot-water bottles.....	6
Burners—blue flame Primus type, at least.....	1
(Oil for same.)	
Tea, chocolate, and sugar.	
Antitetanic serum (500 syringes), units each.....	1, 500

(B) The advanced aid post: Under the direction of each battalion surgeon, when necessary, there will be established for each company of Infantry and each battery of Artillery, an advanced aid post to which enlisted men of the Medical Corps will be assigned. These Medical Corps men will have been trained in the speedy and efficient application of splints and in the use of the ordinary stretcher and the trench litter. It is their duty to apply splints in a proper manner to the wounded man where he falls, and to transport him as speedily as possible to the battalion aid post for further treatment by the battalion surgeon. These men will carry forward to the post of the company or battery the following list of supplies. This list should be varied in amount to meet the military situation:

Thomas half-ring thigh and leg splints (B. K.).....	4
Thomas arm splint (hinged) Murray's modification.....	2
Cabot posterior wire leg splint.....	4
Ladder splints.....	12
Wire gauze (rolls).....	6
Light splint wood (3-foot and 4-foot lengths).....	2
Triangular slings.....	24
Cotton (batting-wadding) rolls.....	10
Muslin bandages.....	12
Zinc oxide adhesive plaster (2-inch rolls).....	1
Straps and buckles (2 sizes).....	12
Trench litters.....	2

(c) Ambulance dressing station: The director of ambulance companies will establish in the rear of the battalion aid posts stations which are known as ambulance dressing stations and represent the point to which ambulances may go forward for the evacuation of the wounded. A surgeon of the ambulance company will be in command of each post, and under his direction there will be assigned a certain number of the personnel of an ambulance company. This station is placed in a position convenient for the collection of the wounded, and here the wounded will be loaded into the ambulances after the ambulance surgeon has

passed upon their condition. The ambulance surgeon will supervise the readjustment of splints and dressings and the treatment of surgical shock. Wounded in a condition of shock should be held at this point and treatment given before they are subjected to the additional strain of an ambulance journey. Rapid evacuation of the wounded to that point where definitive treatment may be instituted is necessary and desirable and should be insisted upon, but nothing is gained by evacuating a man whose condition is such that further movement will be attended by grave risk of life. An hour or two of warmth and rest works wonders with such cases and frequently makes it possible to tide them over the critical stage so that they may be evacuated with safety. At the ambulance dressing station the following list of splints and supplies will be maintained:

Thomas half-ring thigh and leg splints (B. K.)	10
Thomas arm splint (hinged) Murray's modification	10
Cabot posterior wire leg splint	10
Ladder splints	25
Wire gauze (rolls)	15
Light splint wood (3-foot and 4-foot lengths)	10
Long Liston splints	1
Litter bars	10
Triangular slings	50
Cotton (batting-wadding) rolls	50
Muslin bandages	25
Zinc oxide adhesive plaster:	
Foot and 5-yard rolls	2
2-inch rolls	12
Straps and buckles (2 sizes)	20
Wire leg rests (for Thomas splints)	25
Front dressing packets:	
1. Red (small)	100
2. White (medium)	100
3. Blue (large)	100
Total	300
Blankets (extra)	50
Hot-water bottles	12
Burners (blue flame, Primus type), at least 3.	
Oil for same.	
Acetylene lamp	1
Carbide for same	pounds 6
Tea, chocolate and sugar.	
Antitetanic serum:	
Syringes	100
Units	1, 500

(d) The ambulance company: The ambulance company will hold in reserve at its headquarters the following list of supplies, as a reserve that can be immediately drawn upon from any particular area in case of necessity.

Thomas half-ring thigh and leg splints (B. K.)	60
Thomas arm splint (hinged) Murray's modification	40
Cabot posterior wire leg splint	50
Ladder splints	100
Wire gauze (rolls)	50
Wire splint wood (3-foot and 4-foot lengths)	50
Long Liston splints	2
Litter bars	25
Triangular slings	200
Cotton (batting-wadding) rolls	200
Muslin bandages	100

Zinc oxide adhesive plaster:	
Foot and 5-yard rolls	12
2-inch rolls	36
Straps and buckles (2 sizes)	50
Wire leg rests (for Thomas splints)	75

(E) Ambulances: Each ambulance will carry the following list of supplies:

Ford ambulance:

Litters	2
Blankets	6
Arm splints (Thomas)	1
Leg splints (Thomas B. K.)	1
Litter bars	1
Hot-water bags	3
Dressing packets (red, white, and blue), each	1
Cabot splints	1
Ladder splints	2
Triangular sling	6
Bandages	12

G. M. C. ambulance:

Litters	4
Blankets	12
Arm splints (Thomas)	1
Leg splints (Thomas B. K.)	1
Cabot splints	1
Litter bars	2
Hot-water bags	3
Shell dressings:	
Large	6
Small	6
Bandages (3 sizes)	24
Ladder splints	4
Triangular slings	6

(a) When a wounded man is placed in an ambulance, the ambulance orderly will replace from his supplies such articles as have been supplied the patient and will, in turn, obtain a duplicate from the hospital, to which the patient is delivered.

(b) In addition to the above list, each ambulance will carry four extra gas masks, French type, for use in case of emergency. These masks will not be used for exchange.

(c) In each ambulance a printed list as above will be posted.

(F) The field hospital: The functions of the field hospital will vary according to the need of the military situation. Each field hospital will hold in its supplies the following list of splints and splint accessories.

Thomas half-ring thigh and leg splints (B. K.)	10
Thomas arm splint (hinged), Murray's modification	10
Cabot posterior wire leg splints	20
Jones humerus traction splint, (right and left)	12
Ladder splints	25
Thomas traction arm splint	10
Wire gauze (rolls)	25
Light splint wood (3-foot and 4-foot lengths)	10
Long Liston splints	2
Jones cock-up splints	10
Sinclair blue	kilo ½
Litter bars	25
Triangular slings	160
Cotton (batting-wadding) rolls	200
Muslin bandages	100
Zinc oxide adhesive plaster:	
Foot and 5-yard rolls	10
2-inch rolls	12
Supporting slings (3 sizes)	100
Straps and buckles (2 sizes)	50
Paper clips	250
Wire leg rests (for Thomas splints)	50
Trench litter	0

(g) The noncombatant units: Each noncombat unit in a division will have the following supplies in splints and dressings for accident and emergency use:

Thomas half-ring thigh and leg splints (B. K.).....	4
Thomas arm splints (hinged), Murray's modification.....	2
Cabot posterior wire leg splint.....	4
Ladder splints.....	12
Wire gauze (rolls).....	5
Light splint wood (3-foot and 4-foot lengths).....	2
Litter bars.....	2
Triangular slings.....	24
Cotton (batting-wadding) rolls.....	10
Muslin bandages.....	12
Zinc oxide adhesive plaster:	
Foot and 5-yard rolls.....	1
2-inch rolls.....	6
Straps and buckles (2 sizes).....	12

3. *Litter bearers for a combat division in the field.*—A combat division in the field consists of 4 regiments of Infantry, 3 regiments of Artillery, and various trains and attached troops. The entire medical personnel is 1,250 enlisted men. There are 48 Medical Corps men attached to each regiment of Infantry, which allows 14 per battalion. These men because of their training should be used primarily as dressers and not be engaged in litter bearing, except under special conditions. The assignment of two or three men per company to care for the wounded and for general sanitary work, their station being the advance aid post with the company in the line, places them in a most useful position for doing effective work. The remaining 6 men should be stationed at the battalion aid post with the battalion medical officer, or distributed as conditions demand.

For litter bearers there are available from the ambulance companies of the division about 300 men. The bandsmen of the division may be used, though this is undesirable for reasons that are obvious; if used, not more than 100 are usually available, giving a total of 400 men for litter bearers. This number is not sufficient to meet the demands of evacuation in times of stress, which is a condition which may arise at any part of the line at any moment. To provide a sufficient working personnel and to maintain an adequate reserve it is necessary to have assigned from the combat troops men who shall be trained by medical officers in first aid, application of splints, and litter bearing to supplement the medical personnel in stress. These men should be used for evacuating the wounded from the front line to the battalion aid post under the direction of the Medical Corps men attached to companies. The use of such "company litter bearers" has two distinct advantages in that they have a personal interest in the wounded of their own organization and are familiar with the terrain over which the evacuation occurs.

The detailing of 8 men from each rifle and machine-gun company for this purpose would furnish about 700 additional bearers. It is necessary in considering such an assignment that these men be placed definitely under the control of the regimental surgeon when called upon for such duty so that he may direct their activity to the best advantage.

The following order is suggested as covering the instruction of this additional supply of litter bearers:

HEADQUARTERS——— DIVISION,
OFFICE OF THE SURGEON, A. E. F.

Memorandum: To surgeons of all organizations:

1. Attention is invited to memorandum from headquarters, —— Division, dated 1916, relative to training of eight men from each rifle and machine-gun company in first aid to the wounded, application of splints, and litter bearing. This is most important, in order to secure a reserve of trained men for use in case of emergency. Surgeons will be held responsible for the training of these men. They will also take the necessary steps to secure their services, when the number of casualties becomes greater than the Medical Department personnel, with the unit, can properly care for and evacuate.

Lieutenant Colonel, Medical Corps, United States Army,
Division Surgeon.

4. *Splint application*.—Regimental, battalion, and ambulance company surgeons will be responsible for the instruction of the Medical Corps personnel under their direction in the proper application of splints and dressings to the wounded. The application of traction to fractures of the long bones is necessary both to save life and to prevent shock. The Thomas half-ring thigh and leg splint (Blake-Keller) should be applied to all fractures of the lower extremity, from the pelvis to the ankle. In fractures of the leg so low down that extension can not be applied and in wounds of the bones and joints of ankle and foot, the Cabot posterior wire leg splint should be used, with such additional ladder or wood splints as may be necessary to secure adequate splinting. The methods of applying traction are simple and can be carried out quickly in the field. The Thomas arm splint (hinged), Murray's modification, should be applied to all fractures of the humerus, using adhesive plaster strips to secure the proper amount of traction. The Cabot posterior wire splint, wire ladder splint material, and splint wood should be used for the protection of wounds of the joints, laceration of the soft parts, and fractures involving the ankle joint and wrist.

The experience of the past four years has shown that traction is the most efficient method of splinting fractures. When the wounded man must be transported for some distance by litter and ambulance, it is particularly valuable, and its use has reduced the mortality in fractures of the femur to a small per cent of what it was before this form of splinting was generally adopted. In the application of the Thomas leg and arm splints, it must always be borne in mind that traction is the essential feature and that the efficiency of these splints is entirely dependent upon getting a sufficient amount of traction to secure fixation of the fragments. Additional supports, as slings, etc., used are but aids to the essential feature which is traction.

NOTE.—It is important that no prolonged attempt should be made to make a diagnosis of fracture. It is better in the field to splint all cases where fracture is probable rather than to waste time and further shock the patient trying to discover the exact nature and location of a possible fracture. In this connection experience has shown that in large wounds of the soft parts without fracture the use of splints has been a material aid in reducing hemorrhage and increasing the comfort of the wounded during transportation, thus reducing shock.

The trench litter, known as the snowshoe litter, is a device found very useful for the evacuation of wounded in the first carry; i. e., from the place where the man is hit to the battalion aid post. On this litter the wounded man can be stood upright, turned sideways, or face downward without discomfort to him; thus aiding in the difficult carry through a trench. When the wounded man has reached the battalion aid post, he can ordinarily be placed on the common type of litter, his splints readjusted, his wounds properly dressed, and his fractured extremity suspended in the splint from the litter bar.

The litter bar should be used as soon as the patient is placed on all ordinary litters, and from it the splint should be suspended. This is necessary when the Thomas splint is used in order that the litter may be placed inside the ambulance.

5. *Shock and hemorrhage*.—The zone through which a wounded man must pass from the time he is wounded until he reaches a hospital may be called the zone of shock and hemorrhage. Shock as the result of hemorrhage, exposure, and pain is the most serious immediate complication of severe wounds; it is of common occurrence in wounds with fractures of the large bones. To combat shock the application of heat in every available form and in fractures adequate splinting are our most valuable aids. In all battalion aid posts and ambulance dressing stations the following memoranda should be posted:

THE PREVENTION AND EARLY TREATMENT OF WOUND SHOCK AT THE BATTALION AID POST OR
AMBULANCE DRESSING STATION

Consider the general condition of the wounded man first and tend his wound second.

Keep one dry stretcher with three dry blankets always in readiness.

Give wounded man a hot drink, with a tablespoonful of sodium bicarbonate dissolved in it as soon as he arrives.

Remove wet boots and leggings and any clothing that covers his wounds. Transfer him to dry stretcher, folding two blankets on stretcher so that he lies on four folds of blankets and the ends fall over sides of stretcher rack forming an air chamber; the Primus or Beatrice stoves for heat.

When wounded man is well warmed and quieted, dress wounds and apply splints properly for ambulance trip. Place well-guarded hot-water bottles in each axilla and one across loins.

Turn the blanket ends which hang down over the sides of the stretcher over the patient after a doubled blanket has been laid over him, and tuck the ends well in.

Finally just before the patient is sent out give him another hot drink.

It is important above all that efficient traction and support be applied to all fractures of the long bones.

Antitetanic serum should be administered at the battalion aid post.

An attitude of cheerfulness and encouragement is of great importance.

DON'TS

Don't annoy, delay, nag, and further injure by taking off shoes or clothing in the front area.

Don't forget to throw Thomas splints as far forward as the soldier goes.

Don't forget that there is a man as well as a wound; the man may be killed while the wound is being cured.

Don't forget that the bottom of the stretcher needs blankets more than the top of the man.

Don't forget the value of reassurance.

Don't give stimulants—the patient is not in need of stimulants, for the battle is a stimulant; the whistling and bursting shell is a stimulant; the shattered bone is a stimulant; in other words,

Don't give the soldier an overdose of the thing which is killing him.

THE FOLLOWING POINTS ARE EMPHASIZED

(1) Surgical operations are prohibited except in a hospital. Treatment at the front and during evacuation to the hospital will be limited to first aid, splints, control of hemorrhage, and shock. Probing for bullets or fragments of any sort is expressly forbidden.

(2) Every effort will be made to secure delivery of the patient to the proper hospital at the earliest possible moment after receipt of the injury. Saving of time during the early period of the injury may mean life or death of the patient.

(3) During the evacuation of the patient, he must be kept as comfortable as it is possible. He must be disturbed as little as possible, and in any event, after the first dressings and splints are applied only so much as is necessary to see that the dressings, splints, etc., have been properly applied and continue in good shape.

(4) Warmth will be continuously applied. This is our best preventive for shock. It will be secured by hot-water bags, alcohol or oil stoves, hot bottles, etc.

(5) A constant flow of supplies will be kept up from the rear to the front lines by a system of exchange noted above.

Army Sanitary School No. 121.

BACTERIA OF WAR WOUNDS

By M. Magrou, of the Institute Pasteur

Infection of wounds.—War wounds may be said to always contain bacteria. Bacteria come into the wound at the very moment that the wound is made. They are conveyed by the projectile itself, but chiefly by foreign bodies carried with it (pieces of clothing, dirt, etc.). It is well known also that there exist, on the surface of the skin and in the hair follicles, numerous organisms which may, subsequently, invade wounds. With few exceptions bacteria penetrating into wounds in this way are incapable of development in living tissues; they can, on the other hand, live in necrotic tissues, wherein they multiply as in culture media. These bacteria find very favorable conditions in wounds. Muscular attrition brought about by the traumatism invites sepsis of more or less extended areas. Vascular lesions and ischemia, which follow them, act in a like manner. In the zone of necrosis thus constituted, several types of bacterial flora may begin to develop; these organisms, while develop-

ing, produce chemical modifications in their medium, which render the latter favorable to the propagation of other types. Thus, certain microorganisms prepare the soil for others; therefore microbic associations play a preponderant rôle in the bacteriology of war wounds. This explains why types that multiply in wounds are not the same at all the different evolutionary stages of the wound; there takes place in the wound an evolution of the bacterial flora the general habits of which it is easy for us to make out.

General evolution of the flora of wounds.—In a general manner, wounds will appear contaminated from the first. Observations conducted during the first few hours immediately following the production of the wound reveal the existence of a small number of bacteria belonging, usually, to common saprophytic groups (*Staphylococcus albus*, *B. anthracoides*, *B. cutis*, *i. e.*). Later on, between the eleventh and twelfth hours, as a rule, anaerobic bacteria will begin to multiply in remarkable numbers, so that at the end of the first or second day they make up the whole or the major part of the wound flora. In the days following, the anaerobic flora decrease and finally disappear, save in cases where they find particularly favorable conditions for their development. (Notably, should an incomplete surgical operation have left a number of necrotic foci.) Aerobic types, among them the pyogenic microbes, such as staphylococcus and streptococcus, assume a preponderating influence, which afterwards becomes complete. We have given only extremely general rules which admit of many exceptions.

Classification.—After expounding the foregoing general principles, we shall review the most common bacterial species to be found in war wounds.

(1) Direct examination of stained smears, of pathologic products (pus or serum) taken from the wound, gives an idea of the number and nature of organisms contained therein. However, data furnished through this process are incomplete; precise determination can only be obtained from culture. Any bacteriological examination of the suspected material includes aerobic culture (on peptone agar) and anaerobic (on Veillon agar). For special cases, certain special technique may be more suitable, especially, as will be seen later, for the rapid determination of streptococcus.

Wound bacteria may be divided into several groups. We shall consider successively: Spore-bearing bacilli; Gram-negative bacilli; Gram-positive micrococci; branching bacteria.

I. SPORE-BEARING BACILLI

General characteristics.—Spore-bearing bacilli form a well-defined natural group; small rods, Gram-positive with reproduction by endospores. In regard to these there are two fundamental peculiarities of the group: (1) Their ability to "take up the Gram" may be very fugacious; (2) not all culture media are favorable in the same degree to the production of spores; it is in poor media, generally, that they are most easily obtained.

Endospores multiply as follows: A portion of the bacterial protoplasm becomes condensed at a certain point in the bacillus. A thick refracting membrane, difficult to stain, appears around the condensed protoplasm. In some species, the spore formed as described is just as broad as the mother bacillus. In other species it grows broader than the mother cell; the latter becoming deformed thereby, with its contour swollen at that point. In this case, the spore may occupy a central or a subterminal position (clostridium), or terminal, which gives the new bacillus the aspect of a pin or drumstick (*paraplectrum* or *plectridium*).

Spore-bearing anaerobic bacilli.—Among the spore-bearing bacilli, some are anaerobic, others aerobic. Spore-bearing anaerobic bacilli are among the most important genera found in wounds; the organisms causing gas gangrene belong to this group. Some are motionless; others are mobile.

Bacillus perfringens.—The type of immobile anaerobes is the *Bacillus perfringens* Veillon (*B. aerogenes*), *capsulatus* Welch, *B. de Frankel*). It appears in the form of straight rods, thick, squat, immobile, capsulated, Gram-positive, usually isolated or in pairs, not forming long chains. Spores are median or subterminal; they never multiply in sugar media. Colonies

in Veillon's agar^a are lenticular, with regular outline, sometimes adopting the shape of a heart; their growth is accompanied with an abundant production of gas, which breaks up the agar. Bouillon cultures are uniformly turbid at first, but clear up later, leaving a sediment.

The isolation of anaerobes in Veillon agar is accomplished as follows: A number of Veillon tubes are boiled in a water bath for 15 minutes, so as to expel the air contained in the agar. They are then cooled down to 42° to 45°, after this the substance to be examined (pus or serum, for instance) is taken on a platinum loop and sown in one of the tubes. Then, with the same loop, a drop of the first tube is sown in the second, the third from the second, etc. We obtain from the first tube numerous colonies, but in the subsequent tubes they are sparse and well isolated.

B. perfringens coagulates milk and gives a spongy clot; it digests boiled-egg albumin very slowly.

B. perfringens is one of the most common microorganisms in war wounds. It is the most frequent cause of gas gangrene, but it becomes dangerous only when favored by its surroundings. If an early and complete surgical operation has excised the dead tissues, and if the *B. perfringens* is not associated with the aerobes, notably with staphylococcus, and more especially with streptococcus, it always disappears from the wound which contains it. Sometimes wounds containing only *B. perfringens* can be observed to heal perfectly after primary suture.

Septic vibron and related species.—The type of mobile anaerobic bacilla is the septic vibron, discovered by Pasteur (*B. oedematis maligni* Flugge). It is a more slender rod than the *B. perfringens*, generally rather long, straight or bent, mobile, and ciliated. They are unassociated or form long chains of bacilli, joined endwise. Spores are median, sometimes subterminal; they are broader than the body of the bacillus, which becomes swollen at the point where they are developed (*clostridium* form). Colonies in Veillon agar are cloudy, finely hairy, with the appearance of a felting made of fine, wavy filaments. This last characteristic is not permanent, for the septic vibron has been observed to produce lenticular or cordlike colonies. Bouillon cultures produce a putrid odor and the medium is at first uniformly turbid. These cultures eventually clear up, leaving a deposit. The septic vibron is specifically agglutinated by the septic and antivibron serum.

Less frequent in wounds than the *B. perfringens*, the septic vibron has been observed in a number of serious cases of gas gangrene.

To the septic vibron type are related several types presenting morphological similarity. These types differing from the septic vibron "sensu stricto" differ also from each other in their pathogenic properties and in the strictly specific action of corresponding antitoxins or agglutinins. Of this number is the *Bacillus sporogenes* Metchnikoff, formerly described among intestinal flora and since rediscovered in war wounds. This organism generally appears in spherical, opaque colonies, covered with short hairs, giving it the appearance of a ball of wool. To the same group belong some species discovered since the outbreak of the war in different cases of gas gangrene: *Bacillus bellonensis* Saequepée; *Bacillus oedematiens*, Weinberg and Seguin, which produces a very active toxin; *Bacillus histolyticus*, whose characteristic is the rapid liquefaction of tissues invaded.

Lastly, another anaerobe belonging also to the intestinal flora is to be found in war wounds: *Bacillus putrificus*. It is a straight rod, very mobile, ciliated, Gram-positive. Its spores are either terminal (*paraplectrum*, Bienstock type) or median, or subterminal (Metchnikoff type). Colonies in agar are formed of a central nucleus surrounded by numerous filaments. Egg albumin, coagulated, is readily digested. Cultures in different media give a distinct putrid odor.

Spore-bearing aerobic bacilli.—Spore-bearing aerobic bacilli found in war wounds are far less important than the anaerobes of the same group. They are saprophytic bacteria and are innocuous. They are also classified as mobile and nonmobile.

^a Veillon's agar: Ordinary peptonized agar, 1,000 gm.; glucose, 15 gm.; potassium nitrate, 1 gm., to be put into deep tubes filling up about half of their depth. In this medium, glucose acts as a reducer; it prevents oxygen from getting to the depths of the agar as thus anaerobes are enabled to thrive. After the tube has been inoculated, there remains in the upper portion of the agar a zone (more or less extended according to the exigency of the anaerobe) wherein microbes do not live. Potassium nitrate is added to the medium with the object of absorbing the greater part of the gases which the culture gives rise to.

Nonmobile bacilli are represented by the *Bacillus anthracoides*, which is one of the most common bacteria of war wounds. By its morphological characteristics it is related to the bacillus of anthrax (*B. anthracis*); it differs in its lack of pathogenicity. It is a large Gram-positive bacillus, with median spores. It is often seen in chains, but not always. Colonies in agar are round, flat, dull-whitish and gelatin is liquefied.

Among the aerobic spore-bearing bacilli, which are mobile, we may mention the *B. mesentericus*, whose colonies are convoluted. The *B. mycoides* produce colonies with hazy edges; they spread by delicate flexuous prolongations.

B. subtilis is also seen, on whose whitish colonies fine clear drops are noted. This bacillus, widely spread in nature, is only exceptionally encountered in wounds.

Finally, there is a terminal spore bacillus (*paraplectrum*) not often seen, giving on agar, round, flat, transparent colonies.

Branching bacilli: Gram-positive, non-spore-bearing bacilli will be studied with the streptothrices (streptothrix) to which they are similar on account of their power to ramify, which they possess to an unusual degree.

II. GRAM-NEGATIVE BACILLI

Gram-negative bacilli can be classified as mobile and nonmobile, as in the spore-bearing bacilli. Mobile bacilli of this group are subdivided, according to their reaction on protein, into two new groups: Those which liquefy gelatin and coagulate serum and those which liquefy neither one or the other.

Bacillus proteus.—Gram-negative, gelatinolytic and proteolytic bacilli are represented in wounds by the *B. proteus* and the *B. pyocyaneus*. *B. proteus* is a very mobile, ciliated bacillus. On agar it gives rapidly spreading colonies, forming a thin iridescent veil and producing a fetid odor. It is a facultative anaerobe.

Bacillus pyocyaneus.—*B. proteus* is a common inhabitant of war wounds, generally found in a relatively late period of their evolution. Such is also the case with *B. pyocyaneus*. This organism, mobile and provided with a single terminal cilium, is characterized by the production of two pigments which diffuse throughout the culture media; a blue pigment, pyocyanin, and a fluorescent green one. Either one or both pigments may be lacking, but it is easy to cause them to reappear by cultivating the organism in an appropriate medium.

(NOTE.—Gessard medium: Peptone, 2; glycerin, 5; agar, 5; in 100 parts of water.)

B. pyocyaneus, when a flourishing growth takes place, leads to the formation of a blue pus. Its pathogenic power, like that of *B. proteus*, practically amounts to nothing; consequently, its presence in a wound does not impede suture.

Bacillus coli.—Mobile, Gram-negative bacilli, liquefying neither gelatin nor serum, form the vast colon-typhoid group. Only one representative is found in war wounds, and this one is rare—*Bacillus coli*. It is ciliated, mobile, ferments lactose with the production of acids and gas; it produces indol in peptonized media.

Bacillus Friedlander.—Immobile, Gram-negative bacilli are represented in wounds by *B. Friedlander*. It is a capsulated bacillus, variable in form; its elements, more or less elongated, generally thick set, are often grouped in twos. Sometimes short and even perfectly round forms can be seen (micrococcus or diplococcus). Colonies in agar are porcelain white, raised, hemispheric, greasy, and stringy. Gelatin is not liquefied. Stab cultures in gelatin take the characteristic shape of a nail, with convex disk on the surface and a white prolongation along the track of inoculation. *B. Friedlander* is a facultative anaerobe; its development in Veillon agar is accompanied by the production of gas, sometimes abundant. It is commonly found in war wounds, but its presence does not seem to be productive of harm.

III. GRAM-POSITIVE MICROCOCCI

The group of Gram-positive micrococci includes war wounds aerobes of greater importance. Two subgroups may be differentiated according to the mode of arrangements of the individual cells, chainlike or in bunches.

Chainlike micrococci comprise two closely related species entirely different in their pathogenic effects: Streptococci and enterococci.

Streptococcus.—In liquid media, it forms long chains, generally flexuous, or coiled up. In solid media, especially in pathogenic products, these chains are often short.

(NOTE.—Not rarely, streptococci presenting the aspect of diplococci can be seen in pus. In bouillon cultures flakes are formed that sink to the bottom of the tube where they make up a clotted deposit, without clouding the medium. Agar colonies are very fine, transparent acuminated, with slightly crenated edges; in agar media, to which albuminoid substances (serum of ascitic fluid) have been added, they retain the same aspect but are generally more luxuriantly developed. The streptococcus is an anaerobe facultative; certain races prosper better as anaerobes than as aerobes. In agar cultures, examination of the water of condensation shows the characteristic long chains.)

Finally, the streptococcus has a most important characteristic; it is generally hemolytic; cultures in bouillon containing washed red blood cells hemolyze the latter; hemoglobin thus released is secondarily attacked by the streptococcus and the liquid becomes thence of a tint resembling that of onion parings or old wine.

The genus streptococcus is subdivided into many species, whose differentiation depends mainly on their hemolytic properties. It is admitted generally that hemolytic streptococci are the most pathogenic; it is assumed that there exists correlation between the hemolytic power and the pathogenic activity of the coccus. Therefore it is important to ascertain whether a streptococcus isolated from a wound is or is not hemolytic.

The streptococcus has proved itself to be one of the most dangerous microbes of war wounds. In association with the anaerobes it favors their reproduction and, therefore, the appearance of serious accidents, i. e., gas gangrene. Furthermore, it is the only wound aerobe observed to cause general septicemia. Finally, when it effects a foot hold in a wound, it proves extremely tenacious, giving rise to protracted suppuration and sometimes constitutional affections as, for instance, sudden and violent fever, or even distant complications (arthritis, osteitis, empyema, etc.).

Hence the presence of streptococci is in itself the most important contraindication to the suture of the wound; so much so that it has been established as a general rule that sutured wounds in which bacteriological examination demonstrates the existence of this organism must be reopened immediately. As a matter of fact, in almost every unsuccessful primary suture, bacteriological examination has demonstrated that the streptococcus was concerned in the failure. Not all strains, however, seem to be equally virulent; in some cases, primary suture has been partially and even completely successful, in spite of the presence of the hemolytic streptococcus.

Be that as it may, it is of the utmost importance that the surgeon be informed as quickly as possible of the presence of true hemolytic streptococci in wounds. To accomplish this end it is recommended to inoculate liberally from all suspicious parts of the wound in bouillon, or, better yet, peptonized water, with glucose at 2 per 1,000 and an albuminous liquid ascitic fluid or egg albumen.

(NOTE.—For further details, see Weissenbach's technique, appended.)

In this medium, the development of the streptococcus is very rapid, so that it can be made out after 6 to 8 hours incubation and, indeed, often after 4 hours. If after this lapse of time the presence in the cultures of micrococci forming long chains is verified, it may be concluded that an organism of the streptococcus group exists in the wound.

(NOTE.—To examine, secure with a pipette from the bottom of the test tube a drop of the culture, stain by Gram and also make an examination of the unstained, unfixed organism in a hanging drop, thus preventing the disassociation of the little chains.)

It suffices to transplant the culture to a blood medium (preferably blood agar plates in order to obtain isolated colonies) to be able to judge if the strain found is hemolytic or not.

Enterococcus.—This organism, very common in war wounds, appears like the streptococcus in the form of Gram-positive micrococci arranged in chains; but the chains are short, some quite short, and diplococci forms are frequent. Besides, individual cells are generally more elongated. Bouillon cultures are uniformly turbid; secondarily, a stringy deposit appears in the shape of a gimlet, rising through the liquid when the test tube is shaken. The culture medium does not present the clotted aspect of the deposit left by the true streptococcus. Colonies on agar are fine, but somewhat larger than those of the streptococcus; they are milky in color, evenly rounded and not acuminated. The enterococcus is not hemolytic.

This organism, unlike the streptococcus, has no bad effect on the evolution of war wounds.

Gram-positive, irregular, clusterlike micrococci are comprised under the name staphylococci. The *Sarcina* form geometric clusters.

The staphylococcus.—Staphylococci form irregular clusters, more or less voluminous, resembling bunches of grapes. Diplococcus and tetrad forms occur in pus. According to the color of the colonies, three species of the staphylococcus are recognizable.

The white staphylococcus (*Staphylococcus albus*) gives pigmentless, porcelain-white colonies. It does not liquefy gelatin. Its pathogenic power is more often weak or nil. To this species may be related several other species of lesser importance as yet not well defined (*Micrococcus candidus*, *Micrococcus*). It is useless to describe them, as they are not pathogenic.

The "gilded" staphylococcus (*Staphylococcus aureus*) occurs more frequently and is of greater importance. Its colonies are at first grayish; thence they become a more or less intense golden yellow color, especially if the test tubes are kept at ordinary temperature. Certain races are only feebly pigmented and must not be mistaken for the white staphylococcus. Gelatin is liquefied in a funnel shape. The staphylococcus may live as an anaerobe, but its growth is favored by oxygen.

The occurrence of *Staphylococcus aureus* in war wounds may cause several phenomena:

(1) In association with anaerobes it favors their development, although to a lesser degree than the streptococcus.

(2) Locally it often brings about suppuration.

(3) Sometimes distant localizations take place (arthritis, osteomyelitis) which may become tenacious.

When they invade tissue deeply, as demonstrated by Masson, the colonies may be encysted, forming grains or nodules like those of the *Botryomycosis equinus*.

However, the presence of staphylococcus, when it is not abundant and not associated with anaerobes, is not a sufficient reason to prohibit the suture of wounds.

Sarcina.—Sarcinae are Gram-positive micrococci arranged in regular cubic clusters. Such arrangement is the result of the mode of their reproduction; one sarcina, through three successive mitoses in the three dimensions of space, gives eight coherent cells; through sequences of the same process, more or less voluminous cubic clusters are found in the shape of bales of cotton.

(NOTE.—This arrangement is better seen in liquid culture media or in the water of condensation of agar cultures.)

Several species of sarcina have been differentiated according to the color of the colonies. White sarcina (*Sarcina alba*), yellow sarcina (*Sarcina lutea*), pink sarcina (*Sarcina cornea*).

When found in wounds, sarcinae are not abundant; they are saprophytes, having no pathogenicity whatsoever.

IV. RAMIFIED BACTERIA

We shall include in this group bacteria only exceptionally producing branches and bacteria ordinarily branched.

Corynebacterium.—Bacteria, exceptionally branched, look ordinarily like bacilli. They have been grouped under the name Corynebacterium, type of the *Bacillus diphtheria*. They are Gram-positive bacilli, irregular in shape, often bent, nail-shaped, or beaded; generally grouped by twos (V-shape), or forming palisades or thornlike clusters.

A representative of this genus is frequently found in wounds, *Bacillus* (*Corynebacterium*) *cutis*, a normal inhabitant of the skin. It has the appearance of cuneiform rods, hardly any longer than broad, resembling the short diphtheria bacillus. In certain strains, however, individual cells are more elongated, approaching the medium and long varieties of the *Bacillus diphtheria*. It is very simple to recognize the *B. cutis*, which is strictly aerobic; the *Bacillus diphtheria* is a facultative anaerobe. Culture in Veillon agar makes it easy to distinguish this difference. *B. cutis* only multiplies on the surface or in the upper layers of the agar, while the diphtheria bacillus produces its colonies throughout the whole medium. *B. cutis* is not pathogenic.

A few cases of infection of wounds by the diphtheria bacillus have been reported. This organism, when it invades the wounds, gives rise to the local formation of false membranes; at the same time, general symptoms of more or less serious toxemia appear which yield to subcutaneous injections of diphtheria antitoxin, while the local development of the bacillus can be stopped by applying specific antitoxin serum on the wound.

Streptothrix.—Normally branched bacteria makes up the streptothrix group, which many authors consign to the fungi *imperfecti*. But the cytologic coloring of these organisms never reveals in the interior of their filaments the presence of definite nuclei such as exist in all fungi. This characteristic suffices to classify them still among the bacteria.

The streptothrices, which include the organisms of actinomycosis, have only one representative in the flora of wounds, *Nocardia dassonvillei*. This organism is composed of slender filaments, Gram-positive, branched, and complex; it is reduced to débris (arthrospores) in old cultures. Colonies on agar are very hard and at first cream colored. They become covered secondarily with a white "pruine," which gives them the appearance of fresh plaster blocks. Cultures produce an intense musty odor. *Nocardia dassonvillei* is only accidentally found in war wounds; it has no pathogenic significance.

The following table sums up the main characteristics of the most common wound bacteria. To facilitate the reading, the species have been grouped according to the system of dichotomic keys.

I. Endospores:

Anaerobes—

Mobile—

- B. Sporogenes.*
- B. Putrificus.*
- B. Bellonensis.*
- B. Oedamiens mal.*
- B. Histolyticus.*
- Vibrio septique.*

Nonmobile—*B. Perfringens.*

Aerobes—

Nonmobile—*B. Anthracoides.*

Mobile—

- B. Mesentericus.*
- B. Mucoides.*
- B. Subtilis.*

II. Non spore:

Gram-positive—

- B. eutis* of pseudo-diphtheria—a true aerobe.
- B. diphtheria*, a facultative anaerobe.

Gram-negative.

(a) Those which liquefy gelatin—

- B. proteus*, foul odor.
- B. pyocyaneus*, blue or green color.

(b) Those which do not liquefy gelatin—*B. coli*.

III. Micrococci:

(a) Growing in chains—

- Streptococcus.*
- Enterococcus.*

(b) Grow in groups—

(1) *Staphylococcus*—

- Irregular.
- Albus.
- Aureus.
- Citrus.

(2) *Sarcina*, regular.

IV. Streptothrices (fungi?).

V. *Nocardia* (fungi?).

APPENDIX

Culture in peptonized glucose water containing alkaline, egg albumen. A special method for rapid and certain definition of streptococci in war wounds containing a varied bacterial flora. By R. J. Weissenbach.

I. PREPARATION OF CULTURE MEDIUM

The two following solutions must be prepared separately.

1. *Peptonized glucose water*.—Water, 100 c. c.; Pepton Chapoteaut, 4 gm.; salt, 0.50 gm. Neutralize, or, better, render slightly alkaline to litmus; subject to 15 minutes in autoclave at 120° temperature, then filter and add to 100 c. c., glucose, 0.20 gm. (It is not necessary to use chemically pure glucose.)

2. *Alkaline egg albumin*.—Mix: Egg albumin, 1 part; distilled water, 3 parts. Two whites of eggs from 200 to 250 c. c. of mixture. Mix and shake in a large cup. Add 0.50 c. c. of soda solution (10 per cent) to 100 c. c. of the water and albumin mixture. Keep in autoclave 15 minutes at 115° to precipitate. Filter while warm.

Mix the two preceding solutions: Peptonized glucose water, 50 c. c.; alkaline egg albumin, 50 c. c. Distribute in test tubes, 5 c. c. to a tube. Sterilize in autoclave 15 minutes at 110°.

II. INOCULATION

The quantity of pus or exudate to be inoculated should be relatively considerable, grossly approximating one-twentieth to one-tenth cubic centimeter of a properly collected specimen containing from 20 to 40 cocci per microscopic field (oil immersion, objective one-twelfth—compensation ocular 4) and in this smears. After the inoculation, shake the test tube to obtain a uniform mixture. Then place in autoclave at 37° to 38°. If the result must be known as early as possible (primary suture), the culture must be tested successively after 4, 6, and 8 hours. In other cases (secondary suture) it suffices to test it once between the eighth and tenth hours for the development of other organisms may render the discovery of streptococci very difficult. Should this single test prove negative, proceed to make another between the eighteenth and twenty-fourth hours, only as a control. Practically, according to the nature of the specimen in which inoculation is performed, the result is obtained, in half the cases, after 6 hours at 37°, in one-fourth of the cases after 4 hours; and in the remaining fourth after 8 hours.

Examination of the culture should be carried out as follows:

Without shaking the tube, get from the bottom of it, with a capillary pipette, a small quantity of liquid containing the pus globules sedimented during the time they remained in the incubator; the most numerous and most characteristic chains will be found in these cells at least during the first few hours.

A drop of the culture medium, obtained under these conditions, is placed on a slide, covered with a cover glass, and examined directly without staining, with a strong dry objective. These are the best conditions to observe the long sinuous chains of 30 or 40 cocci or the more voluminous clusters out of which spring the chains; such is the appearance of the streptococcus as it occurs in this culture medium. Another drop is transferred to the slide and stained by the Gram method for the study of the morphological character of the cocci. The chains appear more disunited, shorter, and therefore less characteristic than in the preceding preparation. It is imperative to make, each time, this double examination.

The development of the other associated bacteria, not very active as a rule, but variable according to their relative number and nature, is not confusing. This method causes less errors than any other.

As soon as direct examination has revealed in the medium the presence of Gram-positive chainlike micrococci, which suggests the existence of streptococci, a new inoculation is conducted on blood agar in order to obtain isolated colonies which will permit us to identify them and also to bring out their hemolytic properties. Two 10 c. c. test tubes containing ordinary liquefied agar kept at 45°, each receive 1 c. c. of defibrinated or citrated (human blood). One platinum loop is taken from the culture medium containing micrococci; the contents of the loop are distributed in the liquid in the first tube of blood agar. Then, without refilling the

loop, the same procedure is carried out with the second tube of blood agar; the contents of each tube are powdered into a Petri dish. After solidification it is taken to the incubator (37° to 38°). At the end of 12 to 18 hours, if there exist hemolytic streptococci, we will find very small colonies surrounded with a yellowish white halo of hemoglobinolysis of $\frac{1}{2}$, then 1, and later 2 mm. in diameter. These colonies differ from other isolated hemolytic bacteria of wounds; nevertheless, its nature must be always verified by examination of stained smears (Gram method). These isolated colonies will serve as a starting point for the study of the other differential biochemic characters needed for a valid identification of bacteria.

Army Sanitary School No. 122.

CONVALESCENT CAMPS

By Col. Bailey K. Ashford, M. C., commandant, Field Service School for Medical Officers, A. E. F.

There are at least four features in the work of the medical corps of an army to-day which have recently placed medical officers in the position of being among the most active of the forces with which the enemy has to count, for by its medical corps an army can to a large extent delay and repair the ravages of war in men lost to the fighting line; in other words, the medical corps of an army has ceased to be a corps of doctors pure and simple, appendages of an army and noncombatant in every sense as far as war goes, who employ their profession to alleviate pain and repair the damaged individual. To-day they constitute the most valuable of all salvage corps—the salvage corps for men, the only corps by which damaged men can be salvaged. Naturally these officers are rewarded for the application of the medical sciences to the art of war by being deliberately bombed, gassed, and shelled by an enemy who has not failed at all to realize the importance and value of their contribution. There are at least four outstanding factors in this new conception of the duties of a medical officer which make him willy-nilly an active participant in the winning of battles:

- (1) The prevention of disease by sanitary art and by preventive medicine;
- (2) The rapid collection and forwarding of the wounded and gassed, with intelligent first aid, such as the transportation of fractures in extension, the preventive treatment of shock, the immediate relief of the gassed, and the direct removal in the most comfortable and expeditious manner of all casualties to hospitals adequately provided to fulfill the requirements of modern military medicine and surgery;
- (3) The prevention of infection of wounds by the surgical removal of the contaminated dead and dying tissue upon which organisms have heretofore been able to thrive; and
- (4) The rapid return to duty, through convalescent camps, of men who heretofore have spent months in the zone of the interior, many never returning to the lines and being lost to the army.

It is with this last desideratum that we have to deal here.

The whole idea of a convalescent camp or depot is a point which the Medical Department operates to salvage men who would otherwise occupy a bed in a base hospital or be sent back to their homes or some watering place where the military spirit into which they have been inducted is more or less rapidly lost without any corresponding real benefit to their physique. The object is to get men away from base hospitals who will need no further active medical or surgical treatment, but merely medical surveillance, and who especially need to be brought back into a military atmosphere rather than be allowed to remain in a convalescent frame of mind. The two absolute essentials of a good convalescent camp are (1) that it should be commanded and administered by medical officers and (2) that it should be a place which should combine all the pleasanter features of military life and its comforts without supplying luxuries or permitting vices which tend to pamper the soldier and unfit him for his better return to the lines.

To show what can be done in this respect, Convalescent Camp No. 1, of the British has returned to the front direct 5,000 men in six months and Convalescent Hospital No. 10 about 1,500 per month. In general the statements from the convalescent depots and camps

seen to date make it clear that the time spent in convalescence by men at base hospitals has by means of these camps been reduced from nine months to one month in the 50 per cent of cases that are returned to duty at the front. These figures are approximate, but were given me by their commanding officers. Maj. Gen. C. H. Burchaell, now director of medical services, British Expeditionary Force, in France, stated that out of 1,015 men at a convalescent camp 756 were returned to duty cured as type A men, 127 remained as P. B., 123 were returned to base hospitals, and only 9 sent home to England.

In connection with the first essential of a good convalescent camp—that it should be run entirely by medical officers—it should be remembered that if such camps are placed in the hands of nonprofessional men, line officers, they will be looked upon as training areas, and these they are not. It should be remembered that they are points at which damaged men are salvaged, and damaged men can not be salvaged save by the scientific medical officer whose aim and ambition is to put as many able-bodied men back in the fighting line as soon as he can and whose military sense is developed *pari passu* with his specialty. Such men can not be salvaged by mere doctors nor by mere scientists, however well meaning they may be. This is the legitimate field of a well-trained officer of the Medical Corps who has really learned to apply his profession to the conditions of war.

THE GENERAL PLAN OF A CONVALESCENT CAMP

A convalescent camp should be carefully laid out and should be a barrack and not a tent affair. The site should be pleasant and healthful; above all it should be in the country away from all other centers, with plenty of room to expand. It should communicate by good roads with necessary centers, and should be laid out with a view to ornateness, with well-turfed lawns and abundant shade, with gardens and flowers, and with good walks, which should include surroundings that would be pleasing to the eye and which would lead into the open country. These camps should accommodate from 2,000 to 3,000 men, who should be divided into companies of 250 each, under the immediate charge of experienced noncommissioned officers. There should be regular hours for meals, and such formations as are decided upon should be observed with military exactness. Great care should be taken at these places to provide for the men all military comforts and necessities with a minimum amount of the annoying petty details of a soldier's life. For example, the barrack itself. This should be attractively painted, with stained floor and stained rafters; with kalsomined walls and ceiling. It is an enormous advantage to have the floors waxed, or at least oiled. Beds are by no means a necessity; a straw mattress with a sufficient number of blankets, and a set of hooks and shelves above each man's head for his clothing and equipment being quite sufficient, provided the barrack itself is spotlessly clean, neat, and attractive. The chill should be taken off the barrack by enough stoves, but the stuffy heat without ventilation too often seen in such barracks should be prevented. The men should sleep with the windows wide open. Both latrines and baths should be accessible, and these should be as clean and as decent as the sleeping quarters.

There should be at each one of these convalescent camps an excellent quartermaster storehouse, where an ample supply of clothing, field equipment, etc., should be kept at all times, so that no man need go dirty or slouchy, and every man when he goes away may be properly equipped to join his organization. There should be certain features about this quartermaster's storehouse that might be with benefit much more elaborate and detailed than in one of an ordinary depot type. Here considerable effort should be made to provide shoes for the men that will fit. This work, begun in times of peace in our country by our Medical Corps and with such success, finds a peculiarly important mission to perform at these convalescent camps. In connection with these storehouses there should be a set of shops which could be used for the employment of men in the army who have become partially disabled for front-line service—the so-called B men. Two such men should be permanently assigned here as tailors, and their shops should be used not only for the convenience of the men but for the instruction of certain convalescents who will probably be unable to return to the fighting lines and who may be advantageously placed in the lines of communication for the good of the Army when they are sufficiently trained. This same policy should apply to all other industrial shops, which should form a feature of a convalescent camp. Thus a

practical outcome of these camps will be a provision for training schools for artisans needed in the Army. There should be, therefore, cobblers, tinsmiths, electricians, carpenters, blacksmiths, leather workers, laundrymen, cooks, musicians for bands, and others trained here.

The bathing, disinfecting, and laundry systems should be unusually complete. In addition to the usual care taken to cleanse and disinfect the soldier upon his arrival, means should be provided to keep him clean and neat until he goes away. A delouser should be kept at this plant, which should be central and accessible, and the belongings of all men should be disinfested once a week. In addition to showers, it is well to afford other varieties of baths. For instance, we noted in some of the convalescent camps that cement baths had been sunk in the floor for about a foot, underneath the shower, and that these baths were curtained off and made individual; both hot and cold water was available. It is well to have, also, a room for a Turkish bath; but the men should be made to go in in groups to prevent accident, and a cool or temperate shower should be exacted of every man bathing thus before leaving the establishment. The baths should have attendants who are well versed in skin disease to pick out men who are lousy, who have the itch, or some other contagious disease of the skin. Fresh clothing should be freely supplied, as well as soap and towels. There should be a good barber shop in connection with this bath, where men should not be required to pay for the cutting of their hair, although a small charge could be made for shaving and shampooing. A good chiropodist should also be on duty at the baths.

Above all, these baths should be scrupulously clean and the men should be shown that the Army can and will provide better bathing establishments than those for which high prices are paid in cities under conditions of peace. In this connection it is believed that the Section d'Hygiene Corporelle of the French could be used with advantage as the basis for an American bathing establishment.

Some provision should be made for a good laundry, and this should be in charge of an experienced laundryman. No women should be employed at this place. It is believed that the sterilizing of clothing could best be accomplished either by the Herseher apparatus of the French or the Foden Thresh of the English. By this time there may be some steam sterilizing apparatus on the plan of the Kny-Scheerer made in our own country.

FEEDING THE MEN

The feeding of the men requires a very highly specialized department. The kitchen should be a large one, well ventilated, attractive, and furnished with a sufficient number of stoves to permit the cooks to devote themselves to specialties. There should be stoves for stews, stoves for baking, stoves for pastry, pies, cakes, etc., each being separate and each having its own cook. In this way there is great improvement in the quality of the food.

It was brought very forcibly to my attention that the method of the British at Boulogne in feeding the men should be copied, in the interest of economy in our own service. All men should be given to understand at the outset that they can have all that they want to eat and just as many helpings as they want, but that it is their duty never to take more on their plate than they think will satisfy their appetite—that they are sure they are going to eat. The kitchens adjoin the dining hall, a long counter for serving the men with food being interposed.

The men are introduced into the dining hall by companies, five minutes apart, instead of sitting them all at once. On entering the hall each man is given eating utensils, cups, plates, and paper napkins from the store of the mess hall. Armed with these, he proceeds, after the manner of a Childs restaurant, to the counter mentioned. By enlisting the cooperation of the men to the end that no more food will be taken on the plate than is needed, I was told by the commanding officer of one of the camps that in this way 10,000 pounds a year was saved in food which had previously been wasted by the portioning out of fixed amounts to each man.

In connection with this kitchen there are two important side issues. One is the convalescent-camp garden. In general terms a convalescent camp should produce all the vegetables it needs for its own support, but this garden should be utilized for the employment of men who will not go back to the firing line, rather than for the men who simply need to be rapidly built up for duty at the front. The distinction is thus made for the reason following.

Men who are to go back in a short time to the conditions of trench warfare should not be allowed to browse about too long in agricultural pursuits; their military life should be kept before them at all times. As one commanding officer of these camps states, "It seems like when they get into a garden they get to thinking what a terrible thing war is." Now, this we don't mind in the case of permanent base men, but we don't want to make our men who have to go back to the front feel bad unnecessarily.

The other adjunct is the conservation of food.

1. *Fat conservation.*—This is important for two reasons: (1) It provides suet for cooking and (2) it serves as a source of much material for certain munitions of war. The first necessity is subserved by the saving and rendering of fat trimmed from meat and taken from plates of men who have not consumed all that has been served them. The second is obtained from the fats of the kitchen waste, the garbage, and the scouring from kitchen sinks. This non-edible fat is rendered and is shipped in 300-pound casks to a salvage depot. The English render these fats on Soyer stoves, which are excellent for the purpose. The important part of this conservation is that the organization is paid a few cents a pound by the Ordnance Department for all fat thus saved for munitions.

2. *Conservation of food scraps.*—An enormous amount of meat and bread can be conserved for the making of hash, rissoles, and other dishes. It is noteworthy that these big kitchens have very few garbage cans—only one or two for a kitchen serving two to three thousand men.

3. *Conservation of solder from tins.*—At several convalescent depots we saw a large melting pot into which were thrown all tin cans. A hot fire was lighted two or three times a day and the solder allowed to run out through a funnel in the bottom. This was an important source of revenue for the camp, as the lead was sold in sticks of solder to the Government.

These camps require the most exacting sort of a sanitary officer. They should be models of sanitation. There should be night urinals placed between all barracks and, as before referred to, the latrines should be as perfect as it is possible to make them. Personally, I believe that the best possible disposition of feces at these camps is by incineration, and there is no objection at all to having these incinerators used for kitchen waste as well as feces; it will depend entirely upon the cleanliness of the latrine as to how near it can be placed to a kitchen. The pail system was so run in the British service that never in all of my many visits to their institutions have I smelt feces or seen filth in connection with such a system. Of course a good sewer system is best, but it will be rarely possible to attain. Fly-proof boxes for deep pits, after the American plan, is a possibility in certain terrain and is preferred by many British to their bucket latrine. The great point is that it is not only sanitation that we are after, but we are trying to preserve the sanitary conscience of our soldiers by appealing to their sense of decency. Therefore, these places should be always free from odor, always spotlessly clean, always provided with a comfortable seat and good paper with which the men may cleanse themselves. The urine should be allowed to flow away into a soakage pit, and an orderly should always be stationed on duty in charge of the latrine and the incinerator serving it.

As to the amount of fuel required for an incinerator, as will be seen from many papers issued by this school, that quantity is negligible. With a good camp refuse conservancy system 2 pounds of coke a day per incinerator for starting the fire is sufficient. But all camp refuse should be promptly dumped here daily.

The morning ablutions of the soldiers should be provided for by ablution benches, under cover, and with hot water for shaving. These can be near the latrine and the hot water obtained from pipes running through the fire box of the incinerator. In fact a washhouse for hands and face is best located in this vicinity.

It should be emphasized that there is no part of the upkeep and the daily service of a convalescent camp which should not be run by the convalescents themselves; gradually a permanent detail will be formed from P. B. men who can not go back to the front, men who have shown themselves to be particularly well prepared for identification with one or another of the services in the camp and who will always serve as nuclei around which men for these services will be grouped. The commanding officer will inculcate in these men, in addition to the strictest regard for military discipline, a decent regard for the ornate, and, as a result thereof, for the clean and neat. It should be deliberately taught men that it is not enough merely

to have the "rough stuff," the bare necessities; that men should improve their condition, that they should keep themselves and their surroundings clean if they expect to keep well; that they should keep their initiative, their ambition, their imagination active; that to make their barracks, their reading rooms, their camp attractive to the eye is to preserve those illusions of life which are necessary to make them contented and happy.

ENTERTAINMENTS

It should be noted that all too frequently the poorest form of entertainment for a soldier is the formula which somebody else has provided him to enjoy himself by. The most perfect entertainments that we have seen since we have been in France, generally vaudeville, it is true, but some serious concerts, have been provided by the soldiers.

The programs they have made up themselves from jokes which nobody ever wrote and from bits of waggy which you do not always find among professional comedians. The American people are especially gifted with a keen sense of humor, and we never see any humor keener than that displayed by our own healthy and care-free soldiers at the front. Civil societies who have taken unto themselves the diversion of the soldier can do their best work at these camps by providing the wherewithal for the soldier himself, and quite in his own way furnish his own amusement. Such entertainments, "hand made" by the soldier himself, plus the excellent ones provided so lavishly by our patriotic professional artists, musicians, and orators, work marvels in keeping a normal and healthful psychology among our men.

For a camp of 2,500 there should be at least one drum and fife corps, two brass bands, one orchestra, and one mandolin, guitar, and banjo club. By furnishing the instruments for these bands there never will be a dearth of musicians, and, as has been intimated previously, these camps can be a source of unborn bands for military services. The English made the great mistake of losing a great many of their bands, and in a general way it can be said that with music and healthful theatrical entertainment the spirits of the men never flag. Bands have an enormous influence in reviving the drooping spirits of men, and it is at these camps that such an influence is most needed. There should be some systematic effort, however, to train bands here, and just as there are trainers for physical exercises (to be spoken of later) there should be trainers in music and theatricals. There should be always plenty of music; the drills, games, etc., should be accompanied by music; there should be a drum and fife corps for parade, a band for retreat, and an orchestra for evening entertainments and dancing. There should be some music, good music, and not always merely a more or less agreeable noise. In addition to the amusement offered by bands, systematic effort should be made to draw out the men to take part in the theatrical entertainments above referred to. This requires a considerable amount of tact on the part of the commanding officer and really should receive the constant attention of some one person, because sometimes the most talented entertainers will go clear through a camp without displaying an iota of native ability which they have to a very high degree if properly brought out. Some of the best comedians we have seen have been quite accidentally discovered at these places. For these theatrical entertainments and minstrelsy, to which the American soldier takes very kindly, costumes should be freely supplied by the same patriotic civil societies who furnish the instruments for the bands.

Nor should these societies neglect to provide club rooms for noncommissioned officers and for men, reading rooms, writing rooms, libraries, a good gymnasium where many sports can be taught and practiced—boxing, wrestling, fencing, etc.

A sporting goods exchange should be provided where golf clubs can be obtained, tennis rackets, bats, balls, and all the paraphernalia that indoor and outdoor sports require. Some of the more expensive things should be rented. Some things, like tennis balls, baseballs, etc., sold.

This is an enormously important feature of these camps, and here it is that these civil societies can be seen at their best. For instance, it is believed that in the exercises and the games which they are taught, regular physical trainers should be employed rather than Army sergeants, for the simple reason that when men are being drilled by an Army sergeant or any one to whom they are in a military sense beholden, the tension of military discipline at these games, after the manner of a drill, places the muscles in abnormal positions and

under tension instead of relaxing them and freeing them from strain, which should be the object in exercising men for their physical good. These trainers should be good mixers and must learn how to tell when a man is bored or tired, and before the period of physical tire comes the mental tire should be recognized, and if it can not be gotten rid of by personal address the man should be switched rapidly to some other form of game or exercise. These games and exercises should be held at fixed hours, and medical officers on duty at the camps should always be on hand among the groups to see that everything goes well. Regarding this participation of civil societies, it is believed that it is the manifest destiny of the Red Cross to take hold of this matter inasmuch as this is a medical unit and is being used to return the soldier fit to the lines. In other words, this is a good opportunity for the Red Cross to cooperate actively with the Medical Corps, not merely to furnish candy and cigarettes. For this purpose not more than two experienced and matter of fact middle-aged women of the Red Cross Society could preside in a hut in which indoor games, checkers, whist, billiards, etc., should be conducted; little tables for writing provided, etc.

In other words, the whole spirit should be to make a man as comfortable as he can be and amuse him; at the same time he is being kept in a military atmosphere. There should not be too many orders, but general good discipline should be exacted, especially as regards cleanliness of person and surroundings, the rendering of proper salutes and the punctual attendance upon all formations. Loafers should always be kept busy at something.

THE PROFESSIONAL CARE OF MEN

Men should be given one general examination when they come in, but they should not be examined too often—every five or six days is enough. Men who have disordered action of the heart should be gone over carefully, and if the surgeon is satisfied that there is nothing the matter with their hearts of an organic nature he should not repeat the examination again unless absolutely obliged to do so from symptoms. In other words, it is not wise to have attention drawn to organic diseases at these centers. In fact the whole atmosphere of treatment—medicine, disease, etc.—should be avoided. The spirit of the place should be: "Here is the place for men to get fit in, and you need it. It depends on yourself how soon you fit yourself for the duties of a man." As a matter of fact in most of these convalescent camps there were very few actually in bed. In one (which cared for 3,000 men) there was only one hut which was known as a sick bay and that was empty but for one man. A powerful influence is the grading of men into the weaklings, those able to do something, and those who are getting husky and can do about everything. A spirit of self-betterment is thus fostered by appeal to the pride of the man.

As a matter of fact, these convalescent camps should be toward the zone of the army. I believe it would be inadvisable to have them way back in the rear, especially near large towns, although such centers will have to be placed near important bases for men who come to us sick from the States or who sicken after they get here. It seems that there are at least five kinds of institutions that could be grouped under this general heading "Convalescent camps" and that these institutions could all be administered along certain broad basic principles identical for all.

(1) A convalescent camp for the sick convalescents from disease, not venereal or neurological. All base hospitals should have or be near one of these.

(2) A convalescent camp to which men of (1) can be sent after a few weeks for hardening in order to enable them to return to the front. This camp could also receive men from the divisions direct who need a rest and change to prevent their breakdown.

(3) A camp for the correction of vicious postures and results of war wounds requiring reeducation and prescribed exercises.

(4) A camp for the handling of war neuroses.

(5) A venereal labor camp.

Army Sanitary School No. 124.

ICTERUS IN THE ARMY

Translation of summary of a lecture by M. le Medecin-Major Tanon

We will omit the study of icterus due to retention of the bile or obstruction of the bile passages. They are not of special importance and have been rarely observed. Angiocholitis perhaps may be noted as occurring in the course of an infection. Catarrhal icterus is rare. Some authors confuse it with ieteric spirocheetosis. It is necessary, however, to preserve it among the list of diseases to which soldiers are subject. The experience of war has shown that one finds most frequently two varieties of icterus among soldiers: First, picric acid-icterus, and, second, the hemorrhagic spirochetal icterus.

I. PICRIC ACID ICTERUS

This is an icterus due to simulation. It appears from two to four hours after the ingestion of 2 to 5 eg. of picric acid. It is a clear yellow, without constitutional symptoms, fever, or slowing of the pulse.

Diagnosis.—Chemical analysis of the urine can give us the diagnosis. The amount is diminished; it has a brownish yellow color and it has no biliary pigment. One finds picric acid when there has been a large dose ingested, or picric-pieramic acid—the chemical substance most frequently found, which gives with the hydrosulphide of ammonia a red color. But this examination is a delicate one. Numerous methods of technic have been proposed, none of which has an absolute value over others. Besides, men who have breathed gases liberated by the explosives whose base is a picric acid once have seemed to eliminate pieramic acid afterward. One finds it in the serum and in the secretions, which are yellow. In order to strengthen the diagnosis, it is necessary to question the patient closely and examine his haversack and his money pouch, where one may frequently find a little of the acid laid by.

Prognosis.—Benign. Intoxication even after a dose of from 5 to 20 gm. produces only vomiting and diarrhea and never death. Experimental (Roger) picric acid poisoning causes convulsions in a rabbit in a dose of 14 eg. and death after the administration of 19 eg. In man a fatal dose ought to be very high, because in a case of attempt at suicide with 25 gm. death was not produced.

B. ictero-hemorrhagiae spirochetosis, formerly known as relapsing infectious icterus, benign hepatic type, Mathieu (1889). Demonstrated to be due to a spirochete by Inada and Ido in 1916.

Spirillum.—*Spirochæta hemorrhagica* studied by the Japanese and afterward by the English and French. It is long; the spirals are few and broad, and easy to stain. It is found rarely in blood but always in urine after the tenth day. It causes icterus in 3 to 10 days, with hemorrhages in the guinea pig. At the autopsy we find a generalized icterus, muscular and subperitoneal hemorrhages, and the spirillum in the liver, kidney, and suprarenal capsules. It has not been cultivated, but the reaction of fixation by Martin and Petit is positive with the serum of those attacked by the disease.

Symptoms: Type, medium; infectious relapsing icterus.

(a) Preicteric period; weakness; digestive disturbances and temperature of $38\frac{1}{2}^{\circ}$ C.; rapid pulse, scanty urine, and muscular pains.

(b) Icteric period; begins on the fourth day; definite icterus of an ocher color. Constantly the symptoms improve and the temperature falls. Hemorrhage sometimes takes place (in half the cases); note the skin and mucous membranes; sometimes these may be serious. The urine increases in quantity and when this takes place the spirilla are abundant. There are biliary pigments and the normal color of feces disappears.

(c) The second febrile period; with temperature, rapid pulse, myalgia and frequently albuminuria. This period is more endurable to the patient.

(d) Convalescence is marked by a pronounced anemia, with albuminuria.

Throughout the attack the liver is a little enlarged and a little painful. The spleen is scarcely increased in size. The serum contains an excess of urea, which is of itself a factor of gravity.

Clinical forms: Type of "malignant icterus," with deep icterus, although never greenish; nervous phenomena, hemorrhages, symptoms of acute insufficiency of the liver, disassociation of pulse and temperature and retention of urea in the blood, from 0.50 to 2 gm.

The benign form and the catarrhal icteric type; examination of the urine and inoculation of guinea pigs fixes the diagnosis.

The aberrant forms: Myalgic or meningal, with stiffening of muscles of the neck.

There is a form without icterus, and the disease in such case is suspected in the presence of an epidemic. Examination of the spinal fluid would give us an opportunity to verify the presence of the spirochete.

Renal forms: Such forms may be the nephritis of the trenches.

Diagnosis.—Clinically, by the appearance and the icterus in four to eight days from the commencement of the disease, and by the recurrent type of the fever.

Bacteriologically, from an examination of the urine and inoculation of a guinea pig.

Prognosis.—Bad in the malignant forms of icterus; 40 to 80 per cent of deaths in Japan. Good in the medium form, which lasts from two to three weeks. It is necessary to watch the albuminuria and the anemia.

Pathological anatomy.—The lesions are superimposed upon those which one finds in the guinea pig. There is generalized icterus, spirilla in the liver, in the suprarenal capsules, and in the kidneys; there are hemorrhages under the skin, in the muscles, in the lungs, and upon the surface of organs.

Serotherapy of Martin and Petit.—The serum is prepared by injecting a horse 10 times with infected liver. Eighty cubic centimeters are injected subcutaneously in the patient, or 40 intravenously. It has been injected into the spinal canal with success in the meningal forms. Unfortunately, it does not take effect except at the early state of the disease.

Other drugs.—Arsenical preparations tried out by the Japanese have not been effective. It is necessary to support the heart and the fever diuresis in order to avoid the accumulation of unconsumed products of metabolism in the blood by cold baths. Salicylate of soda, 3 gm. a day, as an intestinal antiseptic and the chloride of calcium are useful.

Prophylaxis.—This is important and is based upon what is known of the etiology.

Etiology.—This is known, but incompletely. The rat seems to be always the reservoir of the virus (Inada and Ido). This is confirmed by English and French physicians in the trench rats. At Lyon even 5 per cent of sewer rats have been found to be infected. The flea may be the vector. The affection is always contagious, and it is necessary to disinfect the urine, the feces, and the sputum. The urine can still be found to contain the spirochete up to the sixth week. Wilmaers and Renaux have demonstrated it up to the thirteenth week. Before the tenth the spirillum is rare in the urine.

Conclusion.—Should all cases of icterus in which the pathogenesis is not clearly demonstrated clinically and from the history be considered as due to ictero-hemorrhagic spirochaetes? The answer is, No. One can suspect such cases, but the spirilla are not found in every case of icterus, and inoculations of guinea pigs are frequently negative (Fourth and Fifth Armies). It seems likely that there are some foci among our forces; for example, in the region of the Somme and in Argonne.

The etiology, the clinical picture, and the epidemiology are still the object of study.

An effort will be made to add only such notes as are not explained in the very full summary which accompanies the abstract of the lecture.

If a man takes more than from 2 to 5 cg. of picric acid, vomiting is produced. These cases of simulation come on just before an offensive or a raid, as a rule. There is no fever, no bradycardia, no bile in the urine, and no white stool. The symptoms appear from two to five hours after taking the drug. As picric acid is used in the manufacture of explosives, cases have been brought in after an attack by the enemy with jaundice and picric acid in their urine who had not taken the drug internally but had breathed in the gases and products liberated by the explosion of shells. Catarrhal jaundice is a rare disease at the front. The test for picramic acid in the urine is a very delicate one and one must be careful in reporting a positive finding. The general one employed is the hydrosulphide of ammonium which is added to urine containing picramic acid and which gives a red color. Picramic acid is said to be a derivative of picric acid, and the form in which it usually appears in the urine.

Another test is to add to the urine a solution of the hydrochlorate of cocaine. Pierie acid causes a dark yellow urine, insufficient in quantity. As the tests are fallacious at times, and as even in ease of a positive a man may aver to have inhaled pierie acid from the burst of shells, it is necessary to reinforce such evidence by a careful history taking, a sort of psychological research in the case and a prompt examination of the soldier's effects, particularly his pocketbook, in which one will often find some of the drug. This latter method can be used when the man will not acknowledge having taken the drug. In order to make him confess, it is perhaps better to present the matter to him in this way: "I personally know that you have taken pierie acid with the idea of avoiding your duty, and with that knowledge in my possession you are in a most dangerous position. Whatever legal evidence may be lacking will be insignificant in the face of the exposure of your case to your officers and your comrades, no matter whether we get you by trial or not. If you will tell me frankly how you came to take this drug and in what doses, you will be forgiven and nothing more will be said of it. Otherwise, you will be discovered sooner or later, for I am not going to drop the matter, as it is my business to follow these case to their termination, and then your sentence will be a heavy one—perhaps death."

A speech like this will generally produce the goods, and it saves a lot of trouble, for thus one is enabled to administer the only prophylaxis possible, a moral one by means of a good talking to; and the battalion will very soon find out that they won't be able to fool the doctor. One should always remember that these moral diseases are very contagious, and discovery and proper treatment in the first ones determine the size of the epidemic.

SPIROCHETAL JAUNDICE

Spirochetosis is a sporadic and not an epidemic disease. The urine must be sedimented by centrifuge and a smear of the sediment stained by Leishman or Levaditi. The spirillum has evenly pointed ends, but to make the diagnosis positive 5 c. c. of the suspected blood should be injected into animals and they will develop the disease in from three to five days. On autopsy you see a high degree of infiltration in the kidneys and hemorrhages in the pleura. The spirillum of hemorrhagic jaundice has a tendency to have buttonhook ends, and is found in the urine after the tenth day from the beginning of the disease. It is rare to find it in the blood, and it has not been successfully cultivated. Be exceedingly careful in reporting spirochetal hemorrhagic jaundice when you depend on the technic of staining by Chinese ink, as this ink contains very frequently a spirillum very similar in appearance which will confuse the diagnosis.

Spirochetal jaundice first appeared in the French Army in 1916 and there were 200 cases, but many of them had no jaundice.

Symptoms.—These are extremely variable.

The icteric period of the disease may come on the second or third day. The color of the patient is never greenish nor as deep as that of obstructive jaundice, and at the fall of the temperature when the icterus begins the patient feels well. Nor is the jaundice like that of yellow fever or malaria because the color is ochre. The convalescence is very long and marked by asthenia, anemia, and trace of albuminuria. The following temperature chart roughly gives the temperature by days:

The malignant form is very rare. It has not been seen in France. Benign forms are very common. Catarrhal forms are also uncommon. If you do not find the spirillum, do not call the disease spirochetal jaundice.

As in yellow fever, there is a second febrile stage with rapid pulse and albuminuria. The fever at the outset being about 39.2, gradually falls to a little subnormal the morning of the fifth day in a typical case, but in a few hours rises again to 39. In the recurrence of the fever the jaundice persists and purpura and albuminuria may occur, but generally the patient feels better and does not suffer much in this second attack. In the grave form the jaundice is deep; there are symptoms of acute degeneration of the liver; there is urea in the blood and the entire type is marked by severe nervous symptoms. The aberrant forms are very varied. Besides those mentioned in the summary, M. Tanon mentioned a grippal form. These forms are the ones which spread the disease because the diagnosis is arrived at too late. That is what happened in Champagne, in which epidemic foci did not exist. In the renal

form the icterus comes on from four to eight days after onset. There is an aberrant form which has been likened to dengue, and another to rheumatism or myalgia. The meningeal form resembles cerebrospinal meningitis. The form without icterus is doubted by M. Tanon in the majority of cases, and the renal form is similar to trench nephritis. There are two foci of infection: In the Argonne and the Somme. He is sure that whatever foci may to-day exist they are not in the Second and Fifth Armies, and if there are any cases they are only sporadic, which is usually the form which the epidemic takes. It should always be remembered that in spirochetosis there is bile pigment in the urine.

The pathological anatomy.—The organs especially affected are the liver, kidneys, suprarenal capsules, lungs, the surfaces of organs, and the skin (purpura).

The diagnosis.—This is made by examination of the urine, by the symptoms, and by inoculation of animals.

Prognosis.—In epidemics here the mortality has been 1 to 2 per cent, but the convalescences are slow, and it is a costly disease to troops from inaction of the sick over long periods. It is 80 per cent in the malignant forms.

Prophylaxis.—The rat is probably the carrier and food soiled by them will convey the disease, as also will the sputum of infected persons. It should be remembered in this connection that the spirochete may remain from five to six weeks in the urine. He mentions the fact that the rat flea may carry the disease, in addition to the urine and feces of rats.

From the beginning of the war there have been 500 cases in the French Army and 2 per cent of deaths.

The treatment.—First, serologic. This is not a prophylactic and does not go after the icterus.

Second, medicinal. All medicines are mere palliatives. Horse serum and calcium chloride can be used for hemorrhages, and the drug is salicylate of soda given in doses of 3 gm. per day.

Army Sanitary School No. 127.

ROUTING AND HOSPITALIZATION OF EAR, NOSE, AND THROAT CASES

By Lieut. Col. James F. McKernon, M. C., N. A., senior consultant, ear, nose, and throat surgery

1. Simple acute ear and throat conditions will be held wherever possible at camp and field hospitals until recovery.

2. *Evacuation hospitals.*—(a) Injuries confined to ear, nose, and throat will be evacuated directly to Base Hospital No. 115. Cases of multiple injuries requiring special treatment will be evacuated to Base Hospital No. 115 whenever general condition of patients warrants. (b) Shell-shock cases, either deaf-mute, totally deaf, or markedly hard of hearing, to be evacuated directly to Base Hospital No. 115.

3. *Base hospitals.*—Will transfer following to Base Hospital No. 115:

(a) Cases requiring reconstructive treatment.

(b) Cases of multiple injuries requiring special ear, nose, and throat treatment whenever general condition of patient warrants.

(c) Patients with prolonged ear suppuration and the condition of whose hearing would permit their continued service overseas.

(d) Patients showing disturbances of stasis labyrinth.

(e) All shell-shock cases, either deaf-mute, totally deaf, or markedly hard of hearing.

(f) Patients with chronic accessory sinus infections.

(g) Patients requiring laryngoscopy, bronchoscopy or oesophagoscopy.

CONDENSED SCHEDULE OF TREATMENT EAR, NOSE, AND THROAT CASES

Wounds of ear, nose, and throat to be treated according to the principles of general surgical procedure—removal of missiles and other foreign material, debridement with primary suture or drainage as indicated.

Tubal catarrh: Inflation and vaporization of tube and middle ear, local applications, 2 per cent silver nitrate to pharyngeal end of tube.

Acute otitis: Free incision of drum membrane in posterior, inferior quadrant, extending into Shrapnell's membrane. Follow by hot saline or boric acid irrigation, 2 quarts q. 2 h.

Furunculosis: Free incision followed by hot saline dressings. Recurring and multiple, vaccines, preferably autogenous. Stock vaccines—mixed staphylococcus for furunculosis to be obtained from central laboratory.

Mastoiditis: Nonoperative—treatment of acute otitis as above, observation, period limited to few days. Operative—removal of diseased bone, establish free drainage between mastoid cavity and middle ear, close superior angle of wound with sutures and treat as open wound by packing.

Brain abscess: Suspected cases to be reported immediately to senior consultant.

Sinus thrombosis: Substantiate by blood cultures where possible; uncover sinus from above knee well downward toward bulb. If parietal or organized clot, evacuate, pack and treat as open wound. If clot broken down and pus present, treat as above, and in addition ligate and resect internal jugular vein from clavicle to point above facial vein. Close neck wound and drain from lower angle.

Nose: In all mucous membrane irritations due to gas, local application of lime-water or bicarbonate of soda. In larynx and trachea, inhalations of camphor and menthol (aa Gr. xxx), oil of eucalyptus (5iv), compound tincture of benzoin, q. s. ad ounces ii. Intralaryngeal injections guaiacol, 2 per cent camphor and menthol 4 per cent in liquid albolene or boiled linseed oil. Where deviation of septum is sufficient to obstruct respiration, a submucous resection should be done. Otherwise let alone. Accessory sinuses, acute involvement, shrinking tissue, inhalations and warm saline irrigations, suction followed by sprays. Remove middle turbinate if necessary to establish drainage. With pus discharging, open and drain.

Pharynx: Acute follicular tonsillitis—frequent hot saline gargles, medication, sodium salicylate, etc. Tonsils to be removed only when markedly hypertrophic or diseased, and then by method producing a minimum of trauma. No tonsils to be removed during acute inflammatory process.

Adenoids: When present and causing obstruction to be removed.

Abscess: Peri-tonsillar and retro-pharyngeal—free incision and drainage.

Larynx: In acute conditions, warm inhalations, sprays, cold compresses, external. In gas cases, as noted under "Nose."

Laryngeal edema: External applications of ice when obtainable. Spray of adrenalin, or lemon juice, following in half an hour by deep pharyngeal irrigations of hot saline solution, 2 or 3 quarts at each sitting.

Trachea; pharynx: Foreign bodies, laryngoscopy, bronchoscopy, tracheotomy, when indicated.

Army Sanitary School No. 128.

VISIT TO BRITISH CONVALESCENT CAMPS IN THE VICINITY OF X——, BY GROUP
UNDER COL. BAILEY K. ASHFORD, THIRD SESSION, FIELD SERVICE SCHOOL FOR
MEDICAL OFFICERS.

CONVALESCENT CAMP NO. 10

Under the command of Lieut. Col. C. D. Myles, R. A. M. C.

This camp is one of the best in the British Army. It has accommodations for from 3,000 to 5,000 patients. It is out in the open country on a high plateau, surrounded on three sides by a deep ravine, well wooded, through which runs a pleasant stream of water. It is exposed to wind, but is well furnished with hard roads and adorned with pretty gardens. There was no shade, however, in the camp itself. Every bit of it had been built by the convalescents themselves.

It is under the command of Lieut. Col. C. D. Myles, R. A. M. C., and is about 5 miles south of a city. Colonel Myles says that he tries to make requisition for as little as possible, and every particle of work, construction as well as upkeep, is done by means of convalescents, with the exception of a little assistance now and then from skilled tradesmen sent out for the purpose; the ablution benches, cookhouses, and latrines, however, were built

by contract. He made the remark that the cookhouse is in the wrong place, because they had put it on level ground. He states that it should be an axiom in a convalescent camp to use the level ground for recreation; everything in the shape of a house should go on rough ground. The cookhouse is the only house that was built by tradesmen. He started with 70 patients and they put up 67 huts in 7 weeks, each hut being 20 by 60 feet. In one instance, 3 huts were put up in 12 hours. At present there are 2,500 men, divided into 2 divisions of 1,250 men each. The present staff consists of one first-class officer and four second-class officers. He states that you need a tremendous amount of space in a convalescent camp. As he expressed it: "You have 2,000 men to keep moving, and they need room to move in. Otherwise you have to send them out on route marches, and a little of that sort of thing is all right, but too much is not only no good but a positive detriment, as there are not enough noncommissioned officers to enforce the discipline on long marches. When you get two or three thousand men on a hike it is a pretty big affair. They all go out for about an hour and a half every day, and every Sunday we turn them all out." This camp was begun on the 8th of April, 1917.

Amusements.—When we reached this place two of their bands were playing during exercises which were going on. There were four bands and an orchestra—in all 130 instruments. We went into the theater, which was well painted and decorated. The curtain was especially lively, inasmuch as it was decorated with a choice variety of witty advertisements. The Red Cross hut had a good billiard table, separate small tables for writing letters, library, music by an orchestra, and the lady in charge stated that they have a fancy dress ball on Tuesday nights and that they had two dances a week. I asked Colonel Myles whom they danced with, and he said they danced with each other.

Games.—Tennis, cricket, football, baseball, and golf were favorites, and also boxing. Every kind of athletic apparatus was furnished. Most of these goods could be drawn on memorandum receipt. Some of the things could be bought—baseballs, tennis balls, golf balls, etc. The Canadians are fond of baseball; the Scotchmen like golf and cricket. One hut is used for a post office. They have a very good canteen, which was well furnished, and there were all kinds of pleasing lithographs on the wall.

The latrines were of the usual bucket type, with incinerators. These incinerators were kept up by camp refuse, and altogether provided 120 gallons of hot water a day, which is given the men for washing up in the morning at the ablution benches.

The gardens were run by P. B. men as a rule, and effort is made to make the place as ornate and neat and attractive as possible.

As a sidelight on the manner in which the camp was embellished, he showed us a Japanese garden of some oriental queen, with a fanciful name given it by the soldiers. It seems that an English officer had a faithful Japanese body servant, over 65 years of age, who broke down from arduous service at the front and was sent here with the remark that he had to be kept and provided for as long as there was an English Army. Colonel Myles stated that he was a "Canadian Jap" who had been 10 years in America and couldn't speak a word of English, and that at first he only moped around. He used to go off by himself and be gone all the afternoon. "The first thing I knew I was always running across some of his whirligigs like those things over here"—we were at that time inspecting the garden—"He said he wanted to work out a Japanese garden, and this is the result. Everything is his own idea and has been done by himself. That is his idea of a lighthouse on the top of a mountain. He never saw a lighthouse, but that's where he thinks it belongs, and he has made a prayer tower of it. He is a quiet and peaceable man and but for an incident with the carpenter, after which he spent some days in hospital, his record is good, and you see he has certainly beautified the place. The only thing is we can't let him near the carpenter shop. It cost him an argument the first time he went. He don't know a chisel from a saw and uses both for the same purpose." What we had seen was simply a little Japanese garden into which on uneven ground this Japanese had all by himself led water from a stream which he had dammed up, and utilized the power thus obtained to turn windmills and manikins which he had fashioned himself out of wood.

We were interested to find out that the only game at the place for which a charge is made is golf, and that was 2 pence an afternoon.

It was interesting to watch the games. A circle was formed consisting of some 50 men, and some pretty lively games were started. One of the favorite amusements was to imitate the trainer in certain exercises in which he gave the command "Do this" or "Do that." All orders worded "Do this" were to be obeyed and all those worded "Do that" were not to be obeyed. The result was that the men were kept not only thoroughly alive physically but mentally as to what was going on and their alertness was thus brought back, inasmuch as there is a punishment for doing something from a false command, a run of 100 or 200 yards or something equivalent thereto. These games take place in the morning and the hikes in the afternoon.

We heard some excellent music by a Scottish bagpipe band, and these bands all had very elegant uniforms.

One of the most interesting little details in neatness and ornateness of an attractive sort was noted at the entrances to the barracks of the men. There were usually two steps leading to the door, and at the base was a neat little space inlaid with baking-powder cans turned upside down, giving a model doormat, as it were, for getting rid of mud before entering the house.

The sergeants were messes separately from the men. The kitchens and dining rooms were models, both for men and noncommissioned officers. It was here that we saw a particularly good plan for salvaging solder and fat. The men sleep on a bed of straw and are furnished three blankets. As we walked through, all these beds were neatly rolled up and not a wisp of straw was visible. The floors were polished and the place was immaculate. There was only 1 hut out of 67 given over to hospital and there were only 2 or 3 patients in it. There is a dental surgeon on duty here who is said to be kept pretty busy. Carpenter shops, tailor shops, ironworking shops, etc., were noted for industrial education.

Colonel Myles said the men spent an average of three weeks at this camp and are not allowed to stay over six. This entire depot was a model of excellence in every particular. Everything was in its proper place and everything was clean and orderly. There was no waste of any kind of water, food, or material.

On leaving I asked the commanding officer if he didn't have a hard time getting all the buildings and stuff together to make this village of 3,000 men. He looked at me very expressively and said: "I have lost all of my friends I think that I ever had in the Army; I am afraid to go out because every stick on the place represents an argument."

CONVALESCENT DEPOT NO. 6, AT ETAPLES

This officer describes D. A. H. as treated at Etaples. The diagnosis of D. A. H. is recognized by the regimental medical officer, generally on the following symptoms: Dyspnea, pain over the heart, rapidity of pulse, etc. On these symptoms, generally, without any particular analysis of signs for lack of time in which to make a fine diagnosis, he is sent to the C. C. S., where his diagnosis may change to V. D. H. which causes him to be conveyed to the base. Here the correct diagnosis is arrived at by methods familiar to scientific medicine. It is not necessary to take cardiographs in every case because (1) in simple irregularity of the heart nothing shows and (2) it is a costly thing to always take a cardiogram. It should be made, however, if the patient's age is over 40; also if there is any serious irregularity or any organic signs.

The disposal of heart cases.—(1) Those in which there is really no disease—nothing radically wrong with them. Such are sent back to the line.

(2) The rest, divided into: (a) Those fit for garrison duty; (b) those fit for labor duties in the lines of communication or at the base; (c) those fit for clerical duties or as cooks.

(3) Cases which have to be sent home.

If now, at the general hospital, we clear up a focus of infection and, after treating everything that we can treat, we still find that the man is not even fit for garrison duty on account of D. A. H., that man should go to the convalescent camp. It is necessary that a man should go through a convalescent camp before going to a training camp; there is too wide a difference, too big a gap, between the sick bed and the training camp to be bridged in any other way. The D. A. H. cases should spend six weeks at a convalescent camp; two weeks on the first exercises; two weeks on the first and second exercises; and two weeks on the first, second, and third exercises.

The following classification, G. R. O. 2959 of the British Army, is rehearsed as follows:
Classification of personnel by categories:

A. Fit for general service.

B. Not fit for general service, but liable to reclassification as A.

B (1). Fit for garrison units, division employment companies. Area employment (G. Gd) companies, labor companies, employed at the front; N. C. O.'s as permanent staff for reinforcement camps and convalescent depots; men for employment in lieu of R. A. M. C.; nursing or general duty orderlies and stretcher bearers in the lines of communication.

B (2). Fit for labor corps units employed on L. of C. or other duties of an analogous nature.

B (3). Fit for sedentary work as clerks, storemen, batmen, cooks, orderlies, other than R. A. M. C., sanitary duties, or, if skilled tradesmen, at their trades.

MB. Officers and other ranks sent from hospitals and convalescent depots to medical board base ports for classification in A, B, or E.

E. Unfit for service in France or at home. To be sent home, discharged as unfit for further service.

I visited the gymnasium and watched the sergeant-major directing the games, etc. The men taking exercises were all smiling, enjoying the work, and had plenty of music. They have old country-style dances under the direction of a woman and two assistants for 30 minutes. All the class did it and thoroughly enjoyed it. From what I saw, no true cardiac could have stood it. One hour in the afternoon is devoted to hikes with music if possible.

They have five classes:

A, the first week—for light exercises;

B, the second week—heavier exercises;

C, the third week—heavier still;

D, the fourth week—heavier still;

E, the fifth week—very heavy exercises. Course for trained men.

At the end of each course the medical officer inspects the cases.

Disposal of D. A. H.

First 900 cases:	Percentage
Total placed on courses.....	52.3
Not considered suitable for courses.....	47.7
Disposal of those not considered suitable:	
1. To their unit.....	1.1
2. Ordinary prolonged convalescence.....	10.9
3. To hospital.....	5.0
4. Recommended base work.....	29.5
5. Recommended dental treatment.....	1.2

CONVALESCENT DEPOT NO. 1

Convalescent Depot No. 1 is under the command of Lieut. Col. J. E. Campbell, by whom we were taken through on the 18th of March, and afterwards entertained by Lieut. Col. W. E. Hume in a lecture on disordered action of the heart (D. A. H.).

This camp was beautifully situated on the top of a hill near a statue of Napoleon. This particular hospital receives heart cases. The average stay here is 29 days. In the last six months 5,100 cases have passed through and been returned to the front. In the old days

these men used to hang around base hospitals from eight to nine months. This depot is a most comfortable barrack camp of 54 Nissen huts, with two large courts, leveled off and hard bedded with broken stone, in which many groups of men are seen doing exercises or playing games to the music of bands. The men all looked happy and interested and there were no slackers. All bands are composed of convalescents or P. B. men. It was explained to us that the men were divided into three classes for exercises; the third class, in which the games are light, sometimes little more than looking on while the instructor goes through the movements. These instructors are civilians and are regular trainers in physical exercises. If the men are observed to be bored during the course of these exercises, they are rapidly changed to games. In this class exercises are prescribed from 9 to 9.20 and from 11 to 11.20 a. m. When they get stronger they are taken for a light route march of an hour or an hour and a half in the afternoon.

In the second class the games are more energetic and the marches longer.

In the first class the games are strenuous—football, baseball, etc., and the marches approximate military conditions.

In commenting on the class of cases admitted to the hospital, the commanding officer states that there all men are examined on admission and graded into one of three classes without regard to their ability to do exercises. First, the nervous cases; second, the cases of general debility; and third, those heart cases of which we have spoken. There are 10 companies of 250 men each when the hospital is full, and each company has a sergeant major in command of it. It is organized on regimental lines. The commanding officer states that tobacco is not so bad in upsetting men, but that alcoholics are a pretty difficult lot to get fit. He also states that the dentist is kept busy pretty much of the time. It is recognized among the English that much chronic ill health is due to dental disease.

We were told that there are two types of convalescent depots in the British Army. One that receives hospital cases direct, of which this is a type, and another, which this one feeds, for country and rough work, and has about 5,000 men. Exercises here are more lively. In his hospital the men rise at 6 a. m. He states that although there is a garden he doesn't believe very much in putting men there if they are going back to the front because "they are liable to get to thinking how terrible a thing war is." On the other hand, the work on roads and walks and flower gardens, the landscape gardening, as well as the regular upkeep of the hospital falls on the convalescent patients.

We saw a fife and drum corps, band, and orchestra. The band was playing in a Red Cross recreation room, where there was a "sister" in charge, some 45 years of age, a very bright, sensible woman. She organized games and concerts and had a fine, well-furnished hut, with stained paneling and rafters, billiard table, reading room, with small tables and individual lights for writing letters, library, etc. She said that they have concerts on Thursday nights at which the program is furnished by the men, by whom, indeed, practically all their amusements are.

The hospital has beds for 2,600 patients and is 10 miles in the country, on the top of a sandy hill overlooking the channel. There are 120 acres for all kinds of games, golf, tennis, cricket, etc. All men entering the camp are questioned as to their particular fitness for work as artisans, and as a matter of fact there are carpenter shops, tin shops, barber shops, cobbler shops, leather shops, electrical shops, paint shops, etc., to accommodate all workers at the common trades. The Horsfall incinerators were used at this camp. They were allowed one bag of coal a day, but as a matter of fact they saved all their fuel allowance after starting the fire with coke, as camp refuse is used to keep them going. Coke cinders and used tea leaves are considered splendid fuel as they give a hot fire. In this camp the urine from the buckets in the latrines is drained off into a septic tank. Near the latrine is an ablution room with hot water for shaving which comes from the pipes which surround the fire box of the incinerator. This camp has been bombed, and they are engaged in making a dugout for patients with a system of trenches.

The disinfectant used here was the Foden-Thresh.

The bathhouse had individual showers and 12-inch cement basins used as tubs under same for reclining baths; steam rooms for Turkish baths, etc. Some of these bathrooms were separated by curtains and everything was neat and clean. The material of which the

buildings were constructed was a composite in which asbestos and cement took prominent parts. The men are bathed three times a week in a body; that is, they make a parade of it. Both hot and cold water is furnished at all times and many comforts are provided, such as duck-board seats for dressing, bathing, and foot rests, etc. Twenty men can bathe in this wooden hut at once. The pipes are all wrapped to prevent freezing and the water is heated by the Charles Blanc heater, familiar to us all. All men who get a steam bath get a temperate douche afterwards, and there is an alarm bell inside for men who might be overcome from the heat, which rarely happens. In spite of the fact that this hospital is filled with heart cases, it is not considered dangerous to send them in there to bathe. In connection with all this, there is a good barber shop where the hair is cut free, but two pence are charged for a shampoo and 1 penny for a shave.

They have a laundry in connection with this bath, but they washed only towels, shirts, and underclothing there. The men have no sheets or pillowcases, but sleep between blankets. This laundry handles 1,200 articles a day and the personnel are convalescents. There is a hand-mangle laundry and a drying room heated by a stove; this drying room is ventilated by a removable intake of air through a flue in which the outside air is passed through the fire grate before diffusing into the room. Next to this was a place for examining the clothing for nits of lice. If any are found the seams are ironed. The anterooms for dressing and undressing in this bath were very commodious, and near by was a gymnasium where, among other things, boxing was evidently well thought of. In fact they were teaching some Portuguese soldiers to box when we reached there, and they put up a very nice little contest. They had some pretty lively intercompany boxing.

The kitchen.—The kitchen was attractively arranged and had many simple, neat devices. Very little food is thrown away; there are only two refuse cans for the entire day's waste for 3,000 men, and 10,000 pounds were saved on food last year from ration allowance. Besides this, 1 ton of fat a month is saved for munitions. The kitchen is run by B class men, and they have 13 cooks in this hospital. They say they never turn out of the Army any man who is able to do light work, and many are kept here, either in the shops or kitchens or band. A great specialty is made of the conservancy of fats, the first grade being used as drippings for cooking and the second class recovered from slops and garbage for munitions. It is sent back in 300-pound casks to be utilized for the latter purpose, after being previously rendered in Soyer stoves. The stoves were labeled "Roast," "Stews," "Fries," "Pastry," etc. There was one for rissoles, puddings, and porridge, and another for tea. Each stove was presided over by its own cook and was neat and clean. The stoves were English. The cooks are B men and the assistants are B (1) and B (2). At the time we were there there were 7 companies of 250 men each. Each company entered the dining hall five minutes after the other to facilitate serving and the nearest table is filled first, so that those coming in last are near the door. No smoking is allowed during meals. They are served from a counter and eating utensils are furnished at entrance. Any man can have as many helpings as he pleases. As a result there was a saving of 10,000 pounds a year at this hospital on food alone.

In connection with this kitchen there was also a melting pot for rendering solder from tin cans, which made a handsome saving on lead, amounting to a hundred pounds a week. The tins are rolled out and at the tin shop many useful articles are made from them.

There was a fine clubroom for noncommissioned officers, with its own private bar, billiard room, writing rooms, etc. A feature of this hospital also was the clothing and equipment department. When a man arrives from the hospital he comes with a statement as to his equipment and this shows what he needs, which is furnished from the pack store. The sergeants have a separate mess, in addition to a separate canteen.

There was only one hut for medicine and surgery together, and that had only one patient in it. We saw a cobbler shop, carpenter shop, and electrical shop, in addition to those mentioned heretofore.

NOTES ON COLONEL HUME'S LECTURE

At this hospital, to which an endeavor is made to send all the D. A. H. cases, there is a medical board base department (M. B. B. D.). This is in addition to the hospital and the distributing center (D. C.).

Men who come recently from civil practice are apt to put too many cases down as vascular disease of the heart (V. D. H.), where, as a matter of fact, such cases are apt to be doubtful. As an illustration of the mistakes in diagnosis which are made in regard to heart conditions, of 55 cases sent in as V. D. H. 22 were really D. A. H. and 1 N. Y. D. H. (not yet diagnosed, nervous). A man with V. D. H. ought not to be kept in the Army at all but sent to England. Such cases are often a sequela of rheumatism, but D. A. H. comes from all kinds of disease and is only a symptom; even any fever can cause it. The rate of the heart is increased always in D. A. H. at least 50 per cent. Generally it is between 90 and 100, but while the patient is sleeping it is apt to be very slow. For instance, a man may have a pulse of 140 while he is awake which may drop to 70 while he is sleeping, and this in itself is a distinctive point between it and Graves's disease in which you never see the pulse drop in this dramatic way. If you find a murmur and you can not prove that the heart is enlarged and there is no accentuation of the second sound, and no history of rheumatic fever, and no deviation of the apex of the heart to the left, you can throw out that murmur as functional. But remember that the outline of the heart by percussion is fallacious and not to be depended upon; radiologic evidence is much better. It is very easy to get a functional murmur in exhausted states. The systolic blood pressure in D. A. H. is apt to run high—130 to 135; the diastolic pressure from 100 to 110, but the peripheral pulses are apt to be poor. When there is pyrexia due to trench fever there is apt to be a leucocytosis.

About half of these cases had no symptoms before they came into the Army and they are often people who worked at light jobs and had led sedentary lives before they came into active service. These two classes of cases, V. D. H. and D. A. H., used to be distributed throughout the general and base hospitals with their diagnosis stuck persistently to them. They were known as heart cases, and it was no secret to the patients themselves. Some of these cases of D. A. H. thought to be organic diseases were partly, if not entirely, neuroses, and in this manner they became fixed ideas.* As before stated, their average stay in the hospital was eight to nine months. The difficulty was that no one had the courage to say that the man had no disease of the heart at all. What ought to have been done was that when the man came in from the C. C. S. with diagnosis of D. A. H. or V. D. H. he should have been sent direct to this sort of a convalescent camp. The custom here is to have a careful history taken and the previous health and habits looked into, and after the history is taken a physical examination is made. That is to say, an attempt is made to definitely fix at this examination whether the man is or is not D. A. H. or V. D. H., and according to this examination men are either put to bed or sent to light duty or exercise. The men with pyrexia of unknown origin (P. U. O.) are put to bed, and when they are convalescent you can get them up and give them exercise, beginning in the morning with 20 minutes at 9 o'clock and 20 minutes at 11, and a light march of an hour or an hour and a half in the afternoon. Every fifth or sixth day there is a reexamination, but a man's heart is never examined more than once when you are satisfied there is nothing the matter with him. There is really no such clinical entity as D. A. H., and all cases of V. D. H. are discharged. The following shows the number and percentage of the diseases entering the hospital under the name of V. D. H. and D. A. H. after proper diagnosis.

Diseases	Number	Percentage
Other diseases.....	83	8.3
V. D. H.....	55	5.5
D. A. H.....	562	56.2

Distribution of a thousand cases definitely known as heart cases after examination

30 to 35 years.....	13.8	13.05			

In a thousand cases of D. A. H., 108 had suffered from rheumatic fever, or 10.8 per cent. Shortness of breath sometimes becomes hyperpnea and you may notice as many as 60 to 80 respirations, but this is a hysterical trick and not real breathlessness. Giddiness is common; so is palpitation. The fits and faintings are not hysterical and should be separated out from petit mal. Hyperesthesia is precordial.

In general 50 per cent of the cases complain of "heart trouble" before enlistment.

There are three great types of individuals who furnish the heart cases: (1) Young men who never played games or took exercises; (2) the trench fever cases; (3) the functional (hysterics and malingerers) which form part and parcel of shell shock. In this shell-shock group the bad nervous symptoms are apt to disappear in a whirl of tachycardia. True malingering is extremely rare.

Army Sanitary School No. 131.

INDICATIONS AND GENERAL TECHNIQUE OF AMPUTATIONS IN FRESH WAR WOUNDS

By Medecin-Major Mocquot

(Translation of summary)

WHEN, WHERE, AND HOW MUST ONE AMPUTATE?

1. *When must one amputate?*—Amputation may be indicated, primarily, before the appearance of the clinical signs of infection; secondarily, after their appearance.

a. In what cases is primary amputation indicated?

(1) When amputation is quite or almost accomplished by the trauma.

(2) In complete crushing where mortification of the distal part is unavoidable.

(3) In certain cases of grave injuries of bone and soft parts not necessarily productive of gangrene. In such cases the decision is based on—

(a) General factors: Shock. Certain patients in shock, especially after bleeding, must suffer amputation; perhaps some other forms of shock also. On the other hand, operation is fatal in other cases.

General condition of the wounded, their age, etc.

(b) Local conditions: Distinction between the upper and lower limb. In the upper limb conservative surgery is less dangerous, gangrene not so common, and an artificial limb far less efficient; therefore indication to amputate is less common.

The opposite is true of the lower limb whose essential function is solidity; amputation is more frequently indicated here. Existence of bilateral lesions is in favor of conservation. Prolonged application of a tourniquet indicates amputation. The same is true when the wound is very badly soiled.

(c) Extrinsic factors: One is obliged to amputate more frequently in periods of great activity, because having the limb necessitates much more care of the case, which is impossible at such a time.

b. When is secondary amputation indicated?

In ischemic gangrene.

In septic gangrene, massive gas gangrene.

In certain deep gas phlegmons that spread rapidly.

In certain comminuted fractures with grave sepsis and secondary hemorrhage.

In purulent arthritis when expert treatment is without effect.

Perhaps sometimes in tetanus to do away with the toxin producing focus.

2. *Where must one amputate?*—The seat of the amputation is determined first by the nature of the injuries and secondly by prosthetic considerations.

a. Nature of the injuries:

(a) Primary amputation must as a rule be performed at the seat of injury and be as conservative as possible.

(b) Ischemic gangrene calls for amputation in healthy tissues at the limit of the lesion.

(c) In septic gangrene amputate in healthy tissues as low as possible. There are two exceptions:

I. When above the zone of massive gangrene there is one of superficial emphysema or bronzed erysipelas, one can amputate in the latter zone, provided the stump be treated so as to check the process.

II. When section in altogether healthy tissues would entail a much graver operation (subtrochanteric amputation of the thigh, instead of an exarticulation of the hip).

(d) In amputations for grave infections (shattered bones or arthritis), early secondary amputations, it is often advisable to amputate above the lesion in healthy tissues.

In late secondary amputations, on the contrary, one can often perform an atypical amputation at the focus of injury; one must take into account the fixing of the future artificial limb.

b. Prosthetic considerations are secondary; however, for each segment of a limb, there is a minimum useful length that ought to be preserved if possible. One must also think of the position of the scar.

3. How must one amputate?—

a. Anesthesia must be light; chloride of ethyl seems to be the anesthetic of choice.

b. Preliminary hemostasis: By elastic compression; by the digital compression of the main artery; by preliminary ligature of the main artery.

c. Mode of amputation.

(a) Atypical amputation:

I. Preliminary amputations—the necessary excision of the soft parts indicates the point where the bone must be cut.

II. Secondary amputations in a focus of suppuration; these are mainly late secondary amputations; cut straight through the seat of fracture or the joint, preserving flaps when possible. These secondary amputations often necessitate late corrective operations.

(b) Typical amputations in healthy tissues (gangrene, grave infection) less frequently primary amputations when the wound is very badly soiled.

I. In the first group of cases amputate by the circular method (preferably with a second section of the muscular cone) without suturing. Amputation by the method of flat section is not a method of choice but of necessity in cases where, the section is made in contaminated tissues (zone of extension in gas gangrene). It would be necessary otherwise to perform a graver operation (hip) or where there is a great interest to preserve as much as possible in order to be able to fit an artificial limb.

II. In the rare cases where one performs primary typical amputations, the circular method (most frequently) or the flap, or elliptical, method will be used according to the seat of amputation and the conditions necessary for fitting the artificial limb; primary suture may be used.

In all cases after treatment (continuous extension and dressings) is of great importance.

When there is much destruction of soft parts, especially those involving important nerves and vessels, amputation is necessary. Shock is by many considered a contraindication to amputation, but one should distinguish clearly between shock and hemorrhage. When shock is due to sepsis, amputate, as well as for uncontrollable hemorrhage. If the man is in true shock at the time of the operation this will kill the patient.

Be conservative in amputating. Amputations of the lower extremity are much more dangerous than those of the upper. It is hard to make a rule, but usually when from 12 to 15 cm. of a femur have been blown away it is best to amputate. The mortality is as high as 30 per cent in amputations of the thigh. Amputate when there is massive gangrene, but in local gangrene it is better to wait. Secondary hemorrhage is an indication for amputation, but it is never proper to amputate for tetanus.

WHERE TO AMPUTATE

One can amputate at the point of the lesion, but if the lesion is very high up in the thigh rather than do an articulation at the hip it is permissible to amputate through the exten-

sion of bronzed erysipelas if you treat the superficial condition. In general, however, it is better to operate in healthy tissue. Always amputate as low as possible when you get near the shoulder or hip joint. In amputations of the thigh immobilize your limb by extension with a weight of from 3 to 6 pounds. This has a tendency to take the pressure of the stitches off the skin as the pull is taken up on the skin above the amputation, and it also serves to keep the member quiet; there is always some amount of jerking of muscles after an amputation. In thigh amputations there is a tendency to reversion to the circular method and the wound is left open. Do not remove 1 c. c. of the periosteum to prevent the formation of osteophytes.

Secondary amputations are less often done in ischemic gangrene and in septic cases. We should amputate any grave septic comminuted fractures or purulent arthritis, especially the knee. Keep the calcaneum and the plantar surface of the feet wherever possible and always at least the femur and the hand. Never use chloroform as ethyl chloride is preferred. In hemorrhage, he saw 61 cases of injury to the femoral artery; 27 had to be amputated and 5 died. It is difficult to make rules for amputation because it depends on the art of the operator.

HOW TO AMPUTATE

As a matter of fact, amputation is generally done in shock, and for this reason these amputations are grave; 7 of 27 in his experience died. Never use lumbar anesthesia. He tried it and had to give it up. Under no conditions use chloroform. It is best to ligate the main vessels before amputating, but if not use a tourniquet. Primary amputations are really not amputations at all, but a shaping up of a limb; only the devitalized tissue should be removed.

Sepsis and gangrene make a serious prognosis. While the best method, as before stated, is the circular, they suture afterward and this diminishes the chance of infection. Flaps may be used, but they almost always are atypical. The surgeon who has only a few methods is not a real surgeon.

Army Sanitary School No. 133.

THE BACTERIOLOGY OF WAR WOUNDS

By Maj. W. J. Elser, M. R. C.

(Lecture to students of the fourth session, Army Sanitary School, at the central laboratory

The subject of wound bacteriology appears at first glance to cover a vast field but, fortunately for us, the recent advances made in the treatment of war wounds by the surgeons of the allied armies has greatly restricted this field. Moreover, the French and British bacteriologists have demonstrated that of the large number and variety of microorganisms which may gain access to a wound, only relatively few deserve serious consideration.

All war wounds are more or less contaminated by microorganisms derived in part from the skin and its appendages, in part from the soil and wearing apparel, and in certain instances from human feces. Experience has shown that the bacterial flora of war wounds varies in different sections of the battle area. Certain microorganisms occurring with great regularity in wounds acquired in certain regions are relatively rare in wounds acquired in other sections of the front. Conclusions drawn therefore from a study of wounds encountered in one sector must be applied with caution to wounds acquired in other areas, a fact which some investigators have apparently lost sight of. An exception to this rule is the tetanus bacillus. Owing to the rich, fertilized state of the soil in France, this organism is widely distributed, a fact which is not only supported by the results of animal experiments but by the very large number of cases of tetanus developing among the troops during the early part of the war, before adequate means for the prevention of this disease had been instituted.

Now while a very large variety of microorganisms may and do gain access to wounds only a certain number are capable of adapting themselves to the conditions prevailing, and this number may be still further reduced by prompt surgical interference. It is well known that many of the organisms found in nature are unable to thrive at body temperature or at temperatures approaching that of the body. These may therefore be disregarded. They

not only fail to develop within the wound, but soon succumb to the protective forces of the body. Others, and this includes many bacteria found in the soil, are incapable of thriving on the complex substances which alone are available as a source of food supply within the wound. These also may be disregarded, although the possibility must be borne in mind that associated microorganisms may prepare the ground, and thus permit of their development. Still other bacteria are incapable of developing in healthy living structures though they thrive well on dead or partially devitalized tissue. The fate of these organisms therefore is determined in part by the presence or absence of such tissue within the wound, and the result to the patient is determined by the disease-producing powers of the particular microorganisms concerned.

Finally, a relatively small number of microorganisms find suitable conditions for development within living tissue. The fate of these is determined in part by the number and the virulence of the organisms which gain access to the wound and in part by the number and the virulence of the local and general resistance exhibited by the wounded individual. Quite a number of these latter organisms are, however, of low virulence or wholly devoid of pathogenic powers and therefore of little practical importance.

While a review of these various single possibilities simplifies a comprehension of the problem which confronts us, it fails to consider the important part played by the interaction of two or several bacterial species; one species may favor the interests of another or they may work against each other, thus favoring the host. When we consider these several possibilities and the various reactions on the part of the infected host, one begins to realize the complexity of the processes going on in an infected wound.

Now, while it is true that all war wounds are contaminated with bacteria, a certain time must elapse before these organisms are able to establish themselves within the wound, before they are able to multiply and elaborate injurious agents in amounts sufficient to produce definite evidences of infection. For practical purposes, therefore, we may divide all wounds into two groups—fresh wounds, which, though contaminated, are not yet the seat of an infection and older wounds in which an infection has already been established. Wounds coming under observation less than six or eight hours after the incurrence of the injury as a rule belong to the former group, while wounds coming under observation at a later period are frequently the seat of an infection. It must be emphasized, however, that the periods here given are more or less arbitrary subdivisions. The time required for an infection to become fully established depends upon a great variety of factors and varies more or less with each individual case. In rare instances, a serious and virulent infection may be fully established within six or eight hours; in others, no definite evidence of infection may be apparent within 15 hours or even longer. As already indicated, this classification is made merely to meet practical ends. A microscopic examination of discharges from a fresh wound as defined above reveals very little information of practical importance and is therefore frequently omitted. The film made from such wounds shows a mixture of blood and serum intermingled, perhaps, with bits of muscle, connective tissue, and foreign material, but shows few leucocytes and, as a rule, no or very few bacteria. Cultures taken from such wounds yield a variety of microorganisms, some of the more important of which will be considered later. After the initial period, varying from 6 to 15 hours, the discharges begin to assume the characters indicative of infection. The polynuclear leucocytes become progressively more numerous, and varying numbers of bacteria begin to make their appearance. During the earlier periods bacillary forms predominate; later the cocci become more prominent. A culture taken during an early stage usually yields a large number of colonies and a varying number of different species. As the process of infection proceeds, some of the purely saprophytic microorganisms found in the early stages are eliminated and the more parasitic or pathogenic forms assume predominance. During the early periods the distribution of the bacteria within the wound is not uniform, and while this becomes partially equalized as the process of infection proceeds, it is important, particularly for the bacteriologist, to remember that in wounds showing evidences of healing different regions may again show a very different bacterial flora.

Of the aerobic forms commonly found in war wounds, the following may be mentioned:

Streptococci (usually the hemolytic types, the occurrence of nonhemolytic forms being relatively rare), staphylococci (both albus and aureus strains) enterococcus, *Bacillus pyocyaneus*, *Bacillus* of Friedlaender, *Bacillus cutis communis*.

Of these, by far the most important is the streptococcus. In fact, some French authorities claim that really serious infections develop only when this organism is present, either alone or associated with anaerobes. While this is in all probability an extreme view and is not endorsed by the majority of surgeons, all are agreed as to the paramount importance of the streptococcus in war-wound infections and practically all regard the presence of this organism in a wound as an absolute contraindication to its closure. Compared to the streptococcus, the remaining aerobes are of minor importance, although complications due to infections with staphylococci, *Bacillus pyocyaneus* and the bacillus of Friedlaender are observed. The presence in a wound of these latter organisms, however, is not regarded as an absolute contraindication to closure. The *Bacillus cutis communis*, on the other hand, is a harmless saprophyte occurring normally on the skin and usually appearing in wounds after the eighth or tenth day.

Of the anaerobes, a great many different species and varieties have been isolated from war wounds. Some of these have been definitely identified and represent organisms well known before the war. Others, occurring less frequently, still await identification.

According to Magrou, the *Bacillus aerogenes capsulatus* of Welch, referred to by the French as *perfringens*, is encountered either alone or associated with other anaerobic forms in about 75 per cent of the wounds. According to the same author, the *Bacillus sporogenes* is next in order of frequency, occurring in about 30 per cent of the cases, but almost invariably associated with the preceding or other anaerobic forms. The *Vibron septique* occurs in about 20 per cent of the wounds, but owing to its slow development and its limited growth in culture media, has apparently escaped the attention of many investigators. Apart from these, a large number of other anaerobes have been encountered by different observers, but the exact significance and importance of these organisms is still under discussion. As already stated, quite a number of these organisms still await identification.

While gas bacillus infections played an important part in the early periods of the war, the remarkable advances made recently in the surgical treatment of wounds, coupled with the improvement in the transportation facilities, permitting of early surgical treatment of the wounded, have greatly reduced the number of such occurrences.

Concerning the significance of anaerobes in wounds, the opinions of surgeons and bacteriologists vary. It appears to be a fact that the mere presence of these organisms in a wound does not lead to the development of gas gangrene. This may be attributed in part to wide differences in point of virulence exhibited by members of the same or different species and in part to the fact that dead or devitalized tissue, blood clots, etc., appear to be essential for the successful anaerobic development.

According to some authorities the clinical features exhibited by the case are of prime importance in estimating the significance of anaerobes in the wound. In the absence of all signs of gas bacillus infection, they attach little importance to the presence of these organisms, the inference being that when they fail to call forth the usual reaction on the part of the host they represent nonvirulent forms. However, such cases must be watched with the greatest care. Others attach more importance to the presence of anaerobes, the degree being determined in part by the location of the wound. Favorable sites for the development of gas bacillus infections being the fleshy parts of the buttocks, thighs, and calves of the legs. The degree of mutilation of the parts, the degree of shock and exsanguination, the degree of impairment of the local blood supply, the presence or absence of fractures, the character and number of associated organisms are all factors considered by them in estimating the significance of anaerobes when present in a given wound.

As I have already stated, some authorities (Tissier and his followers) advance the view that serious infections develop only when streptococci, either alone or associated with anaerobes, are present and that all wounds which do not contain streptococci can be closed with safety. Duval, on the other hand, has observed serious infections developing in partially closed wounds containing only anaerobes associated with nonpathogenic aerobic forms and fatal cases of gas gangrene in which the wound failed to reveal the presence of streptococci are recorded in the literature.

In view of the uncertainty still surrounding this subject, it seems wise to consider the presence of anaerobes as of serious import until our own personal experiences are sufficient to permit us to pass on this question.

Since the bacteriologist at the front works in conjunction with the operating surgeon and since the mode of procedure to be adopted in a given case rests upon the combined experiences of the operator and the bacteriologist, it will be necessary in what follows to enter the realm of surgery, to make clear the exact functions of the laboratory in connection with this particular phase of the work. Whoever undertakes this work must be thoroughly aware of the great responsibility which he assumes. Anything in the nature of a perfunctory examination of a war wound must be avoided. A superficial or careless bacteriological examination may lead to errors resulting in very serious consequences to the wounded man.

As I have already indicated, a fresh wound, according to the terminology adopted, is one that is contaminated but not yet definitely infected. It is in connection with such a wound that the question of the feasibility of a successful primary closure arises. Since a microscopic examination of the discharges in a fresh wound as a rule yields no information which might be of value in deciding this question, the decision rests entirely with the surgeon. Time permitting, cultures should be taken either in the course of the operative procedure or after the wound has been thoroughly cleansed and all foreign bodies and devitalized tissues have been removed. If, after the lapse of a given time, the cultures reveal streptococci the wound should be, according to some authorities, immediately reopened, while if the cultures show only anaerobes and no streptococci the practice of different surgeons varies, as already indicated. If large amounts of material are employed for cultural purposes, the bacteriologist is often in a position to demonstrate the presence of streptococci within six to eight hours and with a view of arriving at an early diagnosis, such culture should be examined early and at frequent intervals thereafter.

When the closure of a wound is deferred, the work of the bacteriologist becomes of the greatest importance because it is in this type of case that the laboratory findings must determine the treatment to be adopted. Every such wound should be made the subject of a thorough microscopic and cultural investigation. Since, in the beginning, the organisms may be very unequally distributed, such an examination should not be confined to a restricted portion of the wound. Particular attention should be paid to the regions which have harbored foreign bodies, and material from all pockets and recesses should be gathered for such examinations. If streptococci are found, the wound should not be closed until their complete removal by one means or another has been accomplished. At least two negative cultures for streptococci on successive days should be secured before the closure of such a wound can be recommended. In the absence of the streptococcus the question of closure depends in a large measure upon clinical experience and judgment. Special care should be exercised in wounds involving the fleshy parts of the buttocks, thighs, and calves when anaerobes are found. The presence or absence of fractures, the type of fractures, the condition of the local circulation, the general condition of the patient, all must be taken into consideration. As already stated, the closure of wounds over organisms other than the streptococcus and the anaerobes may lead at times to disagreeable and even serious consequences.

In wounds which enter the hospital in a serious state of infection, or in which such a condition develops subsequently, the Carrel-Dakin method of treatment is frequently practiced. Here it is the duty of the bacteriologist to determine by daily or less frequent microscopic examinations of the exudate the numerical evolution or involution of the bacterial flora. While such determinations furnish some idea of the progress of the case, it is not the number but the type of organism in the wound which is of prime importance. These numerical determinations which were relied upon originally to decide when a wound was ready for secondary closure are now supplemented by cultural investigations. When streptococci have once been demonstrated in a wound, two consecutive negative cultures must be secured before secondary closure of the wound can be practiced with safety. It may be well to repeat here that in making these cultivations material should be gathered from many different points in the wound since experiments have shown that streptococci may be absent from the greater part of the wound surface yet present in certain restricted

areas. This fact probably explains partial failure attending secondary closures made after cultural examinations for streptococci yielded negative results. Moreover the viability of these organisms seems to be reduced as healing supervenes in the wound. To secure reliable results at this stage of the process, media especially suited for the development of the streptococcus should be employed. The addition of so-called enriching fluid, horse serum or ascitic fluid, to the culture media is advisable for the same reason. A persistently high bacterial count suggests defective technique in applying the treatment or the presence of foreign material or dead bone within the wound, and under these circumstances secondary closure should not be attempted. In view of the relative innocuousness of many of the organisms found in older wounds, cultural investigations to establish the disappearance or absence of pathogenic forms should be undertaken early. Much valuable time may thus be saved to the patient.

In the preceding pages I have attempted to give a brief outline of the more important points bearing on the subject of wound bacteriology. I have said nothing about the peculiarities of the organisms recovered from war wounds nor about our methods of isolating and identifying these bacteria. These are matters which only concern the professional bacteriologist.

The treatment of gas-bacillus infections by means of specific antitoxin sera has also been omitted. Such sera have given favorable results in experimental infections in animals, but their value in the treatment of gas-bacillus infections in man remains to be established. The prophylactic value of these sera is now being tested by some of the allied forces.

Thus far, I have referred to the tetanus bacillus only in connection with other organisms which may gain access to war wounds. That this organism frequently gains access to wounds is amply borne out by the experience gained in the early part of the war, and we now proceed on the assumption that every war wound—and this includes even trivial wounds, such as abrasions occurring in connection with trench foot and frostbites—is very apt to be the seat of such infections. Fortunately, we are in possession of an efficient antiserum which when properly used protects the vast majority of individuals against serious consequences resulting from infections with this organism. This serum, as you know, accomplishes its results by neutralizing toxic products elaborated by the tetanus bacillus. It does not exert a destructive action on tetanus spores and it remains in the system for a relatively short period, from 10 to 14 days. If, therefore, the germination of the tetanus spore is delayed beyond this period, tetanus may develop although prophylactic injections of tetanus antitoxin have been administered. It is because of this possibility that at least two injections at intervals of one week should be given. The advisability of giving even a greater number of injections should be considered in all cases of very severe injury followed by prolonged suppuration and attended by much necrosis of tissue. Experience has also shown that tetanus is apt to develop, following secondary operative procedures undertaken after the tetanus antitoxin has been eliminated from the system. It is recommended that all cases subjected to secondary operative procedures should be given a protective dose of antitoxin serum if more than seven days have elapsed since the administration of the preceding dose. By adopting these precautions the incidence of tetanus in the British Army has been reduced to the point where this disease can no longer be regarded as a serious war problem. Tetanus, however, has not been entirely eliminated. This may be due to the fact that tetanus spores have in certain cases remained dormant for an unusually long period and have germinated after the protective agents introduced into the system have been eliminated, or to the fact that in some cases the administration of antitoxin was unintentionally omitted, or, finally, to the possibility that certain members of this group of organism produce a toxic agent which is not neutralized, or not completely neutralized, by the antitoxic sera now in use. Captain Tulloe, of the British Army, has shown that at least three serological types of tetanus bacilli exist, but whether these types produce the same or different toxic agents has not been established as yet.

In conclusion, I wish to say that the information here presented has been secured from the various French, Belgian, and British authorities active on the various fronts. To assign to each one the exact part played by him in clarifying this subject would be difficult or impossible. It is for this reason that I have refrained from quoting the various sources of my information.

Army Sanitary School No. 134.

MILITARY DERMATOLOGY

By Capt. H. A. MacGruer, M. R. C.

In considering the skin, one must not forget that it is an important organ intimately connected with and influenced by all the various bodily functions. It should be borne in mind that one of the most important functions of the skin is protection, and that a healthy epidermis with its various layers intact defends the body against the invasion of all kinds of organisms. It has been well said that "The stratum corneum is the first line of defense of the skin." Skin diseases are the cause of the greatest wastage in our Army at present.

"Every man incapacitated from duty—it matters not by what means—is a gain to the enemy. From the point of view of the Army, and of military efficiency, those diseases ought to rank highest in importance which cause most casualties. Judged from this aspect diseases of the skin occupy one of the premier positions, for under the conditions of trench warfare it is inevitable that they are met with in large numbers. The exact extent of the wastage for which they are responsible is known only to the authorities, but it is apparent to all that since many are contagious, successful efforts directed toward prevention and cure will amply repay by a very large gain of fighting men."—McCormac.

A dermatologist accomplishes a real economy by returning men suffering from skin diseases back to the front in the shortest space of time. The skin department not only relieves the surgical department but safeguards it from contamination from such contagious skin diseases as occur. The general practitioner is only too glad to disclaim any great knowledge of skin diseases, and this holds equally true with the volunteer Army surgeon.

There is a general belief that skin diseases as a whole are indicative of filth and uncleanness, and no one can deny that they are contributing factors in some of the cutaneous eruptions. These factors naturally tend to make the distinctly parasitic affections more numerous. It is not necessary to enumerate the large number of diseases that might be placed under the etiologic heading of parasites. We are particularly interested in the prevention and cure of pediculosis, scabies, impetigo, ecthyma, furuncle, and other infectious skin diseases common in our Army. We know positively that this can be performed under ideal conditions, but we are not at present working under ideal conditions, and will therefore have to perform unlimited labor to accomplish the results necessary. Our first and, undoubtedly, our greatest task is to prevent these diseases, and this is a task which calls for the hardest and most persistent kind of work. The officers and medical men of the armies of other countries, all working for the same end, efficiency, have accomplished wonders. We, starting at what might be termed the nucleus of our great Army, should profit by the mistakes of others and their thorough investigations, and should institute such prophylactic measures as will insure us an army of men capable and efficient and unencumbered by often unnecessary conditions which increase discouragement and lower self-respect, vitality, and efficiency.

Among the prophylactic measures necessary to prevent the many skin lesions which have been so prevalent in the Army, cleanliness is of the first importance, and by cleanliness I mean regular bathing and disinfestation. The medical officer can not order the men to bathe, nor can he himself always see that facilities for bathing are established, but by virtue of his knowledge of the results of lack of bathing as well as the relations he should establish between himself and the commanding officer, he should by every proper means bring to the attention of the latter the full realization of the decrease in skin diseases possible through regular baths and the consequent marked gain in the efficiency of the company. All officers take pride in their men and organizations and are anxious to have them physically and mentally fit for whatever duties they may be called upon to perform, and with proper cooperation between the medical officers and the commanding officer much of the necessary prophylaxis can be accomplished. I said prophylaxis because this is the first duty not only of the medical officers but of all officers and men. The greatest prophylaxis we have at present against the great majority of lesions of the skin is cleanliness. It is not probable nor is it possible that we will be able to carry out measures in the front line that will keep the bodies of the men clean enough to ward off these pests, but preparations are being made which will insure a great lessening of all the conditions which give rise to so many skin lesions and consequent bad condition, lost time, and lowered efficiency.

Provisions have been made to preclude such infestation of lice and scabies as has been common during transportation of troops to Europe. Special efforts are now being made to see that all commands are clean and free from infestation before embarking. Disinfestation of quarters and blankets on shipboard is now provided for. Such supervision of personal hygiene on shipboard as will insure continuous bodily cleanliness and adequate clean under-clothing has been called for by request of the chief surgeon. The chief quartermaster has, with approval of the chief surgeon, arranged a more logical supervision of the facilities for bathing, laundry work, and disinfestation. The Quartermaster Corps, upon recommendation of the Medical Corps, has purchased several Thresh horse-drawn disinfectors and several Fodden-Thresh steam-propelled disinfectors. This apparatus has been or is being distributed under direction of the Medical Corps.

General Order 38, general headquarters, A. E. F., 1917, paragraph 2, "authorizes for each battalion area a bathhouse approximately 26 by 22 feet, with a concrete floor, containing a dressing room and a bathroom with from 8 to 12 shower heads, together with the necessary arrangements for heating the same."

General Order 13, general headquarters, A. E. F., 1918, paragraph 5: "Organizations moving into the zone of the advance will take with them their portable shower baths, to be installed in suitable shelters, with the least possible delay after arrival. Engineer troops, when available, should make the necessary installation."

General Order 11, general headquarters, A. E. F., 1918, Paragraph IV., subparagraph 2, deals at great length on the prevention of trench foot and states that "the occurrence of this condition among the troops of a command is an indication of a lack of good sanitary discipline. Organization commanders are directly responsible, and by constant personal observation and supervision will satisfy themselves that the facilities are available, and that the members of the command are making full use of the opportunities afforded thereby. The commanding officers of all units will be held personally responsible that means for prevention enumerated in General Order 11 are carried out under the personal supervision of a commissioned officer."

I have mentioned these general orders to impress upon you the fact that general headquarters fully realizes and appreciates the great importance of preventing, as far as lies in their power, the several skin diseases to which the soldiers of this war are subjected.

It is very unsatisfactory to cleanse men by baths if they have to put on unclean, vermin-infested clothing afterwards. Bathing and changing to clean clothes will not only prevent the infestation of lice and relieve the soldier of his very friendly and persistent pests, but will also probably prevent many of the other annoying conditions of the skin; such cleansing not only removes infectious material already present but, by giving the skin the proper resistant power, will prevent infection from other sources.

In addition to causing severe irritation of the skin by their bites, lice carry the virus of typhus fever, relapsing fever, trench fever, and possibly other infectious diseases, from man to man; and when we receive reports from such men as Peacock, who has made some very thorough investigations, that 95 per cent of the men examined who have been in the front area for six months are infested with lice, it makes us realize the great importance of prophylaxis.

The louse is a parasite which is utterly dependent upon man's blood for its sustenance and man's body and clothing for prolonged prosperous longevity and reproduction. The home of the body louse is under the folds of the clothing. Eggs are found chiefly at the fork of the trousers, trousers generally, arm pits, shirt seams, and the neck, but louse eggs have been found in almost all parts of the clothing, even the pockets, the cloth identification tag tape, and the cloth articles of Catholic devotion. Eggs of the body louse are found also on the hair of the axilla and pubis. All a louse seems to want or need is warmth, humidity, and shelter.

We must consider then, first, the measures for promoting personal cleanliness among the troops generally and freeing from vermin those who have become infested; second, measures for freeing clothing from lice and their eggs; third, measures for keeping billets clean.

I. All troops should be inspected at least once a week; in this way not only lousiness may be detected and specially dealt with, but also many other conditions which if treated in their incipency may prevent the spreading of disease. Troops should be required to

bathe as soon as practicable after leaving the trenches and should be required to bathe at regular intervals, at least once a week, while in rest, reserve, or support. The hair of the head, axilla, and pubis should be cropped close. For head louse, petrol, or white precipitate ointment, chloroform, or vinegar will soften the nits so that good soap and water washing will complete the cure. For pubic lice gasoline applied two or three times will usually eradicate the pest, or a prescription of yellow oxide of mercury 10, acid salicylic 1, vaseline 90.

II. All underclothing, shirts, drawers, socks, and tapes should be thoroughly disinfected and washed. Clothing, if in large quantities, should be disinfested by whatever apparatus is available for that purpose—dry heat, steam, or boiling. By the Thresh horse-drawn disinfector it has been found that the garments should be steamed at 215° F. for 45 minutes. With the Fodden-Thresh they should be steamed at 220° F. and 5 pounds pressure for 30 minutes. If clothes are boiled in water for five minutes, lice are killed and eggs destroyed. A thorough ironing of garments, particularly along the seams is very efficient, but very slow. Blankets should be treated either by heat in a Thresh oven, sulphurous acid, by use of the Clayton machine, or, when these are not available, soaped in a hot 3 per cent solution of cresol in water and afterwards rinsed thoroughly in cold water and dried. In using the Thresh or Fodden-Thresh disinfestors it is necessary that certain conditions be carefully observed. Articles should never be packed tightly or rolled up into bundles, but should be loose and so arranged that steam will have access to all surfaces. Sufficient steam pressure and sufficient time for exposure are also necessary.

III. Billets should be sprayed at short intervals with 5 per cent cresol in water or naphthalene. Straw should be changed as frequently as possible and the old straw burned, although it has been proved that dugouts and billets are not important sources for disseminating disease. On the other hand, it is very inefficient to delouse one half of the troops and then allow them to mingle with the other half, as pediculosis is very largely spread by the infected individual. Spraying the clothing with the various solutions as a preventive is not always a benefit, particularly if the substance used is volatile and does not last long enough to prevent the ova from being hatched; under normal conditions ova hatch in from 7 to 12 days, but this may be delayed for a much longer period. Cresol, 1 to 1,000, added to 1 to 1,000 formalin will kill lice and nits on clothing in two hours if clothing is soaked in this solution. Treatment of the underwear with various solutions, such as carbolic, cresol, etc., has been tried, but as yet no satisfactory results have been obtained. The N. C. I. powder of the British (naphthalene 96, cresote 2, iodoform 2) has given excellent results in prevention when properly used, but the soldier will not persist in its use and, in fact, throws it away. Gunn, R. A. M. C., claims that dipping the underclothing in a parasiticide solution composed of 1½ ounce, each, of naphthalene and sulphur in 1 gallon of benzol or petrol has afforded complete protection against the body louse. In all these matters we must consider efficacy, rapidity, practicability, and cost.

The British forces have adopted the dry heat method of disinfesting clothing and equipment. They have found that the ironing method, steam, etc., is not as efficient as the dry heat. Captain Jacobs, R. A. M. C., has carried out experiments and constructed an apparatus which has proven most efficient and has many advantages over others. Experiments have shown that in lousy clothing hung in a hot-air chamber or a chamber heated to 60° C., the lice are dead after 10 minutes. Tests have also been made to see what, if any, ill effects this might have on articles of clothing or articles commonly carried in the pockets. Rubber articles were also tested. It was found that no appreciable deterioration took place. It was then recommended that delousing chambers be established in connection with baths, and a permanent staff attached. About 1,450 men could be bathed and their clothing disinfested by one apparatus and staff each day. The construction of this delousing chamber is not difficult, the materials are not scarce, and although the buildings are not strictly portable they are so simple in construction that they are easily taken down and reconstructed. Personally, I think this is the nearest to an ideal method that has yet been devised. Clothing and equipment is not injured in any way and in fact comes out of the chamber dry and in much better shape than when steam is employed.

Scabies is another one of the contagious diseases so prevalent in the Army; in fact so important are scabies and pediculosis with the resulting pyodermias that the actual loss of

time of our soldiers is becoming a serious matter. McCormick reports that in one hospital where he had seen a great many cases of the resulting pyodermias, and had averaged the loss of time of the men in that hospital alone, such average loss had been 31.67 days per man. This did not take into consideration the time spent in other hospitals nor the time consumed in coming back to the hospital. Scabies is due to an animal parasite, the *Acarus scabiei*. It is contagious to a marked degree and, knowing this, it is readily seen how easily it is contracted, how readily communicated from soldier to soldier under the present living conditions, with the men sleeping together and using the same blankets and with the natural flocking together and intimate contact. The eruptive lesions are the result of the reactionary inflammation provoked by the presence and products of the parasite in the cutaneous tissue. Papules, vesicles, and blebs result and purulent lesions are produced, due to secondary inoculation of pus cocci. The constant scratching gives rise to favorable opportunity for integumentary coccus infection. The female mite is the one which invades the integument. The mite burrows into the skin and deposits its ova and finally perishes in the skin, so that the burrow contains the mite, its excreta and ova. Itching, particularly when the patient warms up in bed, is one of the chief symptoms, although many of the soldiers are occupied with other matters of graver importance and do not notice the itching and many do not report the scabies, as they attribute the itching to pediculi; so in a great number of cases impetigo, ecthyma, boils, and other pyodermias develop which could have been avoided by early diagnosis and treatment. The men should be inspected at least once a week and the examination should be thorough, not merely a glance at the interdigital spaces, wrists, etc. The soldier should be stripped. In this way not only scabies but other skin conditions will be discovered early and the spreading of disease prevented.

But little difficulty need be experienced in the diagnosis of this disease in uncomplicated cases. The distribution, multiformity of the eruption, and the burrows are diagnostic points. One of the sites usually selected is between the fingers and other parts of the hand and on the wrists; however, it is not necessary to find the lesions on these parts and those duties give them opportunity to wash often and care for themselves, as bakers, laundry and oil workers, are free from lesions here. So lesions on hands are often absent and vesicles are more common than burrows. Other sites are about the elbow joint, axilla, umbilicus, lower abdomen, genitalia, anus, buttocks, lower calf, back of knees, and at times the feet. The burrows usually resemble a thin line one-fourth to one-sixteenth inch long, with generally a pinhead-sized vesicle near the end. Many times the mite can be seen, if one is expert and has good eyesight, or uses a magnifying glass. It is found in the blind end of the burrow, where it reposes as a grayish or grayish black dot. If scabies is complicated with impetigo the burrows are more difficult to find. In these cases the hands and feet particularly are the seat of vesicles and perhaps bullæ, crusts, erosions, and inflamed burrows and even ecthyma. In eczema complicating scabies we find red, rough, eczematous areas, either dry or moist, on the hands, arms, thighs, or trunk. Scratching and severe treatment of scabies (overtreatment and sensitive skins) is at times responsible for an eczematous condition. Some cases of impetigo may be severe enough to mask scabies; these secondary impetigos are especially found on the lower part of buttocks, elbows, and knees. Boils are pyodermic complications at times. The chief points of differential diagnosis between scabies and pediculosis are as follows:

Location	
SCABIES	PEDICULOSIS
Hands, wrists, elbows, anterior axillary folds, umbilicus, abdomen, buttocks, knees, penis.	Posterior axillary folds, shoulders, clavical region, upper part of buttocks, groins, thighs, between knees and ankles.
Types of lesions	
Burrows, vesicles, small superficial crusts, papules, pustules, specific erection of the pilosebaceous follicles, scratch marks represented by minute blood crusts at the orifices of the erected follicles.	Superficial and deep pustules with a surrounding red halo; linear impetigo; lesions on the whole much larger than those seen in scabies.

Next to prophylaxis the early diagnosis of scabies, which is made possible by the weekly inspection of the men by competent medical officers, is of the utmost importance. As in the treatment of pediculosis, so in scabies, thoroughness is absolutely necessary. It is a great saving to cure cases by being thorough in the first treatments and not have the soldier return and thereby lose double time. It is not a disgrace to have scabies, although it may become so to keep them if proper remedial measures are supplied.

In the treatment of scabies the bath is a necessity; tub baths have the preference, although with proper thoroughness showers will answer, and showers are what will be used in the Army. Trained men should be at the baths to treat scabies, not only to see that treatment is carried out properly, but to see that the cases are not overtreated and to discover lesions of other diseases. Scabies, in a great percentage of uncomplicated cases, can be cured in one treatment, and if all cases could be diagnosed early it might not be difficult not only to cure the present cases but very greatly to reduce the number of new ones. This again brings up the great necessity of having proper arrangements made for the bathing of the men and thorough disinfection of their clothing, blankets, equipment, etc. In many of the French hospitals I have visited the medical men claim to cure over 90 per cent of scabies cases in one treatment; that is, in one bath and one rub of ointment, and while the patient is being treated the clothing is disinfected and the patient is returned to duty the next day. Vapors have been recommended for treatment of this condition but they do not penetrate nor do they kill the mite nor destroy the ova. Lotions require great skill and necessitate more time and are therefore not as efficient as ointment.

The plan of treatment as adopted by the United States Army for the treatment of uncomplicated scabies is as follows:

The patient, usually with the assistance or under the supervision of a trained assistant, thoroughly applies green soap to all parts of the body except the face, giving special attention to those areas chiefly affected. The thorough and proper application should take about 15 to 20 minutes. Some use a stiff brush for this purpose; it may bring blood, and although it may relieve the patient of the itching, still my personal opinion is that it is not necessary to be so severe. A coarse towel or glove or even the bare hands with the soap is sufficient to remove all dirt, grease, and dead epithelium and open up the vesicles and burrows. After the 15 to 20 minutes the patient is put in the tub, or under the shower of hot water, where he continues to rub himself vigorously with soap. One of the best helps is a roll of felt or very heavy coarse cloth about 6 inches long and an inch in diameter; this the patient uses to rub between the fingers, thus breaking vesicles and opening burrows. After the bath the skin is dried and, except upon the face and scalp, the following ointment is well applied for 15 or 20 minutes: Potassium carbonate, 10; sulphur sublim., 20; adipis (or vaseline), 80. The ointment is again applied that night, as the pajamas or clothing have received some benefit and the skin robbed of that much. The next day, if the skin has not reacted severely to this treatment, the patient is again rubbed with the ointment. If a slight irritation has developed, then a 10 per cent sulphur ointment is used. This treatment will last the patient till the next day when the final application is made. This is a repetition of the 10 per cent sulphur ointment. After this the patient is given another bath and receives his clothing, which has been disinfected by the same methods as advised for pediculosis. In handling these cases care should be exercised to keep the new cases from infecting and re-infecting those who have been treated. In some cases a dermatitis may develop from the treatment of scabies with sulphur; so exercise care, take an interest in the cases, and do not make it too much a matter of routine treatment. In these cases of dermatitis which develop from sulphur, use zinc-oxide ointment containing cornstarch and also about 1 or 2 per cent ichthyol; or a bath with 1 cupful bicarbonate of soda and 2 cupsful cornstarch in tub of warm water, the patient to remain in tub for 20 minutes and afterwards pat himself dry. Other treatment may be by Carriers "water paste," zinc oxide, calcium carbonate, aqua calcis, glycerin aa, and applied with a soft brush, or 1 or 2 per cent phenol solution if itching severe and skin not too greatly inflamed; or coal tar solutions. Albuminuria, which is seen in a small percentage of scabies cases, occurs only when there is secondary infection and is not a contraindication to treatment by sulphur ointment.

Primary as well as secondary streptococcus and staphylococcus infections of the skin are exceedingly common. They are termed pyodermias. The staphylococci infections are important; they are invaliding many able-bodied men. H. G. Adamson divides them as follows:

(1) Sycosis menti and similar affection of their hairy parts, namely, the upper lip, eyebrows, eyelashes, scalp, pubes, axilla.

(2) Chronic furunculosis.

(3) Chronic eozematoid impetigo of the trunk and extremities.

The majority, probably all, of these cases could be avoided were the initial skin complaint correctly diagnosed and efficiently treated. These staphylococci infections may all be included under one term, impetigo of Boeckhart. Many times this condition arises as a secondary complication of contagious impetigo of Tilbury Fox, Sabouraud, in 1900, first clearly demonstrated the distinction between the two groups of impetigo. Contagious impetigo of Tilbury Fox is due to the *Streptococcus pyogenes*; it is highly contagious. It first starts as a superficial blister, which contains clear serum and which rapidly dries into a crust; the crust is amber colored and looks as though it were stuck on. This drying and scabbing process is, many times, so rapid that the vesicle is unobserved. On removal of the crust (with forceps) there is found a superficial erosion, with an overhanging fringe of the horny layer of the epidermis; this is the floor of a broken blister. This disease attacks the chin and cheeks, sometimes from infection in barber shops. It also occurs on the trunk, limbs, and other parts of the body as a complication of scabies and pediculosis. This form of impetigo is easily cured and still, because of lack of early diagnosis and proper treatment, from this condition arise most of the staphylococci infections, sycosis, furunculosis, and chronic impetigo, which may be well termed the impetigo of Boeckhart, and which are most stubborn and very difficult to cure. These staphylococci infections are deep-seated lesions and lead to the formation of pockets of polynuclear leucocytes or pus cells, deep in the tissues around a hair follicle. These lesions may be small and closely set on some hairy region, or they may be larger and scattered over the trunk and limbs (as in furunculosis). Remember then that most of these incurable or stubborn staphylococci infections of the skin arise as a complication of uncured impetigo contagiosus (*Streptococci contagious impetigo* of Tilbury Fox). These infections are the cause of stubborn sycosis, which is not necessarily limited to the beard region but attacks the eyebrows, eyelids, scalp, axilla, and pubes, and it also is the cause of furunculosis, which may affect the skin of the neck, trunk, or limbs.

Then we have that type of case where the patient has scabies complicated by turbid vesicles on the hands and feet, and crusted patches on the limbs and trunk. On the buttocks a severe type is often seen in which the erosion is converted into a shallow ulcer with an inflamed base, with or without a dirty brown crust. Most of these cases of impetigo complicating scabies yield to the sulphur ointment treatment for scabies. Those not treated early and thoroughly may later develop boils or the scratching may convert them into eozematized impetigo, with eczematike, infiltrated itchy, crusted areas on the limbs and trunk; these cases are exceedingly rebellious to treatment.

In treating impetigo the first procedure is to remove all crusts and every overhanging blister margin by mopping with hot water, vaseline, or sweet oil. This procedure must be done two or three times daily and must be very thorough; at times it is necessary to remove crusts by picking off with forceps or pieces of cotton or gauze. When the skin has been cleared of the crusts, etc., then apply Ung. (hydrarg. ammon.) 5 per cent or swab the area with 20 per cent solution of silver nitrate and afterwards apply talcum or cornstarch.

The treatment of the staphylococci infections of the skin is much more difficult. Vaccines are well worth using in sycosis, furunculosis, etc. Shera, R. A. M. C., claims 100 per cent cures of chronic cases of trunk with autogenous vaccines, while Adamson claims the treatment by vaccines has not proved the panacea it was said to be.

These chronic cases should not be handled except in special hospitals or wards, and here facilities for making autogenous vaccines will undoubtedly prove of real value. It is possible by complete depilation with X rays to produce what at first appears to be a cure, but almost always the disease relapses as soon as the hair grows again. If the disease occurs only on a small area, depilation with forceps and the application of antiseptic ointment will usually

effect a cure. Pure carbolic acid carefully applied is often of benefit. In the treatment of furunculosis a most thorough examination of the patient is demanded; the urine should be examined and the general condition of the patient taken into consideration. Tonics and care are of benefit. Stock vaccines are at times beneficial, and autogenous vaccines have given most satisfactory results. Baths, mopping the skin with antiseptic lotions, and sterilization of clothing are prophylactic measures. Carbolic acid and a very small applicator (toothpick, match, etc.) inserted into a boil will destroy and remove infection; this is not painful, carbolic acting as a local anesthesia. If it is necessary, the application of alcohol may follow the carbolic; this will give immediate relief. Ecthyma is best treated by hot applications of boracic acid packs over a period of an hour, three times a day, until ulcerations are clean, then using 1 per cent picric acid; ichthyol ointment 10 per cent, or, when healing slowly, using silver nitrate to stimulate 4 per cent salt. Send to division dermatological hospital.

The treatment of chronic eezematized impetigo is very unsatisfactory, as it is so often a sequel of scabies complicated with impetigo contagiosus and is not properly treated in the beginning. Itching and scratching keep up eczema and adds new pustules and boils. The use of X rays or the following prescription is beneficial: Acid pyrogallie gr. I in 1 dram of zinc oxide.

The early diagnosis and proper treatment of streptococci impetigos is the only sure method for the elimination of these obstinate and often incurable staphylococci infections, as the latter follow as a sequel to the initial and more easily overcome streptococci diseases.

There are other lesions of the skin which you will see in the Army and, although of importance, they will necessarily be treated at skin hospitals: Seborrhea, psoriasis, urticaria, etc. I have endeavored to acquaint you, as far as possible in a lecture, with the most frequently met with skin conditions and sincerely trust these few points will be of value. Familiarize yourselves particularly with the differential diagnosis and treatment of scabies and pediculosis. Be thorough in treatment and in disinfection. Get the reputation of having the skin of the men clean and healthy and you will have performed one of your most important duties.

Army Sanitary School No. 135.

FOOD CONSERVATION AND THE MEDICAL OFFICER (Abstract)

By Capt. Walter H. Eddy, S. C., N. A., August 6, 1918

1. The problem of food conservation in the Army is essentially different from the civil problem. As some one has put it, our job is "to see that the food gets into the belly of the man and not in the garbage pail." I do not wish to burden you to-day with statistics, but a few figures will help to point the necessity for increasing attention to this Army problem.

Weight of the garrison ration, 4 pounds, 3 ounces; bought in France, 1 pound, 3 ounces; by ship from the United States, 3 pounds of actual food, to say nothing of containers. This means 3,750,000 pounds per day, or 1,875 tons. In a year this will amount to 673,800 tons, or one 5,000-ton ship every two or three days.

Potatoes: Refuse and waste as ordinarily peeled, 25 per cent; refuse if carefully peeled, 13 per cent; unnecessary waste, 12 per cent. Ration is 1 pound per man per day, or 1,250,000 pounds \times 12 per cent = 150,000 pounds per day, or enough to feed 150,000 men.

Garbage waste (edible): Should not exceed 12 per cent per day. This results in reducing the value of the ration from 4,200 to 3,696 calories per day.

These figures at least illustrate the fact that small wastes multiplied by the size of the Army are not negligible items, considered either from the viewpoint of money, transportation, or nutrition.

2. The work of detecting waste and instituting measures for its remedy falls directly upon the medical officers of the organizations. As sanitary inspectors they are the men most cognizant with the mess conditions, and it is for that reason that I wish in what follows to consider this problem in terms of the medical officer's duties and responsibilities.

3. To illustrate the relation of the medical man to the problem, let me develop one concrete example—the question of the beef component.

The ration allowance of fresh beef is 20 ounces, and this component is usually issued as 70 per cent beef and 30 per cent bacon or other substitutes. This means 14 ounces of fresh beef per man per day, or approximately 875,000 pounds of fresh beef issued in quarters to the Army every day of the year as a minimum. Beef is now quoted in the United States at 22.5 cents a pound, and this little item then represents \$196,875 per day for beef alone, leaving out of consideration all cost of shipment. One per cent waste then gives us about \$2,000 a day. A little development of your imagination will suggest the significance of these amounts translated into terms of finance, transportation, space robbed from troops, ammunition, and the like.

Looked at from another angle, the Army ration distributes its nutrients as follows:

	Protein	Fat	Carbo- hydrate	Calories
	<i>Grams</i>	<i>Grams</i>	<i>Grams</i>	
Ration.....	146	147	544	4,200
The beef component.....	60	60		

We certainly can not afford to waste this component either from the viewpoint of money value or as protein producer.

Now in this matter of beef conservation you play a most important part. You are the gentlemen whose judgment decides the fate of much of our frozen beef. You are charged with the health of the men and also with the prevention of useless waste of Army property. It is also true in the past that large quantities of beef have been condemned by medical officers and buried or burned, a large portion of which might have been saved by careful trimming. We have ourselves during the month of May salvaged at Dijon 75 per cent of 35,000 pounds of beef that had been condemned and returned to the freezer. That 26,000 pounds of beef should have been trimmed out and issued to the troops and would have saved not only beef but valuable transportation space.

Beef is now shipped frozen from the States. At St. Nazaire it is loaded into insulated cars and travels to the nearest refreezing station, usually Gievres or Dijon. From here it is put into box cars and goes to the organizations as rapidly as possible. It is obvious that with all the delays possible in transit, the chance for partial thawing and surface decomposition is great. But the fact remains that our aim should be to see that as much of this precious material is saved and utilized as possible. That is where you come in. Remember, too, that there are no absolute tests that you can depend upon for beef condemnation and that the experience of a qualified butcher is often of much greater value in selecting the good part than the judgment of the doctor. Let me ask then that in the future when you meet such a situation you follow the procedure outlined below:

(a) First have the carcass unwrapped and then washed thoroughly with salt and water.

(b) Next, with the assistance of the best butcher you can find in the outfit, go over the exposed surfaces and carefully trim off all parts that are tainted. If the covered parts seem to be affected, have the covering tissue removed by the butcher, taking care not to cut into the flesh. Do not condemn any part of the carcass until these preliminary steps have been taken.

(c) You are now ready to examine the joints to see whether decay has started there. Do this by probe at the shoulder and hip joint. The smell on the probe will tell the story, and it is not necessary to slash the quarter. If you find taint have the butcher dissect out the bone and then trim away the meat adjacent until you reach a good layer. Remember always that the problem is to save as much good meat as possible. This sort of procedure, if carefully done, will usually insure a saving of from 60 to 70 per cent of even badly slimed beef.

(d) To prevent flyblow, make sure that fly eggs are washed off the shank immediately after the beef arrives. They will be usually found on the shank and, if left, mean extensive decomposition and waste. In fact a safe procedure with all beef is to have the covers removed as soon as the beef comes in, have it washed with salt and water and then recovered with the cheesecloth. From that time on care will keep it sweet.

(e) The following methods are recommended for the conservation of frozen beef: Hang in an airy, well-ventilated place out of the direct rays of the sun. Meat safes covered with cheesecloth or screening to exclude the flies, but allowing a free access of air, will protect the beef for several days if it is wiped as often as it becomes covered with moisture. Dry mold is harmless; slime is the thing to prevent. If it is necessary to retain cut beef for more than 24 hours, it may be placed in a container and covered with salt-water brine, but in cutting up beef see that the outer skin is removed if tainted before the knife cuts the flesh. A piece of tainted skin carried into the meat will taint the whole batch.

Nobody wishes tainted meat used for food, but that does not necessitate wholesale condemnation.

Your work in beef conservation, however, does not stop here. It is equally important to see that every part of the carcass is used to its maximum nutritional efficiency. The stock pot is an instrument of conservation and also provides material for both soups and gravies. There is no excuse for green bones in the garbage can.

4. I have used the above as one example of how you as medical officers are most important conservation agents. Let me develop other phases of this particular function of yours. Beef in the form of stum, day after day, means both dissatisfaction and waste. Man likes variety in his diet. If he doesn't get it he soon loses appetite and the garbage can gets the food that should nourish him. That idea calls attention to the need for continual inspection of menus. Line officers know little of balanced diets. They depend upon your criticism to cover that point in the feeding of the men. Furthermore, it is a very easy matter to include in your mess inspections a glance from time to time at the posted menu. That of course means that there must be such a thing as a posted menu, and you should insist on finding it. Failure to find one usually means that the cooks and mess sergeants are giving very little attention to variety. You can't vary the garrison ration without giving that attention, and the menu is the key to the situation. Please make that a part of your inspection and, as prophylaxis against nutritional disturbances and lowered morale, it will repay the effort.

5. A second big feature of our ration is bread. The American Army is now the only collection of individuals in the world who are allowed to eat white bread. Your wife and mine can't get it. Every one in the United States of America is straining to save wheat for our use. They are paying 10 cents a pound for Victory bread in New York City to-day. Before the war wheat averaged about \$1 a bushel. It is now worth \$2.18. Since the war began our exports to England have increased 170 per cent, to France 364 per cent, to Italy 330 per cent. We are literally supplying the world with wheat, and at great sacrifice to our families. That should at least make it imperative for us to exercise the greatest care in conserving the supply. There are two sides of this problem where you can be effective.

First. In the utilization by the mess. Watch the garbage can and the bread box. If bread appears in the former it is a matter for drastic action. See that slices are cut thinner or halved and that men take only what they can eat. See that scraps are utilized as bread pudding, as bases for desserts, as croutons for soup. There are many ways of getting full value of the bread ration and no excuse for its wastage.

Second. There has recently been considerable trouble with bread mold. Its cause is even yet uncertain, but we hope the solution is in sight. You can, however, help in the matter. On the bottom of each loaf shipped will be found a paper pasted, giving the date the bread was baked and the number of the company that baked it. These data are significant. Don't take hearsay on mold hereafter. Require the loaf produced. Note the date. Learn from your railhead officer how long it should take to get bread to the outfit. If the date on the loaf indicates it has been abnormally long in the unit, locate the trouble there. Find out the conditions under which it is stored in the mess. In brief, first make sure that the trouble is not in the organization. If sure on all these points, notify us, giving date and bakery company number. We have then got something to work on and do not need to make a long trip to learn facts readily available to you. General complaints mean nothing; facts we can act upon.

6. I have referred before to the value of the garbage pail as a means of diagnosis of mess inefficiency. Another source of information is the mess storeroom. And right here let me interpolate a word as to mess inspection generally. I have seen too many messes that have been O. K'd by the sanitary inspector that were models of cleanliness and absolutely ineffi-

cient as purveyors of food to hungry men. When you inspect a rifle your aim is to see that it is in condition to shoot, to function. The functioning of a kitchen is what we are most concerned about, and unless your inspection insures that, the other features are relatively unimportant. I realize that you are not mess officers, but you are directly concerned with the health and nutrition of the men and responsible for it. That I think justifies the following suggestions.

I have already illustrated in the case of the meat and the bread the way in which the garbage can serves as an indicator of waste. Let me consider a typical case in which the storeroom serves the same purpose. One often finds in the storehouses an accumulation of sugar. You will usually find such messes complaining of lack of sufficient bread. The reason is not immediately obvious. The sugar allowance is ample to provide for the making of desserts, and the garrison ration provides materials for over 30 of such desserts if the cooks will take the trouble to study their Cook's Manuals and work them up. If these desserts are not made, the men crave sweets and the nearest substitute is bread. Try to eat a heavy meat and vegetable meal without a dessert to top it and you will find yourself reaching for the bread to offset the cloying effect of the excess in the other direction. Given a dessert, this need is satisfied. This example is only one of many. An accumulation of any ration article in the storehouse has a meaning that translated into nutritional needs is indicative of some defect in mess management. A little study will reveal these and help greatly in making your kitchen more effective.

Take another example of another sort. Accumulation of lard in the mess-room storerooms under the present ration issue should indicate a defect of the ration and in fact is really complimentary to the cook. The reason lies in the fact that the meat ration supplies so great an amount of fat that if this is properly rendered it is sufficient for practically all cooking needs. In that case the lard component is too large. Now that fact is actually established and steps have been taken to reduce the lard allowance 50 per cent and increase milk and fruit 100 per cent. These changes will go into effect soon. But unless the matter is carefully checked your units will run out of cooking fat, as soon as this change goes into effect. The fat must be saved to permit the change, and by reducing the space taken by the lard we are enabled to increase the bulk of other foods desired without increased shipping space.

This whole question of fat saving in fact assumes very important proportions. The salvage department has arranged to receive all excess fat and to pay the units for it. There are hosts of messes in the American Expeditionary Forces where the installation of a simple grease trap would not only help to keep the dishwater from polluting the ground but will yield an appreciable amount of fat for salvage. A little interest in this feature will go far to realize an appreciable saving of this substance for glycerine and ammunition. We are the only army that has not taken active measures to secure the conservation of this by-product. In England the cooks' salaries are determined in part by their efforts in this fat-saving effort. In our Army we have seen the excess lard used to kindle a green-wood fire. Such things are criminal.

Without enlarging on this point further, I think you will grant that it is worth while for the medical officer to make a careful study of these two diagnostic agencies, the storeroom and the garbage pail, and to develop their significance as indices of mess conditions.

7. Another field that I wish to call your attention to is that of necessity for study of the ration as issued. It is a deplorable fact that very few mess sergeants and cooks have an accurate knowledge of what the ration is. The next time you make your sanitary round ask each mess sergeant how much beef his men are entitled to each day. You will, I think, be greatly surprised to learn how few are informed on this essential subject. The reason is not far to seek. Until the troops reached France the ration was simply a system of accounting. The ration-savings principle had made the sergeant and cook more or less adept at using the ration allowance to obtain variety and build a mess fund. Arrived here, the savings principle stopped; the ration was issued in kind; the sergeant and cook got the idea that their job was to take what was given them by the supply officer and do the best they could with it. They took no trouble to learn what they had a right to demand. As a result there is an appalling ignorance of what the ration as issued entitles them to. There

are very serious consequences arising from this state of affairs, and you can help to remedy it. Will you not see to it that every mess sergeant in your future commands not only knows what ration he is entitled to but also exactly how it is issued. Unless he does his judgment as to the special requirements of his men are absolutely unreliable. I recently investigated a demand for increased ration on the part of a labor troop where the statement was made that more food of a certain sort was needed and that the meat ration could be cut 40 per cent. Investigation showed that the meat ration had through ignorance been overdrawn that month some 40 per cent. Such a condition made it absolutely impossible to tell whether the ration was adequate or not.

8. There is nothing sacred about the ration. It can be changed as needed. It has already been changed in France, and a new set of changes will be issued soon. But at present it supplies nearly 4,200 calories. It is capable of very great variety of menu making to the careful student of its components. You will be asked frequently to pass on requests for changes to meet the needs of particular troops. Please consider these requests food for careful digestion and not for snap judgment. Study the organization. Before recommendation satisfy yourself on the following points:

- (a) Is the organization getting its full ration allowance?
- (b) Is the ration getting into the men and not into the garbage can?
- (c) Is the dissatisfaction due to actual hunger or to failure in menu making and cooking?

If these conditions are satisfactorily complied with, you have a case and quick action can be taken thereon.

9. I have dwelt to-day on a few of the phases of food conservation in the Army that affect the medical officer. They are intended to be suggestive rather than exhaustive of the subject. Venereal inspection and clean dishes are only a small part of the duty of the sanitary inspector who covers mess conditions, and an active interest on his part in the conditions that make for good messing will go far to relieve the troubles occasioned by green cooks, inefficient mess sergeants, and uninformed line officers. The care of the sick is important, but in that care you are looking after the liabilities of an army. There is no way in which you can do more effective work in winning battles than in caring for the assets of the Army, its fighting forces. At the same time you will be actually seeing to it that the food so carefully saved at home by the sacrifices of our families goes where it was intended to go—to win the war.

10. Followed a brief outline of the duties of the food and nutrition section of the chief surgeon's office and the method in which it might serve to assist the medical officer in his work.

(NOTE.—Evaporated potatoes should be soaked till they swell up to nearly their normal size. The time necessary varies with the kind of potato and the character of the water. Tin vessels should not be used for soaking, as they are apt to turn the potatoes dark. They are best served as a mashed or creamed potato.)

(NOTE.—The general orders referring to rations are as follows: General Orders, 1917, 18, 38, 67, 78; General Orders, 1918, 19, 44, 54, 70.)

Army Sanitary School No. 136.

THE EFFORT SYNDROME, TOGETHER WITH A CONSIDERATION OF THE SIGNIFICANCE OF CERTAIN MURMURS

Delivered to the class of the fourth session, Army Sanitary School, April 29, 1918, by
Maj. Alfred E. Cohn, M. R. C., senior consultant in general medicine, A. E. F.

The war has altered opinion of the value of many signs formerly accepted as important indications of the presence of organic heart disease. The chief sign involved in the changed point of view is the systolic murmur. The significance attached to diastolic murmurs, both the diastolic murmur of aortic insufficiency and the presystolic murmur (auriculo-systolic) of mitral stenosis, has remained unaltered. Individuals afflicted with these two diseases have been found not to bear the strain of war satisfactorily, even if at the time of enlistment they were free of any indication of heart failure. They are now accordingly rejected for service.

The significance of systolic murmurs, especially their relation to mitral insufficiency, however, has occasioned much discussion. Systolic murmurs occur in so large a number of individuals that it has become necessary to decide when they are important and denote mitral insufficiency. The need for making the distinction between important and unimportant systolic murmurs occurred infrequently in civil life; young men rarely sought medical advice on account of such murmurs. When they did, as the result of life insurance or other accidental examination, the difficulty in diagnosis was appreciated, but reliable guides for making a decision were wanting. Early in the war men with such murmurs were accepted and many were found after severe service to bear the fatigue incident to campaigning satisfactorily. The conclusion was therefore drawn that the murmur in itself must in these instances be considered unimportant. New criteria were accordingly required to decide which systolic murmurs were and which were not important.

Until now it has been customary to divide murmurs into two groups—functional and organic. To decide in which group a murmur belonged, it was studied from the point of view of the bearing on it of the posture of the body, of the position in the precordial area at which the murmur was best heard, of its character on auscultation, according to its intensity in different respiratory phases, according to the direction of its transmission, and according to its time incidence in the cardiac cycle.

A word should first be said on the use of the words "functional" and "organic" in relation to murmurs. A murmur is of course a physical phenomenon and dependent on the structure of the containing vessels and the arrangement of the surrounding tissues for its production and character. This is true of the so-called functional murmur as well as of the organic variety. All murmurs are in this sense organic. The distinction which the words "functional" and "organic" were intended to convey relates to their importance or unimportance, or perhaps better to their significance or insignificance. The point is in itself not important except in the interest of clear understanding.

Close study has failed to show that systolic murmurs can be classified as significant or insignificant according to the criteria just enumerated—that is to say, posture, position, character, respiratory emphasis, transmission, and position in the cardiac cycle. It is of course true that aid may be obtained from certain of these criteria, but the aid is not definitive. Other criteria have therefore been proposed. These relate (1) to the size of the heart, (2) to the history of infection, especially of rheumatism, (3) to the intensity of the second sound in the second left interspace or third left costo-chondral junction, and (4) to the reaction to exertion. A candidate may be accepted for service in the Army if his heart is normal in size, if there has been no history of rheumatism, if the second cardiac sound is not accentuated, and if the response to a standard exercise test is normal, even though a systolic murmur is present. The terms used require explanation.

The heart is normal in size in adult males in civil life in the third decade, when in the oblique position it measures from 9 to 11 cm. In active military service the size often increases to 11 to 13 cm., and these dimensions are considered normal. The measurements given are based on X-ray plates placed when exposed 2 m. from the target of the X-ray tube. Attention must be called in this connection to the fact that all normal hearts do not lie in this oblique position in the chest. Frequently their outline shows them to have a more vertical position in the mid-thoracic region; sometimes they have a more nearly transverse position. These variations naturally make the diagnosis of hypertrophy difficult and must be taken into consideration in deciding on its presence. An hypertrophied vertical heart may in profile be smaller than a normal transverse organ. In every instance, therefore a correct estimate of size may not be possible.

The second criterion mentioned is the history of infection, and especially rheumatism. Under rheumatism are included acute rheumatic fever, chorea, tertiocolis, tonsillitis, growing pains. It is obvious that a single attack of acute rheumatic fever occurring in childhood, and having been followed by no obvious cardiac disability, is not important as are repeated attacks, the last having occurred within the year.

The third criterion relates to the intensity of the second sound. It is not possible to state that the second sound is invariably accentuated when chronic mitral endocarditis has persisted for a prolonged period, but it is believed to be the rule that after long-standing

disease an accentuation takes place. Its presence is therefore of significance in deciding that disqualifying disease has occurred.

The nature of the response to a standard exercise test is the fourth criterion. The introduction of the test is important, for it gives information of what one desires to know as the result of examination; that is to say, the ability to undergo exertion. The test recommended in Circular 21, Surgeon General's Office, consists in hopping 100 times on the left foot so that the shoulder is elevated from 4 to 6 inches. Two minutes after the end of this exercise the ventricular rate should return to within 10 beats of normal and the blood pressure to normal. The test is recommended because it is simple and can be carried out in a uniform manner.

It is not pretended that one can rely on these criteria always to solve a difficulty in diagnosis when a systolic murmur is present. But they are useful when, in addition to the murmur, the heart is barely enlarged and a history of repeated and recent attacks of rheumatic fever is reported.

A word should be said about the character of the apex impulse. It has been the habit to lay stress on its extent and position and on the force or other slight abnormalities presented by it on palpitation. Recently abundant experience has tended to confirm one in the impression that too much stress is laid on these phenomena. But as an indication of the position of the left border of the area of cardiac dullness, in estimating hypertrophy the location of the apex, especially its furthest extension to the left, is valuable.

These views in respect to the systolic murmur represent the chief alteration which has been made in the point of view of organic heart disease. Of far greater importance is a symptom complex, functional in nature and, although not confined to soldiers, especially common in war. It is a group of symptoms, referred by soldiers to the cardio-vascular system, and forming a frequent cause of more or less serious disability. This group of symptoms was first described as a clinical entity during the Civil War in the United States by Harthorne, and the description was later elaborated in greater detail by DaCosta. By the latter it was called the "irritable heart of soldiers"; and the disorder was known by this name until the present war.

The reason for its occurrence was sought in our own and other armies. Its cause was laid first to one and then to another circumstance. It was found everywhere and under all conditions. During the present war attention was forcibly directed to the affection because of the large numbers of soldiers whom it involved. With the new work on the subject, the name of Thomas Lewis is closely connected. His recommendation that the affection be known by the term "effort syndrome" has fortunately been accepted in the American Expeditionary Forces. It is classed in the British service as disordered action of the heart (D. A. H.).

The affection is characterized principally by the occurrence of breathlessness, giddiness, a sense of fatigue, pain in the chest, often in the region of the precordium, and palpitation. On examination are found, in addition, an anxious facies, tremor or shakiness of the fingers alone or of the extremities or even of the whole trunk, cyanosis, sweating, skin hypersensitiveness, both hyperesthesia or hypesthesia (head zones), tachycardia; and on questioning one learns besides of headache and of unpleasant dreams at night. Many of the symptoms suggest the presence of the heart failure of chronic valvular disease. It will be seen, however, that this affection is strikingly different. It need scarcely be pointed out that both conditions may coexist.

Naturally all these symptoms are not necessarily present in the same patients, and besides the individual symptoms vary in the degree of severity. Indeed the clinical picture varies within wide limits. In consequence experience is required in order to recognize the cases, especially in the milder forms. Patients may, in fact, complain of a single symptom only. The most frequent of them, according to Hume, is pain in the chest occurring in 768 of 1,000 cases. Breathlessness comes next (675), then giddiness (403), palpitation (354), precordial tenderness (268), fainting with loss of consciousness (98), and fainting without loss of consciousness (25). As a matter of fact it happens frequently that only a single of these complaints causes the soldier to report at sick call. But in addition to his complaint

suppose it to be precordial pain, he is likely to look worried, his face drawn, his brow contracted, his eyes unduly anxious, his hands and fingers ashake. Questioning may elicit the fact that he suffers from headache, bad dreams at night, pain of a fugitive nature elsewhere in the body, and an increasing disability to do work. Examination discloses the presence of certain physical signs, to be discussed later. While the clinical picture which has just been drawn is common, the especial cause for sick report may be one of the other chief symptoms. Indeed any one of the chief complaints enumerated may appear alone and dominate the clinical picture. Experience must teach the large variety of combinations in which the chief symptoms occur. The peculiarities they present deserve detailed consideration.

The pain is usually located in the precordium or just above and to the left of it. Its position is not necessarily fixed; it may change from day to day. It may be felt on the right side of the chest, in the flanks or elsewhere. Sometimes, though, it is referred to the shoulders and arms. When the pain is in the chest, its character is usually sharp, sticking, and fleeting; rarely constricting. It is probably not experienced at night and it does not keep the patient awake. Effort tends to bring it on, just as it tends to bring on the other symptoms. Associated with pain, areas of skin hyperesthesia (head zones) are found in a quarter to one-half the cases. The intensity of this symptom varies. Patients may complain of it as due to the pressure of clothing; in other instances its presence is elicited on examination. Pressure between the fingers of the pectoral, deltoid, sternomastoid muscles may elicit unilateral or bilateral tenderness. Boas (personal communication) has in a similar manner found areas of hypesthesia. The frequency with which this occurs is not known.

Breathlessness is likewise a common complaint and often the sole one. It interferes altogether with the normal performance of duty, such as a route march. It may be impossible objectively to detect the symptom, but not infrequently the distress is obvious. The rate of the respiration may be much elevated, especially as the result of effort; frequencies of 60 to 80 per minute have been described. The relief from effort and the recumbent position usually are followed by the return of breathing to normal. But dyspnoea, even when the degree is so striking, does not require the patient to be propped up in the way that heart disease does. Patients sleep quite flat or on one pillow and the rate of breathing is normal. Cough and expectoration are not prominent.

There is, however, one type of case in which difficult breathing comes on, especially at night, in the form of attacks of nocturnal asthma. Such attacks are probably limited to those cases of the effort syndrome which have in addition been gassed. They are manifestations of gas poisoning rather than of the effort syndrome. They come on rather late (four to six weeks) after the gas attack. It is a form of respiratory distress which requires special mention under "Treatment."

In connection with breathlessness, are often combined the sensations of extreme fatigue or lassitude and giddiness. The sense of fatigue alone may be so great as to be incapacitating. Walking on a level for 100 yards may suffice to engage all the patient's effort. Carrying light equipment, using a shovel or rake may be quite beyond the individual's strength. Muscular tone may be low. The patient is then unable to resist the examiner's effort to extend the arm when he has previously been directed to hold it flexed. The muscular weakness may indeed be general.

Giddiness is a very common complaint. It is a type in which objects external to the patient apparently do not tend to circulate about him; it is expressed rather as a desire on his part to steady himself against the impulse to fall. Black spots and other abnormal visual phenomena, common in the vertigo of hypertensive circulatory diseases or in chronic nephritis, are not prominent complaints.

Attacks of fainting occur in a moderate number of men. Sometimes consciousness is retained; more often it is lost.

Cardiac palpitation is a common symptom. It may accompany elevation of the pulse rate, but it need not do so. It may persist during rest.

Examination of the patient brings out a number of signs in addition to those to which the patient has attracted attention. Prominent among these are tremor, sweating, and tachycardia. The tremor is coarse and is a shake rather than a tremor. It involves not only the fingers and hands, but occasionally all the extremities and the head and the entire trunk as well. Patients who have it in a marked degree, and have the anxious facies as well, present

a distressing picture. But the importance of the tremor, striking sign that it is, is easily exaggerated. Examples of it are widely distributed. It may occur in men who give no evidence of suffering from the effort syndrome. It is found in fact in great numbers of men who have never been away from a base port; on the other hand, it is entirely absent in equally large numbers of men who have served fairly long periods in the trenches and have sustained wounds. When it is associated with the effort syndrome, its prominence overshadows the picture, but in spite of that it has not, for the reasons given, been found valuable as a guide in diagnosis nor as an index of progress in treatment.

Profuse sweating is common, even when the weather forms no adequate reason for it. Sweat may stand on the face and drop from the axillæ. And there are other evidences of hyperactivity of the skin such as for instance, the occurrence of weals on stroking. The occurrence of head zones, both of hyperesthesia and hypesthesia, has already been mentioned.

Of special interest is the examination of the heart, to which most of the symptoms, as pain, breathlessness, tachycardia, fatigue, are naturally referred. The pulsation of the pre-cordium is often striking and may extend as a wavelike motion over two or three intercostal spaces. The thrust forward of the apex impulse may be especially forcible. It is often in fact felt to be so. A thrill is not felt, but very frequently the impulse is not the simple, single thrust normally experienced, but rather is split, giving the impression of a major thrust split into a succession of ill-defined minor parts. One is reminded of the thrill in presystole of mitral stenosis. But the thrill in mitral stenosis differs distinctly from this, especially in the matter of its timing; this one, due no doubt to overaction, occurs distinctly in systole, at the time of the first sound. A single sharp shock, synchronous with the second sound, is also often felt both at the apex and at the base. In size the heart is not enlarged; indeed measurement^a made from tele-Röntgenograms show that it tends to be smaller rather than larger than normal. An exact statement of size is, however, difficult to give. Normal size depends on the nature of the individual's activity. It is generally admitted that in the soldier on active field duty the average size is usually greater by 2 cm. than was his heart before enlistment. Estimations of size should take this fact into consideration. The expected total transverse measurement may be given as between 11 to 13 cm. It is doubtful whether in the effort syndrome cases, taking these facts into account, enlargement takes place. The precautions already urged in estimating the size of the heart apply, of course, equally here. On auscultation much difficulty has been experienced, in distinguishing what one hears from the signs of mitral stenosis. The first sound is often unclear; it has, as one might have expected on palpation, a serrated quality, the serrations being equal, confined within the limits of the first sound and replacing it. But it is precisely these serrations that cause confusion with the presystolic murmur of mitral stenosis. It need not be pointed out that serrations in the first sound are not the same as the crescendo murmur before that sound.^b When the rate of the heart is elevated, as is so often the case, the difficulty of accurate auscultation is naturally increased. Usually the second sound is not accentuated either at the apex nor in the base areas. The absence of accentuation is a sign of value, for although the following can not be said always to be true, it is nevertheless generally the fact that where mitral stenosis is actually present the second sound is accentuated. The liability to confusion is emphasized because the error in diagnosis has frequently been made and has wrought harm not only to the service but also to diagnostic standards. Occasionally the diagnosis of mitral stenosis is made because in recent years students and physicians have been urged not to fail to make this diagnosis even if the rumbling presystolic murmur is absent. They have been told that a snapping first sound suffices to establish the presence of the disease. The warning is proper, but insistence ought also to be laid on the fact that then an accentuated second sound should be looked for and be found present. It is not contended that the diagnosis of mitral stenosis can not or should not be made unless the characteristic murmur is present. The murmur is in fact not always present. But insistence should also be laid on the fact that then the diagnosis be made after due attention has been given to the history of the patient and to exact auscultation. Anxiety to avoid one error has led many into making the other.

^a Medical Research Committee, Special Report Series No. 8.

^b It is appreciated that insistence on the crescendo character is not quite proper, for, as Gerhardts has pointed out, the crescendo character of the murmur is not a property of its own, but is lent to it, because it terminates, when the P R time is normal, in a sharp first sound.

On occasion it is a difficult matter even after all precautions have been taken to be certain that a presystolic murmur is present. Various maneuvers have before now been recommended to make it evident; such as altering the posture of the patient holding the breath, undertaking exercises. Morison and Lewis (personal communication) have recently lit on another method, which they say is effective in certain instances. They lay the patient in the recumbent posture and place the bell of the stethoscope at the site where it is anticipated a presystolic murmur may be heard. The patient then inhales 3 minims of amyl nitrite. During the first 10 to 20 beats the only change heard is an acceleration in rate; during the second 10 to 20 beats, the anticipated murmur may appear; during the third 10 to 20 beats the murmur usually disappears. The duration of the test is short. Auscultation must be practiced continuously throughout its performance.

The effort syndrome is not associated with a disturbance in the rhythm of the heart. Regularity, except for sinus arrhythmia, which is a normal phenomenon is maintained. Although the affection does not involve a disordered action of the heart (D. A. H.), irregularities may naturally be found, as they are found accidentally in any large group in the community, but they are not a factor in the syndrome.

The rate of the heart beat is usually accelerated. The range (Table I) is between 90 and 110 in 46.2 per cent and between 110 and 130 in 26 per cent of the cases; or between 90 and 130 in 72.2 per cent of the cases. These figures are taken from Hume. There need be no elevation, as the table shows. It is perhaps important to point out that the rate tends to be unstable. In the same individual it may on the same or on successive days fluctuate between wide limits. Sometimes of course stability at one or another level may be maintained. The fact of instability is mentioned especially because of the tendency to use cardiac rate in estimating prognosis.

The significance of the affection we are considering has been the subject of a great deal of speculation. Certain suppositions in regard to its cause may be dismissed immediately; the importance of others must be weighed. And first may be dismissed the thought that there are racial predispositions toward its occurrence. During the war, cases have been found in all the armies, central as well as allied. And among the Allies it is found in Hindustani, Scotch, Irish, Welsh, Canadians, Australians, and New Zealanders. No race domiciled in the United States is free. It is found in nonsmoking peoples, like East Indians, as well as in smokers. It can not, however, be said that smoking is harmless, so far as aggravating the condition is concerned. Investigation has not shown that it is dependent on a specific infecting organism, nor is it always associated with the occurrence of trench fever or rheumatism. Many who have both diseases have not become subject to the effort syndrome. The liability, however, of men who have suffered from infectious diseases, and especially from trench fever, to suffer from the effort syndrome should not be overlooked. A point of especial importance relates to the tendency of trench fever to recur. Attacks are known to come on after afebrile intervals. The recurrences must be taken to indicate the possibility of residual infection. In view of the fact that on occasion tachycardia and its attendant symptoms are alone manifest, the infection itself may be regarded as involving the heart. It will be recalled that occurrences exactly similar are encountered in convalescence from typhoid fever, dysentery, influenza. The relation of the effort syndrome to acidosis is too vague to attach importance to the few uncertain experiments which have been reported. By the method of respiratory analysis Wilson and Levine (personal communication) failed to find that a deviation from the normal exists.

Of more importance is the possibility of the disturbance of thyroid secretion. Symptoms associated with Graves's disease are in some respects like these found in the effort syndrome. The symptoms in common are nervousness, tremor, and tachycardia. In the effort syndrome exophthalmos or thyroid enlargement are usually absent. There need be no diarrhoea. Tachycardia may be absent. The tremor is really no tremor, but a shake, and attains degrees of severity never seen in the most advanced cases of exophthalmic goiter. On the other hand, when tachycardia in Graves's disease develops to as high a rate as is attained in the effort syndrome, there is usually a certain degree of dyspnoea as well, and the size of the heart is definitely increased, whereas there is no reason for believing that this occurs in the effort syndrome. Between the conditions a striking difference is observed at night. When tachy-

cardia and dyspnoea in Graves's disease are sufficiently severe to attract attention, they persist as a rule. In the effort syndrome on the other hand, both disappear. The presence of small thyroid tumors or slight symmetrical enlargement of the gland can scarcely be taken as evidence in favor of hyperthyroidism. Such enlargements occur in large numbers of persons in certain sections of the United States as elsewhere. They are not necessarily accompanied by symptoms either of developing Graves's disease or of the effort syndrome.

The fact is appreciated that in the minor grades of both conditions, the symptoms may be vaguely defined and might easily be confused. Investigations should be instituted with the view of developing specific methods of diagnosis in the early stages. Such studies should yield important results for diagnosis and consequently for treatment. In the later stages when the cardinal symptoms of both are well established, no difficulty exists. For the present, reliance in diagnosis must be placed on the symptoms and signs already described.

A word should be said about those cases of the effort syndrome which occur after gassing. Confusion has occurred in relation to them. Many gassed cases have the symptoms of the effort syndrome; many, however, have not. But both groups develop the symptoms of nocturnal asthma to which reference has already been made. They have been found to have polycythæmia as well. Barcroft and Haldane and Meakins deserve credit for having called attention to this group of patients. Both symptoms, asthma and polycythæmia, are properly ascribed to a late stage of gassing. They may, of course, occur in individuals who have also the symptoms of the effort syndrome. But it must be clearly understood that such patients are sufferers from two complaints, late gassing and the effort syndrome. The two are not necessarily associated.

The most difficult part of the subject to discuss is its relation to the war psychoneuroses. In their pronounced forms, those naturally present no difficulty in diagnosis. Neither do the effort syndrome cases without psychoneurotic symptoms cause difficulty. But there are cases in large numbers which exhibit symptoms belonging to both groups. These cases present a twofold problem one in classification or diagnosis, the other in therapy. The difficulty in diagnosis lies at the very root of the problem. There is no disposition to add new elements of confusion to the subject, but another attitude toward the subject must be suggested. It is a fact that many effort syndrome cases have not arisen *de novo* as the result of the war. The taking of proper histories brings out the fact that the beginning of the affection is of long standing. The complaints were initially too insignificant and too little insistent to require serious attention. During military service, however, the civil factors of safety fail to suffice for the individual's protection, the defect becomes prominent, and the individual suffers. The important point is that the affection is of long standing but latent. It requires a stimulus, like the stress of war, to make the trouble latent. The stimulus becomes operative in a manner already habitual to the individual; this reaction is cardio-vascular.

Those classed as psychoneurotics have a similar history. The stimulus which drives their latent defects into consciousness is the same. They differ in that their previous histories and their personal psychology predispose them to a different reaction. The manifestations of their affection lie in the domain of neuropsychiatry and require no detailed description here.

There is another group of more complex nature, the individuals in which react to the stimuli of war by more and more varied manifestations, partly psychoneurotic, partly cardiovascular. In the same way reactions may be found which are for instance, gastrointestinal or muscular. In all these varieties the stimuli furnished by the war may be similar. The reaction is a matter partly of chance, partly of predisposition.

TREATMENT

Lewis has offered a most important contribution to the methods for managing the malady, especially from the military point of view. For this purpose there was required a technic for sorting men in grades for service. He concluded that the proper way of sorting men for physical exertion was to try out the men by physical tests. It was an obvious conclusion. Lewis succeeded in doing this by a system of graded exercises. The system works admirably, as is seen by the fact that in a certain group after 11 months of service, the classification then made proved to be substantially correct. But the limitations under

which work was done at the British Military Heart Hospital no doubt prevented the introduction of additions in treatment which a consideration of the affection indicates are obviously desirable.

The variety of origin of the cases must be remembered in arranging for their management. Some are convalescents from acute infections, especially trench fever, bronchitis, pneumonia. The management of convalescence after these infections must be designed to safeguard patients from damage dependent on the relighting of their infection. Relapse after trench fever is known to occur with moderate frequency and should promptly be recognized. When it occurs, it is thought to depend on an involvement of the heart muscle. In such circumstances, physical exertion is naturally not indicated. Other cases are of men who have been gassed. Others have been of long standing and existed before the war. Still others have obviously showed no predisposition to the affection before the war. In any case, the principles of treatment are the same. The general rules of hygiene must of course be observed. The men should be made to understand that they are not ill. They should, therefore, not be collected in hospitals. In hospitals, moreover, the constant contact with disease and the suggestions arising from this contact are undesirable but unavoidable. The proper environment for them is supplied by camps under suitable medico-military discipline. It is necessary to insist on the medical rather than the military side of the management, although there should be no underestimation of the importance of military discipline. The discipline must be rigid, but appropriate to the degree of disability of the men. Occupation must be found for them, and especially occupation for their minds. It is an error to permit them to rely on their own resources alone. When this side of their treatment is neglected, they speedily become bored, listless, and undisciplined; they begin to brood on their disability until their mental background, deranged in the first instance, is worse in the last state than in the first.

In practice, attention should be given to the minor sources of infection, such as infection of the accessory nasal sinuses, the teeth, tonsils, ears. These infections should be removed. Physical exercise should be arranged for them. Three methods are suggested; drill, farm or garden work, and games. The drill should be graded according to the ability of the individual to perform it. It can be varied both as to severity and as to duration. At best, however, drill can occupy only a small portion of the day and may be supplemented by route marches. Farm and garden work can, of course, also be adapted to the capacity for endurance of the individual for work of this kind. It has the advantage of variety and may be performed without that nervous strain which the sharp orders given at drill by the drill sergeant necessarily entails. The introduction of games invites men unconsciously to undertake a great deal of physical exercise without that feeling of compulsion which attaches to the other forms of exercise. Their number may be added to and varied by the imagination of the medical officers. To the forms of exercise may be added, if the facilities are presented, training in occupations of use in the Army. Advice as to these must be sought from time to time. Men are constantly wanted as stenographers, typists, telegraphers, mechanics in gun, automobile, or wagon repairing, railway attendants, and hospital orderlies.

The mention of disturbance in mental background leads naturally to a consideration of the share neuropsychiatrists must have in the treatment of certain of the cases. In point of fact, even when the symptoms are predominantly cardiovascular the neuropathic side of the picture is frequently prominently developed. The importance of this side of the therapeutic problem, if neglected, may actually increase during the period of treatment. The requirements for aid in this direction vary. The difficulties may be mimetic or inherent in the individuals. And again some men, reticent by nature, are troubled, in the attempt to suppress interest in their symptoms, by dreams of an uncomfortable kind.

It has been the purpose of this exposition to indicate the general features of this affection of soldiers. The attempt has been made to show how involved the symptom complex is, and how it touches intimately other domains in medicine aside from cardiovascular. Its etiology can not now be conscientiously indicated nor its exact relation to the numerous processes involved, which are familiar and the connection of which with this entity immediately suggest themselves. It is impossible to lay down rigid laws for treatment; they may be done only when the exact pathological physiology is established. But suggestions are

made for dealing with the problem not only for the purpose of sorting, which is purely military, but also for the purpose of therapeutic improvement, which is the aim of clinical medicine.

Army Sanitary School No. 138.

GENERAL ORGANIZATION OF THE MEDICAL CORPS OF THE FRENCH ARMY

By Major General Ruotte, Medical Corps

(Translation)

Gentlemen, the object of this lecture is to lay before you the organization of the French Army Medical Corps (*Service de Santé*), not as it was conceived at the beginning of hostilities or even before, when the regulations for the Medical Corps in the field were issued, but as it exists to-day, adapted to the newly created needs that the present war has brought forth. I shall try to make it as brief as possible, so as to give you a general view, a comprehensive outline, after which you should be able to fill in all questions of detail which we can not deal with now.

Regulations for the Field Medical Service had been framed upon notions which at that time were considered universally accepted truths, demonstrated by experience; yet observations made throughout nearly four years of warfare have shown that those same truths were just about so many errors, errors as undeniable to-day as these "truths" were undisputed heretofore.

Of these old axioms the principle were:

(1) A rapid war of movement, forcing a provision for light, mobile formations, which would not encumber the Army in its movements, and which from their character and manner of function would supply themselves largely from the locality in which they were cantoned by requisition.

(2) A number of casualties incomparably lower than that observed in almost all previous serious encounters.

(3) Asepsis or trivial infection of the wounds, the majority of which were from bullets, very rarely from shell and shrapnel, with only secondary infections to fear; hence it was sufficient to protect these wounds from the outside inward in order to prevent the serious danger seen in previous wars. As a consequence, surgical intervention was reduced to a minimum and consisted in early dressings and evacuation to the rear, the "packing up and sending" of the wounded, to quote a current expression of that day.

(4) Observance of conventions protecting the wounded and prohibiting the use of certain methods of warfare.

You have already refuted for yourselves those old axioms with the new facts furnished by this war. Nevertheless, let us consider these facts:

(1) War has been a stationary affair, immovable units were obliged to little by little increase their means of action in order to cope with all problems which demanded of them a solution.

(2) The number of casualties has attained a proportion heretofore unsuspected; wounds by large-caliber projectiles have been far more frequent than those caused by bullets. The dream of the humanitarian bullet has vanished at the sight of the dreadful infections com-

plicating such traumatisms, which to prevent has necessitated an earnest treatment immediately following the production of the wound. Hence the necessity for reducing as much as possible the time elapsing between the traumatism and its surgical attention.

Finally, conventions have been more or less rejected and we have had to face in addition to bullets and shell splinters the vesicant and poisonous gases which have laid additional and unlooked for obligations upon us.

Therefore, the medical service has had to adapt itself to meet the problems presented by these new factors, utilizing to that end the experience furnished by daily observations—experience which was not to be had at the outbreak of hostilities.

If the general lines covering the handling of these problems have not changed radically from those laid down at the beginning, there have taken place important modifications in the whole plan, as I hope this lecture will show to you.

To set in order our study, we will divide our subject as follows: Personnel, organization for treatment, organization for transportation, for supplies, of sanitary units, and of vital statistics.

Distinction between service at the front and service in the rear.—The front comprises everything which assures an adequate service in the armies; the rear, everything which assures such service in the territory divided for this purpose into regions.

I. SERVICE IN THE REAR

The chief surgeons of the "Service de Santé" for each region, corresponding geographically to the territories occupied by the army corps in time of peace, provide for the administration of the service in each of these regions, both from the standpoint of personnel as well as of hospital units; they provide for the admission and hospitalization of all sick and wounded which have been evacuated into the interior from the zone of the army, and they control the personnel in the rear liable to be sent to the front to replace the losses ceaselessly occurring.

II. SERVICE AT THE FRONT

Personnel.—At the outbreak of the war the personnel of the military Service de Santé was rated as follows:

Armies in the field:

1. Surgeon inspector general, head of the medical service of all the armies and personally charged with the general direction of the Service de Santé of the armies. Under him are the chief surgeons of each separate army.

The latter have under their immediate command (1) the chief surgeons of the army corps; (2) the chief surgeons of the lines of communication; (3) the chemical and bacteriological laboratory of the army.

Each corps chief surgeon commanded (1) the corps litter-bearer group (*groupe de brancardiers de corps*); (2) the division surgeons.

The division surgeons had under their orders (1) the surgeons of the combatant divisional organizations; (2) the commanding officers of the *groupe de brancardiers divisionnaires* (division litter-bearer group).

The chief surgeon of the *étapes* (lines of communication) had authority over the army units, ambulances, evacuation hospitals, and reserves of personnel, matériel, and medicines.

The organization into groups of armies has given rise to the following modifications in the military hierarchy:

At general headquarters we find, first, an inspector general of the medical corps, a true technical adviser to the *generalissimo*, but not exercising direct control over the medical services. His rôle is to make inspections and to keep the commander in chief informed of his services.

2. A surgeon inspector, who is no longer the chief of the medical services of the armies, but who, with the title of "médecin aide major général," serves as a liaison officer between general headquarters and the chief surgeons of the newly created groups of armies, to whom he transmits orders and instructions from the *generalissimo*. The chief surgeons of groups of armies have under their orders the chief surgeons of the various armies and the chief surgeon of the lines of communication, who has replaced the chief surgeon of the *étape* for each army.

Further down, classification of grades has not changed; the necessities of war have provided for consultants, or specialists, which we will later consider.

The regimental service is going to be described in another lecture; I am going to deal with that part of the organization which, starting with the sick and wounded already transported by the ambulance companies, takes them to sanitary units different from the first-aid stations and regimental infirmaries or cantonment infirmaries.

SANITARY UNITS OF THE ARMIES—AMBULANCES AND EVACUATION HOSPITALS

a. Ambulances.—The first sanitary unit is the ambulance.

At the outbreak of the war ambulances, though called division and army ambulances, were all identical and interchangeable, at least all those created by the 1910 Regulations, for all units existent previously were not as yet provided with this new matériel. The object of such an arrangement was to avoid the work and the loss of time which would result every time an ambulance had to free itself from its wounded before it could follow its division when the latter moved on. The ambulance remained on duty with the wounded until these were all evacuated, and it was substituted in the division by an army ambulance held for that purpose in reserve. Hence, ambulances were mobile units, with nothing but rather limited material capable of being transported in a few wagons. There was added to the ambulance as soon as it became immobilized a unit called a hospitalization section, carrying mainly beds and bedding. In spite of this provision and additional equipment, the ambulance had to rely largely on the requisitioning in the locality where it might happen to have to open up. The character of war developed trench warfare; the immobilization of units was a natural sequence. Ambulances have been so modified as to enhance their efficiency considerably; matériel of the Service de Santé has replaced matériel that used to be requisitioned. A number of these reinforced ambulances have been attached permanently to the divisions, which they follow everywhere, and the number of ambulances attached to divisions and army corps has been reduced.

The number of ambulances has been regulated as follows: To a division, 2 ambulances; to an army corps, 2 ambulances not forming part of the divisions; to an army, an indeterminate number, according to the importance and composition of the army, and subdivided into two categories: (1) Ambulances of the army, strictly interpreted, with their own transportation and teams; (2) *étape* ambulances, without teams, except for the supply truck. When it becomes necessary to move them they are loaded in truck requisitioned especially for the occasion.

The number of hospitalization sections provided to reinforce the matériel of the ambulances is: For a division, 1; for a corps, 2; for an army, an indefinite number.

Animal-drawn ambulances: The personnel consists of surgeons, 5; pharmacist, 1; administrative officer, 1; medical corps attendants, 38, including noncommissioned officers; drivers, 8.

Ambulances, not provided with transport: Surgeons, 5; pharmacist, 1; administrative officer, 1; medical corps attendants, 38, including noncommissioned officers; driver, 1.

Hospital sections: Medical corps attendants, 3, one of them a corporal; drivers, 2.

Animal-drawn ambulances have seven 2-horse wagons, while ambulances not provided with transport have only a supply wagon.

The necessities of war have given birth to a new organization—the surgical automobile ambulance, whose number varies in each army, and which is designed to reinforce an ordinary ambulance, to which it becomes attached where needed; such a unit, possessing a special surgical equipment and five automobiles, comprises the following personnel: Surgeons, 10; assistant surgeons, 10; corps men, 16; nurses, 8. It further includes 1 consulting surgeon and 4 surgical sections, whose composition we shall see later on.

b. Evacuation hospitals.—As a sequel to the ambulances we find the evacuation hospital.

During the first year of the war evacuation hospitals served only their original purpose—that of receiving sick and wounded. They equipped them, cared for them, and evacuated them on sanitary trains either to the interior or to centers for the *éclupes*; they were made up of two sections, each one equivalent to an ambulance; they lacked their own means of transportation and were therefore compelled to use the railroads. For this very reason they established themselves in depots or stations.

Aside from being a burden to railroad centers, the fact that they were to be situated in depots and stations where munitions and provisions and all manner of supplies were being handled, or troops entrained, exposed them to the attacks of the enemy; therefore they have moved out of the stations and main lines and have been established on spurs of the railroads at a respectable distance from these environments; these were often laid purposely to serve these units. On the other hand, not to delay the urgent attention required for sick and wounded and to avoid the useless sending of patients to the hospitals of the interior—men who were too slightly wounded—led to the establishment of a hospital service fused with the evacuation service, which provided for the medical and surgical care of patients. Finally the appearance of vesicant and poisonous gases determined the location of a service for the gassed in each of the larger evacuation hospitals, as will be seen when we study the organizations created to combat gas and its effects.

Evacuation hospitals are indeterminate in number, being employed according to the needs of an army, needs demonstrated not only by its strength but from its location in a given sector.

We have two types of evacuation hospitals, which will probably be fused into one:

Type A, of the beginning of the war, with its own personnel and divided into two sections, each being equivalent to an ambulance.

Type B, whose personnel is formed by a fixed basic element and an element of reinforcement composed of attached ambulances whose number is variable.

We see, then, that the ambulances and evacuation hospitals form the two great technical units of the front.

We have mentioned already the fact that complexity of duties gave rise to specialization; this specialization applies to the units and to the personnel.

SPECIALIZATION OF UNITS

We have already seen how the two division ambulances are specialized units, one being surgical for the intransportable; the other medical and distributive (triage).

The same applies to army corps; one of the two ambulances is reserved for surgery with the consulting surgeon of the army corps; the other receives indiscriminately the very slightly wounded and the sick.

In evacuation hospitals, necessity has led to a certain degree of specialization. Some (Gizancourt) receive only the sick, while others have surgical services annexed and are even exclusively surgical; i. e., Mont-Frenet; that of La Veuve is mixed. In principle, however, the H. O. E. should maintain its three subdivisions.

SURGICAL AND MEDICAL SPECIALTIES

Services for surgical specialties have been created at the front.

Ophthalmology and otology are parts of a special service in each army corps, installed in an ambulance, jointly with the consulting officer of the army corps; and an army service installed in an evacuation hospital with the chief of service of the army.

Dental prosthesis is organized with one service to an army, as well as genitourinary surgery, established in our case at the evacuation hospital of La Veuve.

For contagious and venereal diseases, these are isolated services, generally at evacuation hospitals or at special ambulances kept stationary for this purpose.

There is a service for psychiatry to each army, organized in the specific region.

Maxillo-facial surgery takes place in the zone of the line of communication.

For the serious fractures, the service includes generally two units, one at the front, the other in the region, both served by one and the same surgeon; the two make up a single organism to insure continuity of care in the treatment of these wounded.

SURGICAL TEAMS

For general surgery, surgeons have been organized in teams, with a permanent personnel. These teams possess a supplementary equipment and are liable to be moved in a body.

Each surgical team includes 1 surgeon, 1 assistant surgeon, 1 anesthetist, 2 dressers or nurses. The bringing together of several of these teams to form one unit, in time of great influx, favors steady work and thus insures a large output.

ORGANIZATION AGAINST GAS CASUALTIES—ORGANIZATION OF THE TREATMENT

The appearance of gas as a weapon of war has made it necessary to adopt special measures; some to protect combatants against gas attacks, others to treat men overtaken by them.

Gas is divided into two categories—vesicant gas and poisonous gas. All gassed are directed to special units. General disturbances caused by poisonous gas are treated by ordinary therapeutic methods. Cases of irritating and caustic gas (i. e., "yperite" gas) have compelled the adoption of special measures in view of the necessity for immediately withdrawing those exposed to the continued influence of such products. I shall not deal with the treatment, but will only mention the alkaline baths and the immediate change of impregnated clothing; I shall only speak of the organization for this treatment.

To that effect, several echelons have been created.

At the regimental dressing station.—Surgeons are supplied with soap and alkaline solutions and every man has a package of sodium bicarbonate; besides there are 24 outfits of clothing to replace gas-impregnated garments, as well as oxygen bags.

At the G. B. D. (division litter bearers).—One hundred outfits of clothing; alkaline solutions, and oxygen tanks in sufficient quantities.

At the G. A. D. (division ambulances).—One station for gassed men to a division, each including 3 Bessonneau tents for general service, 5 hospital tents for hospitalization, giving 120 beds and 400 outfits of clothing supplied by the corps litter bearers.

For an army.—One army station for gassed men in each evacuation hospital, with 3 Bessonneau tents for general service and 2 hospital hangars giving 240 beds.

One army convalescent center (centre de recuperation d'armée) to each army corps, capable of sheltering 1,500 gassed cases, the majority of them slight cases.

One line of communications convalescent center (centre de recuperation d'etapes) in the zone of the etapes (line of communications).

Such are the units of the advanced zone. In the rear there are hospitals for every specialty. The task of explaining them is not ours.

TRANSPORTATION AND EVACUATION

Let us study now how these sick and wounded are taken to these units and how they are discharged from them.

From the first-aid stations, to which they have been carried by regimental litter bearers, they are taken successively by division litter bearers or corps litter bearers, as the case may be, and by the sanitary automobile sections.

Division litter bearers (G. B. D.), attached, as the name indicates, to each division, are of two different types:

Type 1, or normal, comprises:

Surgeons.....	3	Chaplain.....	1
Assistant surgeons.....	2	Dentist.....	1
Pharmacists.....	1	Corps men.....	167
Assistant pharmacists.....	6	Trainmen.....	27
Administrative officer.....	1		

The transportation consists of horse-drawn ambulances and one sanitary automobile section, besides wheel litters.

Type 2 comprises:

Surgeons.....	3	Chaplain.....	1
Assistant surgeons.....	1	Dentist.....	1
Pharmacist.....	1	Corps men.....	124
Assistant pharmacist.....	1	Train men.....	23
Administrative officer.....	1		

Army corps litter-bearers (groupe de brancardiers de corps d'Armée) comprises:

Surgeons.....	2	Chaplains (divers denominations).....	4
Assistant surgeons.....	1	Dentist.....	1
Pharmacists.....	2	Corps men.....	164
Assistant pharmacists.....	2	Train men.....	10
Administrative officer.....	1		

There is no sanitary automobile section; instead, horse-drawn ambulances.

To this unit are attached the bathing section (section d'hygiène corporelle), and the laboratory of toxicology.

EVACUATION TAG

At the first-aid station the wounded man is given a diagnosis tag or hospital card; if this has not been done, it is provided for at the triage ambulance. This card is carried by the wounded man. When he leaves the evacuation hospital, he carries an envelope tied to his buttonhole containing the hospital card, evacuation order (No. 46), hospital records in his case, a radiographic tracing of his injury, if of bone; in short, all information useful to the surgeons who will eventually handle his case.

SANITARY AUTOMOBILE SECTIONS

These form an indefinite number of 20-car sanitary automobile sections, in proportion to the needs of the army.

As a general rule, while engagements of importance are going on, the army chief surgeon must have as many sanitary automobile sections as there are divisions engaged, in addition to the division sanitary automobile sections.

In this way, carried in ambulances, the wounded arrive finally at the evacuation hospitals which, as already mentioned, serve a threefold purpose: Evacuation; admission and sojourn of sick and wounded ("hospitalization"); treatment of gassed men.

From the evacuation hospitals, the men are evacuated on the hospitals in the rear (camp and general hospitals), or are sent back to their commands after a 10 days' leave, or else, as in the case of men suffering slightly from "yperite" gas ("yperités"), they are sent back directly without a leave.

All men evacuated as far as the so-called army units are entitled to this leave, while it is refused to men not going beyond army corps units. The barracks for "yperités" (men gassed with yperite gas) in the H. O. E. is considered an army corps unit, as well as the convalescent, gas centers ("centres d'écupération").

Trains take the sick and wounded to the interior; the regulating evacuation hospital ("hôpital d'évacuation régulatrice"), which no longer depends upon the army, but the D. E. ("direction d'étapes") directs these trains to their destination.

They arrive in the interior at the distributing stations and are there given orders for their ultimate destination.

There are three kinds of trains: Permanent trains; semipermanent trains, with vestibuled cars; improvised trains, with cars for seated and recumbent wounded.

Trains leave from the regulating station at scheduled hours or upon the request of the army, according to necessity.

All along the evacuation lines there exist infirmaries and canteens which attend to the wounded soldiers en passage and help carry out and take care of such wounded men as are deemed unable to proceed further with their journey.

SPECIAL SANITARY UNITS

In addition to these basic units of the medical department, we have special units: Army laboratories of bacteriology and chemistry, supervised by the chief surgeon of the army.

Sanitary sections, two per army corps, in charge of sanitation and disinfection of cantonments.

Personal hygiene sections (sections d'hygiène corporelle), variable in number, whose mission is to operate shower baths for the men and to disinfect their clothing.

Corps organizations and other units in charge of the "disinsectization" of men and clothes.

SUPPLY

The supply of sanitary units is carried out through several agencies:

(1) *In the zone of the interior.*—Supply depots which receive from the central storehouse of the medical department and the central drug storehouse all the matériel needed for the armies.

(2) *In each army.*—A sanitary reserve of matériel and a reserve of medicine is established at the regulating depot ("gare régulatrice").

Corps and division units sent in requests to the army chief surgeon and these are verified, approved, and sent to the sanitary reserve of the regulating depot, from which place supplies are shipped on the daily train to the supplying stations, whence they are secured by the corps and division units.

Secondary depots to provide for emergency calls are established in a variable number by the chief surgeon of the army at different points of the sector covered by that army.

Vital statistics are collected by sectors. A specially trained statistical officer gathers all information concerning the dead and their probable heirs and sends it to the returns bureau in Paris.

Army Sanitary School No. 139.

VISIT TO THE HOSPITAL ST. NICOLAS, KNOWN AS THE AMBRINE HOSPITAL, AT ISSY MOULINEUX

First Session, Army Sanitary School, December 7, 1917

This hospital is devoted to the treatment of burns, trench foot, and deformities resulting from cicatrices of the skin, chiefly of the face. The hospital is an old-fashioned one of the time of the Baudeloque hospital, but is comfortable and clean. Ambrine is a proprietary preparation which is furnished this hospital gratis by the manufacturers for the treatment of all of the burns of war. It is supposed to be a mixture of paraffin with certain resinous drugs, and comes in one-half pound cakes of a dull amber color. This is melted in a special room containing water baths, from which room it is conveyed in liquid form to all parts of the hospital for application to burns. Its boiling point is about 230° C., and great care is taken that the temperature shall never rise above this to avoid fire. In fact the heating of this ambrine requires elaborate precaution against fire in this old, wooden floored hospital. Ambrine is an anhydrous substance, capable of conserving heat a long time without burning the skin. It is not only useful for burns but also for indolent ulcers and trench foot; it is excellent for the stimulation of all granulations, and especially for their epidermatization. Ambrine is resterilized and used over and over again. It can be heated, but not above 120° or 125° C.

In its application for burns, the usual technic is to carefully cleanse the burned area and surrounding skin, under the strictest aseptic technic, with sterile water, using rubber gloves, and sponging with sterile gauze sponges, applied by means of dressing forceps. Great emphasis is laid on the fact that at the first and subsequent dressings great care should be exercised to avoid damaging the burned flesh mechanically by rough sponging. The surface should never bleed, nor should soap be used. After this preparation the wound is dried by hot air and dry gauze and hot ambrine is applied at from 50° C. to 60° C. with a soft brush or atomizer. Having applied the first coating of ambrine, a thin layer of sterile gauze or cotton is laid upon the wound and more ambrine is painted over this. The pain is instantly alleviated, and large dressings are applied over all and held by bandages.

Redressings are done as follows:

If pus is present when the old dressing is removed, the burn is carefully washed with boiled water, to which a little peroxide of hydrogen has been added. The wound must be well dried before applying ambrine. Do this by a thin layer of gauze. This drying is accomplished best by an electric hot-air dryer held about 3 feet from the wound. Ether may be used. To test if the surface is dry, apply lightly a thin layer of gauze; this should come away easily without sticking at all if the desired degree of dryness has been attained.

It is well before reapplying the ambrine to spread zinc oxide ointment on the edges of the newly formed skin. The reason why it is so important to dry the wound is that ambrine added to water will burn. When granulations get too high apply a wet dressing of normal salt solution and peroxide of hydrogen for 24 hours. For the treatment of X-ray burns, steam for 20 minutes, by means of a special apparatus, with about half a pint of normal salt solution, applied as a spray with the steam. Now the burn was absolutely dried and ambrine was applied.

When the patient comes in freshly burned and suffering a great deal, no attempt is made to wash the wound, but it is painted at once, and at the first redressing the dirt comes away with the dressing. There is almost always pus under an ambrine dressing, but it does not seem to affect the healing. Blisters are punctured, but the skin is not cut away. These dressings are changed daily at first and later every two days. The dressing is easily removed en masse and the devitalized tissue is promptly sloughed off, leaving clean, red, healthy granulations and islets of new epidermis.

It was interesting to know that ambrine was invented by Dr. Barthe de Sandfort, and it was recommended many years ago as a remedy for burns, but not apparently sufficiently investigated by the general profession.

In burns of the first degree, for economic reasons, the parts, where possible, are immersed in a bath of paraffin for many hours at a time. Care should be taken to have all dressings very loosely applied. All cases of burns and trench foot are given antitetanic serum.

Application of this paraffin bath method for the treatment of trench foot is very interesting. They always use paraffin foot baths for trench foot, even for extreme cases with gangrene. The effect is to hasten the sloughing off of irretrievably lost tissue and to stimulate healthy granulations along the line of demarcation. Such cases are apt to take two to three months in healing. We saw some of these cases and they were proceeding rapidly to a cure. The foot bath is 6 by 16 inches and 6 inches deep. The paraffin is heated slowly by hot-water coils to 60° to 80°. The foot is left 20 minutes in the bath, then it is covered by cotton which is soaked in paraffin, making a shoe or sabot, which the patient wears until next day. When the shoe of paraffin was then removed the feet were massaged with camphor liniment and dressed by absorbent cotton. It is preferred to use this foot bath for three-quarters of an hour every day until a decided improvement, when the interval can be prolonged to every two days.

In general the treatment of burns by ambrine is very remarkable in its results. It was perfectly evident to all of us who saw the large number of cases that if the burns could be got at immediately the results were little short of marvellous, as the cicatrices, especially of the face, and the deforming contractures of the skin in other parts of the body, can be reduced to a minimum. In many of the burns of the face, which looked from photographs taken at the time to have presaged permanent and horrible scars, only the closest observation of the patients seen thereafter could detect that they had been burned. Any one who goes through this hospital will be perfectly convinced of the efficacy of covering these burns with paraffin mixture (whether you call it ambrine or not), and excluding the air.

As to their treatment of trench foot, where it can be applied in a hospital, it seems to be a most excellent method; but this can never be anything but a treatment de luxe, as this condition must be treated at the front, and ambrine can not there be thus applied, ordinarily. It was said that trench foot with gangrene could be more favorably treated with ambrine than by paraffin.

We were also shown that ambrine can be used to combat the remote effects of mustard gas burns. One man there had been burned 20 days before by mustard gas, was quite healed, and stated that the pain was instantly taken away by the use of ambrine. In this case we saw a remarkable pigmentation of the skin for all portions of the body which had been burned. Doctor Pfulbe, in charge of the work of this hospital, stated that he never uses soap to clean up burns of large areas, but in the H. O. E. at Bouleuse the burn is always first cleaned by a neutral soap solution consisting of: 2 kilos of castile soap cut up into small pieces, 10 liters of hot water. Leave to dissolve slowly by contact, filter through gauze, and add cold glycerin, 1 kilo; alcohol (90 per cent) 250 c. c. Neutralize with boric acid.

The faith of the nurses, patients, and, indeed, the physicians in ambrine was almost childlike in its loyalty. The attitude was that burns and trench foot might be bettered rapidly by paraffin, but that if ambrine were used the success was assured in the shortest time. Indeed, one of the statements made was that ordinary gunshot wounds in a state of suppuration, after all the operative procedure necessary had been accomplished, and when it was simply necessary to allow the wound to heal by granulation, healed just as rapidly under ambrine as if Carrel's method had been employed.

One of the most interesting remarks was that made concerning trench foot as we were coming out, after going through the wards, to the effect that in all cases of trench foot it can be noticed that the patient's vitality is at a low ebb; that all of these patients are sad and depressed.

We were not given an opportunity to see the subcutaneous injection of oxygen by an apparatus which not only regulates the rate of delivery but the pressure of the gas. The apparatus costs Fr. 450 for a doctor. The machine is made by Jules Richards, 25 rue Melingie, Paris. If the pressure on the dial upon the apparatus is nil it is a sign that the oxygen is entering the vein, and the needle must be instantly withdrawn and inserted elsewhere. The object is to liberate the oxygen into the subcutaneous tissue and make it effective for whatever purpose it may be used. For instance, it is believed that the subcutaneous injection of oxygen acts as a general tonic as well as a local one to tissues, and not only stimulates granulation but general health. In other words, they utilize it when "the respiratory function of the skin is reduced by burns over large areas." He states it is also a benefit in furnishing oxygen in gassed cases and in the healing of wounds. The instrument is electrically controlled and was really a very pretty one. The oxygen is passed through it from an ordinary tank. Ten cubic centimeters per minute through a needle is the usual rate of delivery. Of course, we were not prepared to accept as logical any such use of oxygen.

The last thing of note seen in this place was a matter in which there may be some value for further study, namely, the injection of beechwood creosote, removed of its irritating properties, in oil (1:15), for the purpose of reducing cicatricial tissue. The chief part of its application is the preparation of the creosote. The method was the injection by an ordinary dental syringe of this creosote and oil, at a distance from or directly into the scar tissue. We saw the results in some 50 ambulatory cases treated by this method, and they certainly were remarkable if the photographs of their previous condition are to be admitted in evidence. The scars were soft and there was a general loosening up of subcutaneous tissue. Absolutely pure beechwood creosote and olive oil were employed. The injection is performed by the dental syringe above noted or by long, fine needles, under one atmosphere of pressure, every other day. In the latter case, they work up from 1 or 2 cubic centimeters to 30 cubic centimeters at a time. Of course, the old faith in creosote injected subcutaneously for the treatment of tuberculosis was immediately revived by this method, and a large clinic for civilians was held at this hospital for the injection of creosote purified by their method for the treatment of tuberculosis. Their faith in it was complete. In injecting the creosote and oil, the operator injects only one-half cubic centimeter at a time when the injection is first made directly under the scar, but Doctor Pfulbe seemed to believe firmly in the injection of 30 cubic centimeter doses anywhere in the body, stating that scars anywhere would be dissolved by that method.

The dispensary where this treatment was going on was conducted by Doctor Le Sieur and Doctor Brisson. Doctor Le Sieur guardedly advanced the theory that overproduction of connective tissue in a scar, as in a burn (always termed a keloid by the workers in this hospital), was apt to be in persons in whom the tuberculin test was positive. Thus the effect of creosote was subtly explained in causing this excess tissue to disappear as the peculiar antiseptic effect of creosote on the tubercle bacillus was accepted as a dictum. In short "pseudo-keloid" tissue, causing excessive and deforming scars, is to be interpreted as a manifestation of serofula or skin tuberculosis, and for this the purified, nonirritating creosote in neutral oil seemed to act as a specific.

For the preparation of this creosote there is a special chemist and a special laboratory. The chemist is an excellent one, and he demonstrated to us his technique. The creosote is distilled at from 200° to 215° C. and thus the irritating phenols and the caustic substances are eliminated. This distilled creosote contains 25 per cent of guaiacol, and this percentage it should have for injection.

The olive oil of commerce is acid and its exact acidity is determined by titration against a decinormal sodium hydrate solution with phenolphthalein as an indicator. It is neutralized by sodium hydrate and to this alcohol is added. It is heated to 100° or 110° C. (because a higher heat would decompose the soaps formed by the addition of sodium hydrate into the

fatty acids and glycerin and nullify all previous work). It is now allowed to sediment and the pure neutral oil is decanted off and filtered. After this washing with alcohol it is ready for use. All bottles are sterilized before they are turned out for distribution.

(NOTE.—The alcohol is added to precipitate the soaps, and after this it is filtered and the alcohol distilled off at the temperature above noted.)

Army Sanitary School No. 140.

LECTURE TO THE MEDICAL OFFICERS, DELEGATES FROM THE NATIONAL MUNITION FACTORIES, TO FOLLOW A COURSE, IN ACCORDANCE WITH INSTRUCTIONS OF THE SECRETARY OF WAR, IN THE "AMBRINE" SERVICE OF THE ANNEX V. R. 61 (ST. NICOLAS), OF THE VER-SAILLES MILITARY HOSPITAL

By Dr. Barthe de Sandfort

(Translated by Maj. Alfred J. Ostheimer, M. R. C.)

Gentlemen, great honor has been done me by your being sent here to become familiar with a form of treatment which may seem paradoxical from certain standpoints, but which, however, is nothing but physiotherapy. Ambrine is a physical and not a chemical nor pharmaceutical agent; it acts only on account of its heat-retaining and contractile qualities. Before you enter my service, I would like you to leave behind all preconceived ideas as to the necessity of draining all wounds. You have already seen, and you will see, islands of skin form and grow, especially in those places where lymph, so copiously secreted under my shell-like dressings, is found in abundance. I have already shown you a burn of the arm where the healing process is going on much more rapidly on the posterior or more dependent surface which is bathed in lymph.

In the trench-foot cases you have seen the granulation tissue climbing over the heads of the metatarsal bones, in which necrosis had begun, and you have seen healthy tissue form about these doubtful bones. Don't stop to argue about the doctrine, but just look at the results obtained. When I discovered, over 16 years ago, the advantage of paraffin, used either alone or in association with resinous gum (ambrine), I believe that I opened up a new and most fertile field in which the work of others will far exceed my modest efforts soon to be forgotten. All that I have to say has no object other than to demonstrate to you a simple method, and one that is sure to allow nature to integrally reconstruct the tissues, solely by affording heat, protection, and isolation under my wax-shelllike dressings.

Ambrine is a mixture of paraffin and resinous gums which occurs in the form of amber-colored plates, of a slightly resinous odor; solid, and in density close to that of the paraffins. This substance liquefies at about 50° C. and its boiling point is 230° C.; this must not be exceeded because the gases then emitted are inflammable and may give rise to accidents. In order not to change its properties, we recommend slow heating by means of a low fire until a temperature of 125° to 130° C. is obtained; it is then unquestionably sterilized. It should then be kept in a water bath at a temperature of about 80° C. so that it may be used at any moment, just like a reserve supply of sterile water. Ambrine contracts on cooling. All that it is necessary to do in order to prove this contractility is to fix a graduated test tube into a small sack filled with water, and submerge the sack in liquid ambrine. It is then noted that the ambrine, on cooling, compresses the water and causes it to rise in the tube. It is easy to understand, therefore, that this physical property, which ambrine has, of contracting on cooling results in a compression of the adjacent organs and in itself constitutes a gentle and continuously compressing dressing.

Another physical property of the substance is its great caloric capacity and its ability to retain heat. Twenty-four hours after its application on the skin the temperature of ambrine is still in the neighborhood of 40° C. This can be proven in the following way: Coat the skin with a sufficiently thick layer of ambrine at 60° C. and include a thermometer, to be covered with cotton, saturated with ambrine, the whole arrangement to be hermetically sealed with wadding and bandages. If the air does not penetrate beneath the ambrine dressing, a temperature close to 39° or 40° will be registered the day after the application. What follows will better fix your ideas on this question of the prolonged conservation of heat. It

has been found that a mixture of cotton and 125 gm. of ambrine stays at about the temperature of solidification—that is, about 50° C.—for more than two hours, while a mixture of cotton and water cools off completely in 25 minutes. We have, therefore, made out of our ambrine dressing a sort of stove or incubator with a constant temperature. This is the explanation of most of the effects noted in the tissues thus protected, and placed in those conditions which are most favorable for cellular proliferation. You must have particularly noted the tolerance of the tissues for heat as applied by the ambrine method. But this point is so important that I will cite a control experiment that is a very simple one. Here are two containers, one of water, at 60° C., and the other with ambrine at the same temperature, which fact can be easily verified by the thermometer; if one puts his finger first in one and then in the other container it will be noted that the finger can not remain in the 60° C. water for more than a few seconds without feeling a scalding sensation, while, on the other hand, the finger can be left indefinitely in the ambrine. If the ambrine is brought up to 80° C. the finger can still be left in it for an appreciable length of time without burning, which is quite impossible in the case of water of the same temperature. At 120° C. immersion of the finger in ambrine is not painful and does not cause any burning; therefore, by the use of ambrine the unaltered skin can, without pain, be subjected to a heat higher than that which might be applied in any other way. The physiologic effects vary in accordance with the temperature at which the application is made. At 60° C. a dilation of the peripheral circulation is noted as well as hyperemia of the skin and a local functional increase in activity. In certain cases, when the coated surface is extensive, the application may produce a passing increase in the arterial pulse, a very slight rise of temperature accompanied by a general sensation of heat and, perhaps, even a slight perspiration.

I have often noticed another peculiarity without being able to determine its cause: Patients with very slight and hardly painful arthritic or traumatic manifestations (without actual wounds), have told me they felt a certain improvement in their symptoms after an application of ambrine. In 1905, in Professor Dantre's laboratory, I was able, together with Doctor Stodel, to control this interesting fact by animal experimentation. Several square centimeters of the skin on the internal surface of the thigh of 20 dogs were shaved, and I noted that for about an hour after the application of ambrine the most of these animals (exactly 17 out of 20) became so drowsy that it was not possible to attract their attention, either by calling them or by offering food. You see, therefore, that ambrine, although it does not contain any medication, still has a general sedative as well as a local analgesic action. Quite recently a man who had an X-ray burn, which I dressed with ambrine for the first time, told me that shortly after the application he became drowsy and in fact slept for three hours. I just mention these facts without trying to explain them, and I will now speak of the most prominent physiologic effect, which is the lessening of pain. I might show you this effect in other conditions, such as rheumatism, neuralgia, herpes zoster, etc., but I will to-day call your attention to those cases particularly connected with your course in this service; that is, burns and trench foot.

You can prove this, gentlemen, by questioning these patients one after the other; for they will all tell you that ever since the first dressing made after they arrived here they have ceased to suffer. You all know how difficult it is for the surgeon to treat burns with any amount of success, either early or late, and you have, no doubt, in the course of your careers had such patients drag on for months, and even years, waiting for cicatrization, which neither grafts, ointments, nor the various kerato-genetic products were able to bring about. When healing was brought about it usually was with some loss of function that necessitated surgical intervention, giving rise in the end to poor results from either an esthetic or a physiologic standpoint. You know how much these poor patients suffered at each change of dressings, so that it became necessary in the case of extensive burns to make use of general anesthesia. You also know how painful and how rebellious to all treatment X-ray or radium burns are. Since the use of ambrine this is no longer true. The dressing is applied and removed without pain, it does away with suffering, the scars are flexible and elastic, allowing the parts to retain movements, and being very rapidly formed, provided that the tissues have not been subjected to prolonged earlier treatment with antiseptic or strong reagents. The most brilliant results occur in those cases that are treated immediately after the accident. These burn cases come

to the dressing room without fear and without a murmur. I don't want to single out any one case particularly; I will, however, call your attention to two cases: One is a noncommissioned officer suffering from an X-ray burn of the left hypochondrium. This is several months old, and ambrine stopped all pain and has brought about a slow but regular healing of the wound. The other is a foreign patient suffering from splenomegaly, who, consequent upon many radium treatments, developed an extremely painful ulceration over the spleen. This wound dates from the month of August, 1916 (that is about six months ago), and after the first application of ambrine the patient was again able to sleep, his pain became considerably less, and healing is going on much faster than we had hoped for. You have been struck by the appearance, in the middle of these wounds, of epidermic islands, truly automatic grafts, resulting from the epithelial proliferation of the near-by skin. You have seen these islands become organized and unite with each other to form new skin in all its elements and as flexible as it was before. (All this repair goes on in a medium of lymph which could almost be taken for pus; it has a strong odor which should cause no surprise and should not under any circumstances interrupt the treatment. It is this point which will surprise you the most and it is one to which I attach the greatest importance.) Some of our dressing assistants are old burn cases whose faces are just as smooth as that of a child. The time of healing depends upon different factors; the nature of the cause of the burn, the depth of the lesion, and the general condition of the patient. It is possible to say, however, that the average duration of treatment for burns of the hand, feet, and of the face, of the second and third degrees, is 30 days, provided that the patient is in good condition, as I have frequently noted that if in the course of a treatment an intercurrent disease, such as angina, or enteritis, intervenes, the wound at once takes on a grayish appearance and healing is delayed, which proves that which I have always said. Ambrine is only a help to nature, an incubator at a regular and constant temperature so that it helps in the proliferation of these elements thus cultivated under cover if they are already vigorous, but if they are lacking in vitality on account of the morbid general condition, ambrine has no marked action. If the doing away with pain and the greater rapidity of cicatrization were the only advantages that ambrine has to offer, these would be quite enough to justify its employment. But there is still another advantage and that is the production of flexible, nonadherent scars; i. e., a reduction to the minimum of the formation of keloids. The histologists have finally begun to investigate the nature of the reparation of the tissues brought about by ambrine. We will take some extracts from the first investigation of Doctor Faure-Fremiet, chief of the histologic laboratory of the College of France, these preliminary notes being a part of the large work that he is about to prepare, after the investigations that he has been kind enough to carry out in this service.

The connective tissue seems to be like the embryonal mesoderm, the blood vessels increase and many of the (caryokinetic) figures of division appear in the cells of the walls of these vessels. The connective tissue framework is fine and delicate; there are no fibrous masses such as are found ordinarily in cicatricial tissue. The Malpighian layer is normal. It is seen to advance by cellular division and by extension, gradually covering the tissues. After ambrine is applied to a wound there is an active call for leucocytes. The serous fluid which is found is made up of an actual broth of polynuclear leucocytes with a few large mononuclears. On the other hand, on the superficial part of the unhealed area (the new reformed connective tissue) is seen a layer of polynuclear cells which seem to be degenerating and surrounded by an albuminoid material, which may be a sort of protecting covering. At all events this disappears when the Malpighian layer comes up to this level. From a bacteriologic standpoint there are few microbes after the second or third dressing, and those that are found are, in general, phagocyted (I have already shown you the photographs in colors of the negro, Medalou, whose second and third degree burns of his face and arm healed so perfectly that not a trace of the wound can be seen. The pigmentation was totally reproduced. There was, therefore, a complete restoration of the skin). Professor Letulle has also done some research work which quite confirms these conclusions in regard to the perfect healing brought about by ambrine. This rapid description suffices to show you the originality of this method, which may seem new in appearance, but which in reality is very much like the old procedures (diachylon cuirass, in Vigo, Guérin's dressing, the hot oil of Ambroise Paré, etc.). It only remains for me to point out some particulars in regard to the method of application which I should

like you to become familiar with by actual practice. It is absolutely necessary that you use the brush yourselves and do this frequently. Ambrine will be given you in the form of tablets; you will put the pounded ambrine in a container; you will melt it in a low fire so as not to destroy its properties. When you hear a slight sizzling of the liquid you will know that it has reached about 135°C ., and you will stop heating. The ambrine is then aseptic. It is not advisable to repeat this operation too often, as there is danger of lessening the efficacy of the ambrine, and after the first time it is well to melt the ambrine by means of a water bath. It is important to avoid having water come in contact with the ambrine, as unfortunate burns are brought about in this way. After having cleansed the wound, removed the blisters, and carefully dried the surface, cover it over with ambrine. To do this a soft brush is used, which is dipped into the sterile material and with which the burnt surface is rapidly sprinkled until it is completely covered. Do not bear down on the brush because you will cause pain and will bruise the delicate surface beneath which the repair is going on. Then a thin layer of cotton wadding is placed on this varnish and this is covered with another layer of ambrine so as to attach the cotton to the first layer. Then the ordinary covering of absorbent cotton and cotton wadding is bandaged on. This dressing is removed with the greatest ease. After the bandage has been cut and the cotton taken off, one comes down to the wax shell-like coat, which is incised and lifted up at the same time in order to avoid touching the wound with the instruments. The affected part comes out of this real mold without the slightest difficulty, and the wound is washed with boiled water; it is not advisable to use any strong antiseptic solution. If it is necessary to do a more complete cleansing, sterilized tampons of absorbent cotton dipped in boiled water are used, and with these it is advisable to limit oneself to a light sweeping off of the wound without rubbing or pressing. I advise you to avoid all friction and any marked stirring up of the tissues. The wound is then dried and the dressing begun as described above.

I won't go any further into this matter because you have seen and applied the procedure yourselves. You have also seen when and why we stop using ambrine in certain grayish-looking wounds and replace it by dressings, moist in a mixture of alcohol and water or in a weak solution of permanganate of potash or of oil of "gomenol." These are points in which clinical experience alone will guide you and upon which I will not dwell further. I will simply add that if healing is delayed it is best to dress with ambrine for two days, and on the third day to dress either with balsam of Peru or with "gomenol" oil. In some instances hot air may be used to advantage and even Dakin's solution. The treatment of chilblains is carried out in the same way. In order to diminish the pain of the neuritis consequent upon frostbites, I give 45-minute foot baths in paraffin melted about 60°C . A container in the form of a glass globe such as is used in an aquarium is filled with ambrine or paraffin; just now we are using paraffin, as it is less expensive than ambrine. Care should be taken that the patient's foot does not touch the bottom or sides of the container if it is a metal one. The paraffin solidifies and forms a shell-like covering which can easily be opened and removed whenever the bathed part is to be taken out. I have used ambrine with good results in old rebellious hyarthroses, in pleurodynias, in neuralgias, in gout cases, in inflammatory conditions of the testes, and in certain skin troubles. Besides in 1904 I published a certain number of observations made in the different services of the hospitals of Paris. In the case of boils and whitlows ambrine gives remarkable results; the course of the trouble is without pain; the core comes away with the dressing and no induration is left. We have a number of case reports of carbuncles in which the lessening of the pain, a rapid and easy elimination of the necrosed tissue, and complete repair of the loss of substance have always been brought about. This method is also the one of election in the case of varicose ulcers in which cicatrization is apt to take a rather long time and at all events much shorter with this than with any other way of dressing. The use of ambrine brings about cicatrization and a filling in of all loss of tissue. You saw in the ward an adjutant who had an enormous loss of substance from his left buttock. This man was sent to me after having spent some time in different hospitals, and in a short time the surface of the wound became considerably smaller. In 1914, I likewise treated a man whose shoulder had been disarticulated without leaving a flap to cover over the yawning surface so that repair was made most difficult. I used ambrine on the wound; cicatrization was very rapidly brought about under good circumstances, as you can see from these photographs. I

have also used this method in the treatment of nontuberculous fistulæ. To elucidate the mechanism of these repairs I would ask you to look at the drawing here. You will thus be able to follow the different phases which mark the repair of a wound under the influence of ambrine even when this wound is deep and uneven. The opening into the wound, whether fistulous or otherwise, is used as an entrance through which the liquid ambrine is injected by means of either an atomizer or a syringe until the waxy liquid pours out; then a small layer of cotton covered with ambrine is applied. It is well to put several layers, covering up a few centimeters around the entrance, as the general hyperemia resulting from this external shell will complete the local action of the injection. At the temperature of the body, ambrine, which was at about 90° C., becomes solid in the interior as well as on the surface, which at the same time brings about a contraction upon itself. The result is that after having become adherent to the sides of the wound for a certain time, thus exerting its germicidal and stimulating action, it is removed from the walls of the wound; it constitutes a small mold of the cavity in which it rests suspended by its connection with the outside shell formed by the skin. It is a waxy cork, a real flexible wick, or drain, absolutely sterile, which allows free escape to the outside of any liquid present or that may be formed inside the cavity. Under the influence of the temperature the walls of the cavity undergo marked changes, and in a very short time granulation begins, as we have observed in large wounds in horses where such observation was easier on account of the dimensions of all the parts concerned.

After 24 to 48 hours the first dressing is taken off; the cavity is diminished in size all all around by the thickness of the layers of granulation which now line it throughout and equally. This regularly progressive proliferation could not have been brought about by the use of a gauze wick or drain which is sure to impinge on certain spots and to miss others, as the will of the operator can not come into play in the execution of this blind procedure; and it is this point which makes our method so much better than all other methods used up to the present time for inducing granulation. Liquid ambrine penetrates everywhere equally, so then when it solidifies there is a uniform pressure and therefore equality in proliferation. In this way the production of connective tissue, advancing everywhere at the same time, fills up the wound without the formation of those irregular masses which become organized into annoying bands formed between granulations which may be some distance apart but which have grown up more rapidly, depending upon the position of the gauze drain. Upon the second application ambrine occupies only that space left by the first layer of granulations; it will be in contact with the granulating tissues for a certain length of time, thus acting as a germicide and inducing lymphocytosis. Its progressive contraction then leaves a new space open for a second growth of granulations, before which the ambrine retracts, maintaining, however, the uniformity of evolution without bruising the new tissues, checking it very slightly, as ambrine stays in a soft enough condition to give way to the pressure of the granulations. Sclerosis is going on at the same time, and it is only necessary to look at the drawings to easily follow the stages in the repair. The drain made of ambrine, at first liquid, then merely soft, grows proportionately smaller as the space left by the granulations and their organization into connective tissue becomes more and more restricted. When the fibrous tissue has arrived at the level of the entrance of the wound, the new epidermis is formed between the edges simply by their becoming united without any traction upon them, which explains the regularity and solidity of our scars. Another use of ambrine which I wish to speak of, which is not as well known as it should be, is the rapid cleansing of a wound in the advanced aid station by using ambrine. Those of you who have been working in the Army must have had wounds to dress which had to be rapidly cleansed and, if you will excuse the expression, the parts packed up so as to cause the least possible amount of attrition of the tissues, so as to immobilize the lesion, and so as to permit transportation of the patient with the least suffering. The cleansing of the wounds by this method is done mechanically. To test this, put in the palm of your hand a certain amount of dust or tobacco ash, then pour several centimeters of liquid ambrine over this; cover with a thin layer of cotton or paper, or any other substance which will become embedded in the wax; after complete cooling you will be able to remove at one time all the particles of dust, etc., which have become included in the cooled ambrine. Thanks to this material, you may also make a sort of rapidly constructed containing apparatus which, without having the

rigidity of plaster, will permit almost painless transportation of cases of open fractures even with fragmentation. It is likewise to be noted that the part done up in ambrine is kept heated, which is an important factor when transportation must be done in cold weather. Try the following experiment: Flex your fingers on the palm of the hand, submerge the hand in liquid ambrine for several seconds, then take the hand out and let it dry; on top of this thin shell place a thin layer of cotton and again dip the hand in liquid ambrine, and if you repeat this operation for four or five times you will note that after cooling the fingers are very firmly held in the position in which you placed them and that it requires a considerable effort to extend them. At the dressing station the surgeon need only split the shell and he will find a clean wound and the fragments in the position in which they were put up. I will close this short talk, gentlemen, in advising you not only to look at the photographs of the patients of this service, but also personally to make several dressings, so that when you return you will be able to make use of the ambrine method, which I am sure will be of service, and not only in cases of burns and frostbites, but also in the case of other injuries. A generalization of this method will be seen in the work which our colleague, Dr. M. Dubar, chief of ward 5, is doing at the present time. As a distinguished ophthalmologist, he is becoming able to make repairs in the case of ectropions which are so frequent in burns, by a very simple operation followed by ambrine dressings. These experiments were begun 10 years ago by the laminated Trousseau. In the same ward, Doctor Lesieur is successfully carrying out the leveling, bleaching, and making flexible of keloids, by injections of creosoted oil. Doctor Pfulbe, in charge of ward 4, will tell you of the good results that he and his colleague, Lesieur, have obtained in the rapid bringing back of the strength in those suffering from burns and trench foot by means of injections of oxygen. I trust you will take away with you, therefore, some interesting notes and ideas that may easily be applied in the organizations to which you belong.

Army Sanitary School No. 145.

LECTURE ON FIELD HOSPITALS

By Col. Bailey K. Ashford, M. C., United States Army

That there is some uncertainty concerning the use of field hospitals in modern warfare is putting it mildly. There is no medical department unit about which so much question has been raised. The first thing you hear on reaching France is that everything in this war is different from what you had been taught it would be. When you mention the field hospital in the midst of a crowd of medical officers who have been here a few months a perfect chorus of contradictory advice, opinion, and fixed ideas assails your ears. Hardly any two people agree on its proper use, no one agrees on what its equipment should be, and some believe it should be entirely abolished. A student officer came to me the other day and said: "I am completely at sea about my unit. We were carefully taught to bring our field hospital up to a certain definite standard for war service over here, and when I get here I hear that it is all wrong, that field hospitals are now being immobilized as venereal labor camps, delousing parlors, bathing establishments, gas hospitals, rest stations, dressing stations, and stations for the treatment of itch—anything but for mobile surgical advanced hospitals for which they were originally intended. What is the truth and where can I go to see something of this war? I don't want to run a medical department junk shop."

Some of our best men in civil surgery say we should be prohibited from doing any surgery in field hospitals, and it depends on the imagination of the speaker just how far he goes. Down at the base hospitals you hear men who have no experience whatsoever with conditions at the front wisely expatiating on the ignorance and unfitness of the men who insist on doing surgery in field hospitals that are not equipped for it. They usually wind up by strafing everything in front of them and by declaring that there ought to be a general order forbidding that any surgery be attempted in such places. "Send them back to us" they exclaim in a grim and saw-like voice, "and we will take care of them"—but there's the question, to send them back. Now, as a matter of fact, there is no real difference between the ability of the men at the front and the men at the big hospitals in the rear. The difference

is that each sees only the world in which he lives and supplies the rest from a mixture of prejudice and lurid imagination or from garbled stories of atrocities and incapacity of individuals he has picked up—chiefly from the soldier. The field hospital people hear about this or get expurgated editions of these fiery speeches, tempered out of politeness for their ears, and imagine the rest. The result is that when one and the other get together the barometer falls rapidly.

Now in a case of this kind, gentlemen, it is necessary that you get some facts before you draw your conclusions. The trouble with many of our people is that we draw our conclusions from our fertile imaginations when we ought to draw them from the facts.

I am going to try to put before you to-day some facts as we have seen them in a year and a half of observation of British, French, and American fronts from the North Sea to Alsace, in which we have talked with field hospital commanders and officers over and under them, as well as with all other medical officers from the humblest battalion surgeon to the chief surgeon of the army. Nor have we been limited to talking with them. We have lived amid these scenes and have seen these organizations functioning. I am going to ask you to remember what you learned about field hospitals out of a book and from training camp and their use in a war of movement. With all this, and then only, can we draw our conclusions.

In the first place war has changed, surgery has changed, everything has changed.

1. The field hospital was equipped and its tactical employment defined when 90 per cent of wounded were clean bullet wounds and troops changed their position every day. Up to very recently this war has been a war of siege in trenches, and 85 per cent of wounds have been due to high-explosive shells, or grenades, and all infected.

2. In addition to this, the range of fire has been greatly increased and especially of indirect fire, in which the reverse slope of a hill ceases to become a safe spot.

3. Visibility has been secured by means of airplanes and balloons and used against by the enemy.

4. The Cross of Geneva has been ruthlessly violated, and even well back out of gun range our hospitals have been attacked by enemy avions.

5. Military surgery, too, has changed. Once an aseptic dressing and rest sufficed to reclaim a large proportion of our wounded. Now all wounds are infected and must be operated upon as soon as possible—certainly within 12 hours if the ideal is to be approached, although operation in slightly wounded may be delayed 24 to 36 hours.

6. Radiology must be done at the front nowadays. No operation involving a lodged missile should be undertaken without it.

7. Antiseptics have given place to surgical sterilization—not by removing all bacteria but by removing the chief source, the clothing carried in by the missile, and by cutting away the dead tissue, the food for bacteria, without which they will be overcome by the living cells in which they fall. Such operations can not be complete under stress of great activity at the front, but they must be begun; and the wound well opened, and the missile and the clothing enveloping it removed.

8. Shock is far better understood because its predisposing causes are better understood. It is not merely hemorrhage, concussion, and pain that precipitate shock, but above all cold and exhaustion. Moreover the lack of rest and comfort plus the depressing influences that surround him have prepared the soldier for shock by reducing resistance—have removed his margin of safety against shock.

9. The fatal hemorrhages of other wars can be often averted by early surgical intervention and blood transfusion.

10. Only 2 to 4 of the 52 weeks of the year are ordinarily lived under combat conditions. The remainder of the time is spent in intrenched positions.

11. Rapid transportation to the first hospital capable of making men comfortable and providing modern surgical equipment for definition, operation, and hospitalization has taken the place of incomplete makeshift dressing stations and many stops on the way to the final destination of the wounded soldier. And the surgery of war has largely moved to the evacuation hospital just in the rear of the troops engaged.

12. In an attack we should prepare for at least 25 per cent of casualties, of which some will be unable to reach an evacuation hospital direct, which is the ideal, on account of distance, delay in transportation, etc., without seriously aggravating their condition or causing their death. It is for these latter that the field hospital is absolutely necessary, particularly in a war of movement by which the evacuation hospital is left farther and farther in the rear. With a near-by evacuation hospital over a good road, direct transport even of seriously wounded is preferred, but even then some must be held for operation or on account of shock at a field hospital.

The conclusions to be drawn from these facts are:

1. Field hospitals must operate farther to the rear than heretofore.
2. They must, at least in a war of movement, operate on some seriously wounded, notably chest and abdominal cases, as well as transfuse, deshoek, and in certain cases amputate.
3. Their equipment must be brought up to modern surgical requirements and their personnel must be reinforced by operating teams from the rear.
4. They must during inactivity be immobilized and made comfortable in hospital cantonments, provided with double-walled tents, good beds, and all of the dependencies necessary to supply good food, warmth, light, comfort, and amusement for the soldier.
5. They must be prepared at all times to advance or retreat with the command, carrying with them a definite part of their equipment, which can be made portable and which should be selected in advance, to permit them to carry on at another point under battle conditions. That is to say, they must be able to rapidly mobilize for movement, taking with them the combat essentials of a field hospital.

Let us see how these requirements are being actually met in this war.

First, in the British lines:

I have made a few brief notes from what is contained in that mass of literature prepared for you by this school, because I have seen it and may be able to tell you things not written there. In the first place General Thompson, chief surgeon of the first British Army, gave us a little sketch of the British field hospital. He said that the British field hospital, known as the field ambulance, is composed of two unequal divisions—a bearer division and a tent division, and that each one of these is divided into three equal parts, or sections. A section of the bearer division had 42 men and a section of a tent division had 23 men. Multiply these figures by 3 and you get the full personnel of the tent division and the bearer division. The total was 10 medical officers and 182 men, plus 49 Army Service Corps men—about 250 men—and you find that is what our field hospital plus ambulance company amounts to. He says in the old days they used to have a field hospital and ambulance company. They called them "field hospital" and "bearer company." This was in the South African War; but they found that they got to strafing each other—the commanding officers of the ambulance company and the field hospital had difficulties in working in harmony—there seems to be a general tendency to do that in all the armies—and as they didn't have time to carry on more than one war they put a lieutenant colonel over both of them and made a field ambulance out of it.

The object of the British field ambulance is to furnish a mobile operating hospital to accompany troops in the field wherever they go, and they are so equipped that they can go wherever a gun can go. That's the object of the British; the object of the French; the object of the American. There are 3 horsedrawn and 7 motor ambulances. They use the horse ambulances for the cantonment work. They use the motor ambulances to connect with the A. D. S. (advance dressing station); that is an outpost of the field ambulance and corresponds to our ambulance dressing station. The headquarters of the field ambulance is the M. D. S. (main dressing station.) The general said that the horse-drawn ambulances were useful when there was lots of mud, because they could put long ropes on the back of the ambulances and tired soldiers could hold on to them and help themselves along into camp on a long march in campaign; that they were very useful also for short hauls and to go where motors could not. He said the main dressing station—that is to say, our field hospital—was not a desirable institution at all where it was possible to get men back promptly to a C. C. S. (casualty clearing station) and, gentlemen, that is the spirit of the entire British

Army. What every man feels down in the bottom of his heart is that they don't want to send their wounded to the M. D. S., but prefer to get them direct to the C. C. S. That means that the British have never made of their field hospital everything they wanted to make of it, the thing we are failing to make of it, what we want to make of it. But when the A. D. S. is small and can't act as a good station, or the C. C. S. is very far to the rear, over a bad road or one liable to be blocked, then the main dressing station, or field hospital, becomes important, and why? Because it becomes an evacuation hospital. That's why, and that's what the French have done. They have made an evacuation hospital of it without calling it that. General Thompson emphasized the thought that all we call hospitals ought to be really hospitals in the modern sense of the war and not mere stopping places to delay a man getting in.

Now Colonel Jones, one of General Thompson's division surgeons, added a few things to that. He got to talking about the transportation, and said that in addition to these ambulances—the 3 horse-drawn and 7 motor—they have 6 general service wagons, just like our mule-drawn wagons, only they have heavy draft animals. They also have what we never had, 4 supply limbers; they even look just exactly like artillery caissons; in fact they are except that the caisson box takes dressings, etc. They have them in order to carry supplies from the main dressing station up to the advance dressing station; that is, from your field hospitals to your ambulance dressing stations. They also supply the R. A. P. (regimental aid posts), as they are called; they are not regimental posts, they are battalion posts—they supply these and are very well suited to that purpose. They are very light and quick and can go over any ground at all. He also told us that the transportation in the rear of the field hospital—from the field hospital to the casualty clearing station (our evacuation hospital) was carried on by the motor ambulance convoy. The motor ambulance convoy is a big company of motor vehicles—finest ambulances in the world; nothing like them that I have seen. There are 50 in a company and they distribute them for withdrawing wounded from the main dressing station to the casualty clearing station. They are an army unit and they are used as needed all over the army area. The French in their service call them S. S. A.—service sanitaire ambulance, I think is the real name for it. The point is that the transportation of the field ambulance doesn't transport any farther back than the M. D. S.; from there back to the casualty clearing station is by motor convoy. Now I asked another officer, an old field hospital commander, to tell me frankly what he thought ought to be changed in their field ambulance, and I was very much surprised to find that he considered it at least debatable that a field hospital is an anachronism. He believes a division should have augmented battalion personnel and augmented motor transportation companies, as well as a company of brigade stretcher bearers. He believes in taking away the tent division of the field ambulance completely; that is to say, taking away that portion of it used for hospitalization, our field hospital, leaving only the ambulance company part of the field ambulance; he believes in taking away the ambulance transportation entirely and would thus create a company of bearers; thus the ambulance service would run by means of the motor company all the way from the advance dressing station back. There are a great many things that would seem to indicate this is the proper thing to do in trench warfare, but in a war of movement I believe it would be a fatal mistake.

Let us review some of the field ambulances that we saw. I want to say that I have never seen, either in the British or the French Army, a mobile field hospital. They are all immobilized. The reason why we didn't see them mobilized was because then they were having a war of siege—trench warfare. Whenever armies come to a standstill and sit down in front of each other, these field ambulances ipso facto become immobilized. Now, it is well for us to remember always that it is force of circumstances and not any plan or army regulation that determines what should be done. Men respond to necessity along the lines of least resistance. This force of circumstances determines the plan.

I was anxious to see what the British were actually doing with their field ambulances. Their field ambulances were the only divisional medical service that they had. What happened was that about 8 km. from the front they would establish the headquarters of their field ambulance, their M. D. S. They would establish in buildings, and they generally have a very keen eye to getting a good place. The British medical officer is a very well accredited

man in his Army and it is, fortunately, an axiom in the British Army that one of the best places shall be given to the field ambulance. Consequently all the places selected for field hospitals were nice places, even pretty places.

Now here comes the spirit of the British. We have got to talk very plainly here to-day; there is no use trying to gloss over facts, and we are talking about facts. There are a number of men in our Army, I hope it is small, who think that the only things that are really necessary shall be supplied; that all things concerning the men's esthetic comfort be scrapped. I am not saying how many believe this, but with too many men it is true. They only think of "the practical things of life." A man must have so many calories. Here are canned beans, canned tomatoes, canned potatoes. There you are. Go out and sit on a manure pile and eat it; the food will do you just as much good there as at a table. You have three blankets; what more do you want? You have something to lie on—a bed sack of straw. That's the only way to make a soldier of you—give you the necessities and scrap all these fancy things. That idea is in the back of the head of the great many officers I have talked to, but it is not the spirit of the British Army. In the British Army the first consideration is the soldier's comfort. A hospital is a place where he will be made comfortable. They take into consideration not only his physical comfort but his esthetic comfort, and that's a strange thing to find in the apparently intensely practical Briton as we have seen him from our side. The British officer will do anything to make his soldiers comfortable in their mind and in their body—and in their soul, if he can. He provides them with chaplains and attaches these to the field ambulance or C. C. S.; he provides them with all kinds of amusements—games, all kinds of recreation. He is very methodical about it. He tries to keep people in good humor—goes to great lengths to do it. He insists on men being clean and takes the ground that good hygiene is nothing more or less than good habits; that no man can think well if he is dirty or slouchy; that his pride as a soldier decreases the moment he gets on a dirty uniform. And they are right; absolutely, unqualifiedly right. Therefore, you always find cobbler shops, tailor shops, etc., in all of these hospitals. Everybody shaves every day and everybody bathes just as often as they can and wears smart clothes. They generally get a château, perhaps along the side of a canal, in a wooded park, and they try to pick out what they call a restful place. I have seen some of them. In fact, one officer told me he always picked out a place for a field hospital where men would sort of forget the war, and then he went on to tell me that the night before they had been bombed and a lot of men killed in one of his wards. That's the spirit of the British Army; the comfort of the men is sought and they go to great lengths to get it.

But no people are more practical about things than the French. Some of their field hospitals are the best I have ever seen. I thought at first that perhaps they were a little behind the British, but each, in his own way, has made a mighty fine place for his men when they are wounded or sick. All the same, the racial characteristics have come out very strongly in sickness and injury. It is very remarkable to step from one to another, from British to French, and see the racial characteristics stand right out, in a hospital more clearly than in any place I know. Now we have to change in our Army very promptly before we really attain what we want to attain—the ideal. We are not making our men comfortable enough; nor is it in the mind of many of our medical officers that they should be comfortable in the sense the British provide comfort. We hustle them around too much at times; only too often we fail to think of whether they are cold or warm; whether their food is properly prepared and served or not. We have regulations covering these things, but do we always carry out the spirit of them? I am not speaking about you, of course; I am talking about what you will find too often. You will find men who will agree with what I am saying, but they won't practice it, and some who will say it isn't so from patriotic motives. Now, heretofore, the school has turned out men with these ideas of making the soldier happy and comfortable fixed in their minds. In those days we all used to go to the front and we saw these things. It requires no argument to convince a man who has once seen it. Anyone who has been through one British hospital will realize the full truth of that. And it is my unfortunate duty to-day to try to convince you without being able to show you. The conditions to-day won't permit our taking you up where this can be visualized, as we have no transportation, although we haven't given up hope of getting it by some means or other.

Now let's take an A. D. S. that I remember having seen in the first session of this school. It was in a château. There was a dressing and operating room—clean, warm, well painted, fully equipped with everything they needed for operation. You had to ask "Is this an evacuation hospital or a field hospital?"—you wouldn't know if you weren't told. It was immobile and was an up-to-date hospital and could meet modern surgical requirements. They had bucket latrines and incinerators. They always have a bucket latrine and always have an incinerator, and there is never any trouble about running them. I want to say, just incidentally, that the latrines are often near their kitchens, and they put them there on purpose. They say, "Keep your latrine clean and there is no danger at all." It makes them keep them clean. The incinerator serves to burn solid garbage as well as to burn feces. There is a man always on duty at that place. He is charged with the duty of keeping the incinerator going, and there is one by day and one by night. He is not put there as punishment, but is given extra pay for it. Now, near it is an ablution bench for soldiers to wash and shave. They get up in the morning, wash and shave, eat, and go to the latrines. That's much better than to go back in the woods. Personally I favor it very much. I never smelt a latrine the whole time I was in the British Army, nor feces anywhere, whether in hospital or anywhere else. It was sanitation under very difficult field conditions, and yet this was in the conscience of every private soldier; it was disgusting to him to be otherwise. Now the British were not always so. It is a gradual evolution of their national character from way back in London plague days. The people are really hygienic at heart. And this is the only real basis for practical hygiene—sanitation, where you convince the whole people.

There were two places in which the famous MacPherson latrine was in operation. It was a sort of adaptation of the Childs restaurant idea. They had taken biscuit tins and cut them down so that they would stand about 2 inches high, and fashioned them so there was a flange on the forward tin that ran over and hooked over the adjacent edge of another tin behind it. A little block was placed in the center under them where they came in contact, tilting the rear one backward and the front one forward. In the rear one was a square piece of newspaper. There were 8 or 10 of these imposing biscuit tin affairs on the cement floor. In front of these toilet facilities was a urine trough that led down to a soakage pit. The British soldier went in there; urinated first; went to the biscuit tin; straddled it, performed his duty; then solemnly got up and after cleansing himself picked up the four corners of the newspaper holding the feces he had evacuated and put them in the incinerator; then went back, took the forward tin which carried the surplus urine, and put that in the urine trough; and then went out. Perfect—perfect; no dirt; very neat and very nice. I asked the commanding officer how they would make a big outfit do that. He said "This is not for a big outfit." The real secret of it is this: The orderly on duty here is a fairly intelligent man. He is kept here all the time, and his orders are that if a man don't do the cleaning up himself he, the orderly, has to do it for him. The orderly selected is generally a husky man. He said if any commands come in that don't know very much about sanitation, this is a very good way to work it into their skulls.

Their kitchens were perfect. They were generally open on one side at least, and they were whitewashed inside, tarred outside. Their stoves were all blacked. They had stew stoves that we don't have—Soyer stoves, which they use a great deal for stews, etc. The point was that these places were absolutely clean, whitewashed or painted; that the cooks had white caps on, white aprons, and were always clean. You don't find somebody with a dirty old hat on the side of his head, and sleeves rolled up to his armpits, or going around with a cut-away effect of underclothing approximating the bathing suit—nothing of that sort at all. Everything was bright and clean, and they all took it very solemnly and seriously. Now, you found yourself looking in there and saying, "How do they get it so clean." The secret was they never had anything showing outside that they weren't using all the time. Now, one of the first things to learn, if you are an inspector, is that if you come to kitchens you will always find a mouthy cook or a cook's assistant that will say to you when you pick up some old piece of cracker box in a disorderly kitchen, "We need that to put something in"—always got a need for some unsightly trash around the place—brooms, brushes, combs, old shoes, etc. Now, people do have a use at times for that stuff—that's a fact; but the British don't allow those things to be out where you can see them. They have a room for such things, cupboards, or

some place where they can't be seen, as well as a clothing room for cooks and kitchen police. The place looks clean all the time; and such things have effect on the soldiers—on the appetite and the respect of a soldier for an orderly, neat-looking place. They say you ought always have a place to stow things away that are not being used every single minute, and those that are out are to be put where they came from when you are through with them. Such things are always spotlessly clean—knives sharp, well polished—everything of metal well polished, absolutely clean. They have food storehouses and their meat is separated from their bread and other things. Food conservation is down to the finest point in the British Army that I have ever seen it in my life—nothing like it. All these kitchens have grease traps: all grease, even grease from the floor, is recovered, rendered, and made into ammunition; every single bit of it, except the clean bits from the meat, which is used in place of lard and called drippings. These are small details of the workings of a field hospital.

They all have their canteen, their baths, their drying room for clothing, etc. The drying room was generally made this way: There was a Thresh disinfector in which they deloused their patient's clothing. This was always housed in and the smokestack, instead of going straight up, went across and then out through the drying room and that heated the room, and in that room they hung their clothing to dry. In connection with this they had their bath. The men went in and took off their outer clothing, passed it out to have it deloused in the Thresh disinfector, which is right there; took off their underclothing, threw it out of the window in a pile; went in, got their soap and towel, took their bath; then went into another room, got clean underclothing and got their sterilized deloused outer clothing; and then went on about their business. That was done with every single solitary man. They had a saddlery and a tailor shop. They have more artisans than we have. They run more to doing work by hand than we do. We have been running to machinery; we have been too much accustomed to having things made by machinery for us, so much so that we have forgotten the humbler trades—cobbler, blacksmith, etc. But in England they have hung onto them. They have an excellent animal corral and their transportation is simply perfect—perfect. When I tell you I saw a number—10 or 12—of their ambulances coming down a road, running a good pace with their quiet motors, slick, shiny, nicely painted, just as if they had just come out of shop, with all the metal gleaming, I said to the commanding officer, "I don't see how you get new machines." He said "Those ambulances are not new; they have been in service three years." I am not exaggerating; you couldn't have told them from new. And their harness. Their leather is pliable; it is perfect. There are absolutely no words that you could use that would be too high an encomium for the English harness. All the metal parts are highly polished; they gleam. It is a very imposing sight to see their transportation. Their wagons are always in a perfect state; they keep them in beautiful condition—much better than we do. No question about it. The care of the transportation, including the animals, is totally different from the care of the transportation of the French and Americans. After you see them yourselves you will be convinced. We attained that here at this school when we had the ambulance company here. It was easy to attain it—not by punishment but by appealing to the pride of the men. When an ambulance comes in, or harness comes in, with a lot of mud on it, their duty is to clean it right there. If the man is hungry, tired, or it is late, somebody else does it; but it is done. I have seen it in pouring rain for weeks at a time and it was done every time, every single time. That is the only way you keep your transportation in proper shape. Do you know that the French themselves have only scrapped about 50 automobiles a month for their entire Army? Now, will you please tell me how many we have scrapped for our entire Army so far?

Now, in the M. D. S. I am speaking about here, they kept their patients 48 hours before bringing them back to the C. C. S. They were wavering about how to employ their M. D. S. They had decided that all serious cases should be sent to the C. C. S. The Englishmen say if a man is seriously wounded his best chance is to get him to a C. C. S. quickly, but they sent some slightly wounded to the field hospitals, the sick, and also cases that were in bad shock or which ought to be stopped on the way back. They had three of these field ambulances per division. I saw a number of them—all very attractive, with plenty of shade, the grounds were kept well, good walks, well laid out, flower gardens provided. The men didn't lie around on the grass. All their men looked well: never slouchy, never; always had their coats buttoned

up, their buttons shined. They were an orderly, clean, God-fearing bunch, and it was a big thing to me because it was at the front, under shell fire, where men are killed from time to time. Now, don't say it can't be done in the midst of mud and ruins, because it is being done in the British Army right to-day.

Now, other things. Mind you, there is always at least one field ambulance used as an M. D. S. per division, which is not very large compared to our divisions; then in front of that they had their advance dressing station with a couple of officers and 20 to 30 men; and they rotated. Every 6 or 7 days they sent out another 2 officers and 20 to 30 men.

These field ambulances were also being used for other things. One of the things they use them for a great deal is a rest station. Now the rest station started out by being a field ambulance of the division, set aside for their slightly sick or gassed or exhausted; they sent the rest to the casualty clearing station. At the present time in the British Army they don't seem to use the field hospital for gas cases; they are sent to the casualty clearing station. This corps rest station will bear inspection, because we want to see what we can do to get something of our own from others, to imitate them or get better things. We saw one corps dressing station which was a field ambulance under the corps surgeon, but detached by roster from the division and kept there for a month or so, in sequence. They would take, say, field ambulance No. 151 for a month, No. 152 for the next month, and so on. That ambulance went in there with its entire combat equipment; but here is the point: The place for it was fixed and it had huts and was fitted up by the Red Cross, and fitted up well. They brought in the medical and surgical boxes and the personnel, but all the beds, etc., everything else, was provided by the Red Cross. They took in the slightly sick and exhausted, trench-foot cases, and cases of trench fever. They didn't do any surgery. They got their cases direct from the advance dressing station, main dressing station, or C. C. S., and this place acted very much as a sort of safety valve for the C. C. S. if it got crowded. The battalion surgeons do a great deal toward keeping up the efficiency of the men by sending them into a rest station before they get sick, men who need a rest, men who are tired out; and General Thompson said that sometimes men will sleep for 48 hours at a stretch. Its capacity is from 300 to 1,000. They give them rest, recreation, entertainments, theatricals, and plenty of open air. They return 80 per cent to their regiments in two weeks and avoided a great deal of sickness in that way. That's a good thing for us to imitate and the place for it is in our gas hospital. They were attractive places with reading and writing rooms, wicker chairs, carpets, etc. It was made as comfortable as it could be made. There was a good gymnasium, library, canteen, barber shop, and all of the usual dependencies. Every one of these places had all these things.

They would pick out a field ambulance here and there for a scabies hospital. That is important because scabies in the British Army is the cause of a great deal of inefficiency. The men get it, but they don't report it until they get impetigo or some other inflammatory skin condition, and then the average time a man is incapacitated is from four to six weeks. It is a tremendously important subject. They have got to get rid of scabies, and these scabies hospitals are very necessary. And how these field hospitals do hate it.

Let us take another main dressing station. Its capacity was 150. It was mainly in Nissen huts; no tents at all. It supplied the A. D. S. and R. A. P. stations. For the benefit of those who have just come in I will say that "A. D. S." corresponds to our ambulance dressing station, and it means in the English service advance dressing station. "R. A. P." is regimental aid post. They showed us the wonderful care of transport that I spoke of yesterday. Harness and wagons in excellent condition, looked like brand new. We also saw in this little hospital, meant to handle 150 patients, a barber shop, saddlery, canteen, baths, separate messes for officers, noncommissioned officers, and privates; incinerators, bucket latrines, beautiful kitchens; ward for medical cases and one for evacuation, and one for emergency surgery. The whole effect was that of a roadside inn. It was well white-washed, neat grounds, attractive château, etc.

At this hospital we saw what we saw at every field hospital and every evacuation hospital, that the kitchen had grease traps and that every bit of grease was saved. Ablution benches for the men, hot water for shaving near the latrine and near the incinerator, of course. The incinerator had a pipe connected with a tank which traversed the fire box, and which gave them hot water for shaving in the morning—to show what little detail the British make

use of to make their places comfortable. They had a lamp-cleaning house, harness shop, blacksmith shop, dugouts in cases of bombardment, which they had very frequently. They calculated that most men will be there only 48 hours, and notwithstanding that they had all of these comforts. I am harping on that to see if we can't create some public sentiment in our Army against this effete military plan of making men uncomfortable in order to look like soldiers. The discipline was perfect, as it was at all of these English hospitals. The only book they kept concerning the sick was the admission and discharge book, which is practically identical to the one we used to have in our service years ago.

Here is another hospital, English hospital, 4 miles from the line, field hospital, where they kept patients for some little while, an evacuation section, and a gas quarter. They had wards for slightly wounded, that digressed from the plan that slightly wounded shall go well to the rear. They had wards for the gassed. The operating preparations were perfect. Electric light and all of the little dependencies that I spoke of yesterday for the other hospitals—shoemakers, etc.

Now we come to the French Army.

We had seen a few of their field ambulances, and I am afraid we made a snapshot diagnosis that they were behind the British; we were still under the influence of the English at that time very strongly. The first one who talked about them was Professor Tuffier. Now Professor Tuffier is a very remarkable man, and all of us know him by reputation. He is a civil surgeon of a very fine type, speaks English very well, by the way; a man who is a very patriotic Frenchman; and at great personal loss—to his health—he has done much in this war; he has been throughout this war one of the chief—if not the chief—of the consulting heads in the department of the Service de Santé. Everyone has looked up to him a great deal. But he is no longer a young man in years; he has not been out under these field conditions for long periods, so he hasn't been through it from the viewpoint of the battalion surgeon. But he has done some wonderful work. He told us that all the field ambulances of the French Army used to be known as the *hopitaux de triage*. Triage has been the bete noir of the French Army. Now, gentlemen, I am going to say something here to-day that is going to be directly contrary to what you have heard some division surgeons advise from their experience in Chateau-Thierry. I don't think there is any question but that the early difficulties of the medical department of the French Army came largely from their early application of the triage. The French are great classifiers. They classify very well, but ideal classification takes time, and in striving for that ideal they lost the other ideal, which was to get the man back. Now war is a very disorderly sort of thing, and to try to carry it out by any fixed rules, to try to produce ideal conditions at any cost, makes ideally impossible conditions, ideally wrong conditions. The French field ambulance was established in the immediate rear of the fighting troops—3 or 4 km., too near to be a field hospital—established there as a triage or sorting place for all the wounded, sick, and gassed, sent there to be classified. They didn't do much of anything else but classify. From that place of course these men, being classified, were sent to the various points which were specialized for treatment of certain classes of cases. But what actually happened? If you want to see what actually happened go to the Val de Grace Museum in Paris and look at that exceedingly fine painting of a triage. It is a work of art, a beautiful thing; and there in the gathering darkness, just about as day was dying, with the wounded lying on stretchers out over the ground in every direction, in all stages of shock, without any protection at all, one or two tense doctors and nurses were going around with lanterns peering into the faces of the men to see what they had; some of the doctors taking off dressings to confirm diagnoses. They were kept under these conditions for hours at a time. What's the result? It's a block interposed in a main path to the rear without being able to remedy the condition. Perfectly unnecessary; absolutely unnecessary. It is improper to hold up all of these wounds in that manner. That's not the way to do triage. The French found that out and stopped it; but they went well into the war with it. Now instead of listening to them and modifying it as they have done, we are beginning it in the old wrong way. That kind of a triage means this: A man comes in wounded from the front. His battalion surgeon has dressed him and he would know more about him than anybody else, and he should put a diagnosis of what he has on the usual tag. That will do to get the man back to the hospital where he can be treated properly. I have

seen diagnoses such as this: "Compound fracture of the femur with probable injury to one of the principal vessels." That's enough. If that man stops anywhere on the way back they will look at it to see if he has been bleeding, but he ought to be sent direct by the battalion surgeon to where he can get proper treatment, and that's what the French do to-day. A formal triage which stops every man and makes him wait until he has been examined or only to have his tag read, without being able to apply a remedy, is courting disaster. Now this is the triage that we don't want to do in the American Army; it is the kind we are starting in to do, but it is a fatal mistake. You shouldn't do triage at any one place; you should do triage at all places, but only by reference to his diagnosis tag. Send the man in as fast as you can to get him to some place where he can have something done for him. Now there is a place where by far the most important triage is done, and that place is the advance surgical hospital for nontransportable cases and that is a field hospital; and Tuffier said "make that hospital a 200-bed hospital with 1 surgeon and four assistants." Certainly 3 or 4 km. is too close to the line; it should be 10. Now at these places of course you treat shock, hemorrhage, and all that sort of thing. You have to have a radiologist and a bacteriologist; no reason at all why you shouldn't.

Here are a few notes from General Ruotte. General Ruotte was chief surgeon of the French Army at Gallipoli. He says there are two ambulances to a division, two to a corps, and an indeterminate number to an army for reinforcement. The old French ambulance used to be an animal-drawn affair with 7 wagons; there were 5 surgeons, 1 pharmacist, 1 administrative officer, 8 drivers, and 38 enlisted men. That has been found not to be well enough equipped so they added to it the new surgical automobile ambulance, which is what they call the auto-chir. You hear of that a great deal, and it is known in our Army as the mobile hospital unit. They send it up and make of it a modern field hospital, with 10 surgeons, 10 assistant surgeons, 8 nurses, 16 enlisted men, and the consulting surgeon, with 4 surgical sections. They have a portable operating, radiologic, and sterilizing outfit, on 5 trucks. He said that one field ambulance was to be used for the nontransportable wounded and one for the sick and triage.

Some time ago we went up to the Sixth Army. This was a very interesting trip because our class had seen the Fourth Army and wanted to see the Sixth, and the Fourth and Sixth Armies were the ones the Germans broke through a few days after we got out. That was the break which took the boches down to Chateau-Thierry. Now Beaurieux was one of the prettiest villages I have seen. Very old, quite romantic, fine château, and all that sort of thing, and in the basement of that château was the field hospital, or rather the field hospital and the advanced surgical hospital. We had a talk with General Laznet, a young man, chief surgeon of the Sixth Army. Very active; like General Ruotte, always out in front somewhere—that's where we found him. He said his idea was to put one field ambulance per division as a triage as near as possible to the line and incorporate with it an advanced surgical team with equipment. He manned this advanced surgical hospital with the best surgeon he could get, a crew of female nurses, provided it with 15 to 50 beds, and saved at least some lives. General Laznet was getting down to what is about right. I never saw better outfits than they had. No private hospital in Paris had much of anything on them—spring beds, spotless linen, central heating, electric light and solid comfort. All of this 7 or 8 km. from the front.

We went to Veilly. That town was pretty well smashed up, but they had a beautiful hospital in the bowels of the earth—just like Beaurieux—and 7 km. from the line. From there some of us went to a famous stone quarry where they had one of these field ambulances and an advanced surgical group. This place was quoted as being the ideal advanced surgical hospital, right under the guns of the enemy. It was very near the line, in a quarry with 20 feet protection of solid rock. They had everything they needed; heat, light, and perfect equipment; and while they had only 15 beds, the place would hold an indefinite number of men.

We went back a little farther and saw another advance surgical hospital that was in a depression on a height 8 to 10 km. from the front. This hospital had a gas quarter and two Bessonneau tents. There was a good resuscitation ward. They kept all gas cases and the nontransportable.

Now, mind you, these were field hospitals, so-called; they preserved the name field ambulance, but in reality they were advance evacuation hospitals, and this was the first echelon of the new French scheme of having their evacuation in three lines. They run about 15 km. apart. That is the best way—no question about it, it is the best. In the second echelon is the field hospital of the corps, or the evacuation hospital.

We now reached this second echelon evacuation hospital, the H. O. E. (hôpital origine évacuation) du corps. This was a large unit holding a thousand. There were 4 Bessonneau hangers which held 250 gassed and 250 wounded. One hangar was filled with the non-evacuable, and there was here an eye and ear department. The rest were housed in small Bessonneaus. This was formed by a group of field ambulances of the corps.

We now reached the group of field hospitals for medical cases. This was one of six such groups for the sixth army and was the chief one. It was well in the rear, in the grounds and buildings of a fine château, near Soissons. In fact all their field hospitals for medical cases seemed well in the rear. The château buildings were surrounded by Service de Santé barracks. This group was the headquarters of the consulting physician of the army, the medical disability board, and the army laboratory. In addition, in an isolated section of the grounds, was a hospital for contagious diseases of some 250 beds. It was an army unit, although composed of field ambulances.

On one occasion we visited a group of three French field ambulances for seriously wounded on the Aisne and near the line. It was in a château reinforced by many barracks. The park was very attractive and no expense or trouble had been spared to make it thoroughly comfortable and ornate and to provide the soldier with every necessity. It was in command of the consulting surgeon of the army, M. Okinczyk, the exponent of advanced surgical hospitals. This one was shelled at times and on one occasion five surgeons had been killed there outright by one shell. The operating group, with its groupe complémentaire de chirurgie (our mobile surgical unit), was lodged in barracks, painted white interiorly, with plenty of electric light, ample central heating, city operating-room furniture, etc. There was an elaborate shock room with electric light canvas hoods for warming patients and windows therein through which the patient could be observed and through which an arm could be protruded for transfusion while the heating went on. The radiologic room was complete. They had an X-ray operating table and outfit, with a fluoroscopic operating bonnet, and a perfect sterilization plant. The hospitalization section was neatness, cleanliness, and comfort itself—linoleum on the floor, iron bunks well made up with sheets and blankets, walls painted (they were decorated the same way in all these hospitals), flowers on the table, nurses in attendance. One of the wards was kept for streptococcus cases, all of which were isolated. There was a good pathological and bacteriologic laboratory. There was here a triage and evacuation section. Only seriously wounded were held here as a rule, and it was a true field hospital—the first echelon surgical hospital of the French. By contrast with this excellent group in which the wounded were lodged in château and barrack buildings, we cite Chalons-sur-Vesle, in many respects the most complete and best administered field hospital group we have ever seen. The site was excellent, in a large château in a wooded park, on a good road and only 5 km. from the front. Here the patients were housed in tents; the operating equipment in a château and in a couple of barracks. This operating equipment was a groupe complémentaire de chirurgie on truck and tractor; and as the operating was done in the château, the portable operation pavillion was used exclusively for radiology. The electric lighting of the hospital was from this group and it yielded 150 32-candlepower lights. Here there were 3 operating rooms and 3 sterilizing rooms. These were all white enameled, centrally heated, and well equipped. Nine operating teams worked here, each composed of one surgeon, one assistant, and three enlisted men. There was a triage here at this hospital, and from the receiving rooms operative cases were sent to the preoperating room or to shock room as indicated. There was one medical officer detached to care for the shock and preoperating room, and he did nothing else.

The evacuation section was in Bessonneau tents and one Bessonneau hangar, and had a capacity of 1,000. It was really extraordinary the amount of equipment they had lavished on these wards and their cleanliness and cheeriness.

There was also a remarkable fine gas quarter here. It had its own triage, and chlorine cases were sent to the wards direct, the mustard gas cases to the bathing pavillion. This bathing and degassing outfit consisted of the following apartments in a partition barracks: Disrobing, bathing, alkaline solution to mucous membranes, fresh clothing, history taking, ward.

This field hospital group only took gassed and the severely wounded. Its capacity was from 500 to 1,500, as needed.

Division medical field ambulance.—This was run by M. Collin, a French medical officer who had been for a long time a regimental surgeon under Colonel Thoris, whose work you know, and he had shown us on a previous visit what we shall always remember as the finest regimental station we have seen to date. This hospital was also in a château, with a large wooded park on a hill which was filled with barrack wards. Its capacity was 300 and it received sick, skin diseases, and the gassed. It, too, was a model of neatness, lavish equipment, and furnishings and scientific work.

Divisional medical field ambulance.—There was a little field hospital, a divisional affair, that was devoted to the treatment of medical cases at Jouaigne. Beautifully situated; it was as pretty a country as I have seen. That hilly country invaded by the Germans is very, very beautiful; and this little hospital was in a château in a park, very comfortable, and devoted to medical cases. Its capacity was 400. It was installed in barracks and in the château itself. I was told there that they divided their cases into the slightly ill, not to be kept more than six days; the cases of incipient tuberculosis, and into other contagious diseases. I found out that this was the first place to which men suspected of tuberculosis came, and they had a radiologic outfit for medical diagnosis of these cases and heart cases. The tubercular never return to the front. The closed cases are sent to work in the rear, somewhere in the base sections, and the open cases are sent to sanatoria. They had a section devoted to the treatment of the ordinary diseases, and the chief diseases seen at that time were influenza and its dependent complications. At that time they were having an epidemic of three-day fever, and they had some very serious cases of pneumonia and pleurisy. Near this hospital was a rest station for officers in a large château, a perfect beauty, where they had all the comforts of home, and a mighty luxurious home, at that. We found both English and French here.

The division field ambulances near ———.—One was for slightly wounded and sick and the other for seriously wounded, with a *groupe complémentaire de chirurgie* attached. The latter was in a large seminary and was most excellent. The other was poor and in barracks. In addition a special army surgical hospital of 320 beds was provided for overflow and serious cases. It was of *Service de Santé* barracks and was also a good example of comfort and completeness. There was a section of this hospital devoted to the ambrine treatment of the burned.

Group of field ambulances for gassed and slightly wounded.—This was in a cantonment area; a rest area. It had a Bessonneau hangar for sitters, a barrack hospital, and a complete operating group with sterilizing, radiologic, and preoperating wards.

Field hospital in ———.—This was only 2 km. from the German trenches and was sheltered in old wine cellars under a municipal hospital. It accommodated 60 patients; but while excellent in equipment and neatness, it was too near the lines and in time of bombardment was cut off. Besides it was on a devious path to the rear. It was a triage and advanced surgical hospital, but the disadvantages of having a triage so near the lines and in an out-of-the-way corner of a ruined city were pointed out very clearly to us. Time was wasted in getting to it that might have been better employed by sending the wounded direct to the rear.

Fracture hospital.—This was also in a fine château on a wooded hill, which was well parked and full of flowers. The wounded were in *Service de Santé* barracks. While every city hospital accommodation was provided under beautiful country surroundings and it was neat, clean, and well equipped, it was too far from the line, and all cases arrived infected. Its capacity was 400.

Visit to the ——— *sector.*—Here the field hospitals were, as in the Sixth Army, frankly grouped as evacuation hospitals. They were, however, still referred to as "field ambulance

groups." One, 10 km. from the front, was fully immobilized in Service de Santé barracks and had a specially constructed operating group. It was as orderly and complete a barrack hospital as one could wish to see, and a feature of the place was its landscape gardening and comfort, even luxury. Its capacity was 1,000, and it received the gassed and the severely wounded. They had female nurses, the usual triage, an exceptionally good deshoeking plant, and operating teams.

The last field hospital I have to call your attention to was at Jouchery. This is destined to be a historic site for military and civil surgeons, for it was here in this little barrack hospital that Lemaitre, the father of the primary suture, bravely worked out under surgical conditions, without radiology or bacteriology to help him, in the face of almost insuperable obstacles, the greatest contribution of surgery to war. It should not be forgotten that it was not in a base hospital, nor even a big evacuation, that this great light to surgical practice was kindled. It was in a modest, even poor, little field hospital within gunfire of the enemy, and it was done by a man who was a plain field hospital man, who had never advanced any claim to being a great civil surgeon. The hospital when we visited it was a tiny affair compared to the splendid big institutions we had seen. It was complete and neat, of wooden barracks on three sides of a court, in the center of which was a Bessonneau tent for the triage, dressing room, preoperating room, and shock room. At this date all of the progress of military surgery was represented—a radiologic room, bacteriological laboratory, etc., but it reminds me of a toy hospital. It bespoke its poverty, but it was clean, cheery, and ornate. I was accompanied by Lemaitre himself, who though promoted to a professorship in the French Medical School, with a huge operating clinic at the H. O. E. of Bouleuse, preserved for it an affection and enthusiasm which was very touching. He exclaimed as we approached, "That is the ideal. Give me a little place like this and my devoted little band of assistants that stuck loyally to me all through the early days of the primary suture, and all alone off here I can do more than if I had the biggest institution in the French Army." There was something very human about this that appealed strongly to me. The big things are often done in these small, poorly equipped places.

At that time M. Okinczye was in command. He had been transferred here from the hospital where we had first seen him. The personnel was 5 medical officers, 1 radiologist, 1 administrator, 1 pharmacist, 42 enlisted men, and 15 drivers. No feature of an evacuation hospital was missing; its capacity was 400. There were two operating rooms. The slightly wounded are classified here as donors for transfusion, but with this exception only the seriously wounded are brought here.

Major Okinczye assembled our student officers in the receiving tent and gave us a short talk on the work of a field hospital in war. It was short, but I believe that it synthesized all that can be laid down as doctrine for the surgical use of field hospitals from the professional standpoint. The field hospital should be primarily for the treatment of the nontransportable; that is to say, for those who can not be moved farther without endangering their lives or seriously aggravating their condition. Such are:

(1) Those suffering from or in danger of a recurrence of hemorrhage, requiring ligature or transfusion, or both. No man should even be evacuated to the rear from a field ambulance with a tourniquet on.

(2) Those with chest or abdominal injuries.

(3) All cases of shock.

(4) Certain compound fractures, especially of the thigh, all of which should be here stopped, carefully examined as to shock and their splinting, and only sent on when it seems safe to do so.

At these hospitals one can not expect to get through without losing at least 30 per cent of the wounded. This brings down the mortality of the evacuation hospital and takes a tremendous load off their operating staff, as they have to spend so much more time on such cases. Besides, as he rightly says, the nontransportable are nonevacuable also and would have to be held at the evacuation hospital anyway. They are also popular with regimental surgeons who, in the confusion and hurry of the front, are unable to handle these desperate cases and unwilling to expose them to a long trip.

Now, gentlemen, we are ready to apply what we have seen—these things that I have cited are facts that we needed before we could really discuss what we are going to do with our own field hospitals. Now take our field hospitals as they are. They are not equipped for this war, but they are being equipped. There are some who think that the field hospital should be a divisional unit and should be looked to to do emergency surgery at the front, and there are many very excellent men here and in the United States—natural leaders in the States in surgery—who say that we divisional people should not be intrusted with the surgical care of the wounded. True this sentiment is not expressed as plainly as that, but it is there. But what are the facts? Are they right about it that we are not equipped; that we haven't got the experience as a class of men? They may be. Some of us, individually, may be very fine surgeons; but, in general, the general practitioner is not equipped to do the delicate work on these desperately wounded men. * It is naturally right and proper that some experience be required of those who are to do this kind of work—that is to say, it is the business of an operating team, or more than one team, at these field hospitals; and it should not be resented by us that we should be required to show our fitness for this delicate surgical work. But we will answer them, as we all will, that we will learn their game; that we are going to fit ourselves to carry on at a field hospital; that we will learn how to do this work from their leaders, through teams. That's the whole question and that is the idea of this school. Surgeons are none too plentiful as it is. I know of one division that organized five teams from their own personnel and had to lend three of them to evacuation hospitals in their rear. We are endeavoring to bring together the base people and the front people, that we may get good cooperation. All the men at the front were at first looked upon in all armies as men capable of handling only emergency surgery that anyone might do, and the men at the front strafed the men at the rear because they said they didn't know anything about the war. And in a way they were both right. We are trying to break that down by bringing these elements into contact, the men at the base and the men at the front, and when we do it we will have a Medical Corps that is an ideal medical corps.

Now these ideas on the field hospital are personal, collected from what we have seen in the course of a year and a half in France. But I believe this is the solution of the problem. If I didn't believe it I wouldn't give it to a class of medical officers. We have four field hospitals. I believe two should be surgical hospitals, one a gas hospital, which, when not receiving gas cases will be receiving men who have become tired out, as a rest station, and the last should be a medical hospital, which will take in not only the current sick but which should have some control over the venereal labor camp, and the hospitals or wards for contagious diseases and skin diseases. If you will look at it in the following way you will understand: Up to the present time, in the 52 weeks of the year, 50 weeks are spent in inactivity and 2 weeks in activity. We should bear in mind that our men should be made comfortable in at least those 50 weeks and in quiet sectors and inactive periods. Conditions approximating civil conditions should prevail under these circumstances wherever possible. We should try to meet the conditions and endeavor to keep men at the front, make them comfortable and keep them from getting lost by being sent back to the rear. The field hospital should be so equipped and so supplied that it should be able to go with its division at a moment's notice, to take part in an advance or retreat, and, when it is stationary, to take care of the sick, wounded, and gassed men to the best possible advantage, and with the proper men and the proper staff it will do that. They are ordinarily immobilized, but when movement comes they should be allowed to cut loose and go ahead. There is only one way to do that and that is to have the correct medical service organization. There should be under the corps surgeon a medical supply depot of an advance nature which should be a receptacle to take care of all stuff of the field hospital which has become immobilized, which should store it and keep it against the day when it becomes again mobilized. Or, when such a thing is feasible, the corps field hospital might come up and take over the hospital which they have immobilized and work it as an evacuation hospital, allowing the field hospital to go on. The field hospital thus loses none of the dignity of its position, but becomes more important than it ever was and is not confronted with the impossible task of caring for all wounded.

Now to get down to bare facts. Our tents are absolutely improper, inadequate for this war. The Bessonneau tent is so far ahead of our tent that there is no comparison; there

is no question about it. The double-walled tent is a warm tent, the single-walled tent is a hot tent in summer, and a mighty cold one in cold weather. The Dixon is a wider tent than the Bessonneau; otherwise they are about the same. They are built on the cantilever bridge style—one portion supporting another. One could be used very well in time of activity as a triage and an office, and this is where they take the men. Why have a dinky little office somewhere else when office work is practically limited in battle to this tent, except if you become immobilized? Another should be used for the preoperating tent where men may be washed up prior to operation, prepared for operation, deshoocked, and transfused if necessary. The other 10 tents are wards. Now in addition to that we have certain other tents. I am going to give you the equipment for these surgical hospitals when they are immobilized and then tell you what things are to be left behind when the field hospital goes into action. Plus the above mentioned tents you should have one large ward tent, old type, for stores; that's the way to use up the old tentage. Another similar ward tent should be provided for a dining room; you should not require the corps men to eat out in the open, and there should be a plain hospital tent for a kitchen and one for kitchen stores. The kitchen should be under cover; the kitchen stores should be separated from other hospital stores, of course. And you should have 10 pyramidal tents for your men. It is perhaps true that they will hold 15 or 16 men, but as a matter of fact that tent will not hold more than 8 or 10 comfortably. You should have 7 wall tents for your officers because you will have more officers in this new surgical hospital than our manual calls for. Our manual calls for 6 officers to a field hospital; 1, the major, has a tent to himself. But to that number of officers you should add those of one or more operating teams. On your operating teams we will have one female anesthetist and one female assistant—we are probably not going to have male assistants to operators. These two girls will have to be put in a tent. Then there is the medical officer of a resuscitation team. Now these resuscitation teams are extremely important. They do nearly as much good as an operating team and they are fully as indispensable. There should be one radiologist and one bacteriologist with the mobile outfit. It is foolish to say you can't use a mobile bacteriological laboratory at the front—you can. The following dependencies are noted only when the hospital is immobilized: A carpenter shop; a machine shop with a "smithy"; a tailor shop to keep your men neat and looking well; a cobbler shop to keep your men well shod; a barber shop; a canteen, and separate from it a recreation hut, which should be furnished by the Red Cross; a bath; a delousing plant, and an office, because when you settle down and are immobilized you want a separate office outside the triage, which is a very noisy place for a steady diet; a laboratory; a feces and garbage incinerator with a bucket latrine, and a pack store, where you take up your equipment and keep it.

Now, this may seem like a lot for a field hospital, but if you haven't got a lot of these things your men are not going to be comfortable in the dreary days of inactivity, as comfortable as you can make them; and these things are furnished universally by the British, as I have seen them. They do it, and the French do it too, and we have got to do it. We are not doing it anywhere near enough, and we have got to do it.

Now, in inactivity—I am talking about when we are not attacking or being attacked—such a place can be kept up as a regular place for the field hospital when the division has taken a certain position, a certain sector; and until that position is changed it should be kept right up, and the corps should keep it up. When the field hospital goes out it takes with it its combat equipment and the outfit replacing it takes the rest of it over and it becomes the property of the next man. A field hospital settles down in a little town, in cellars or perhaps a château where you can accommodate lots of these dependencies or the operating equipment and you won't have to use all your tents. Generally, however, you have to use your Bessonneau tent, your admission tent, and your preoperation tent, and as many ward tents as may be needed to house your patients after houses or barracks are occupied. During inactivity, the post medical supply should be requisitioned—I am saying this advisedly and I am probably going to bring on a storm of disapproval by it. There are plenty of men who say that is theory; that this is war, and you are not back in "posts." I am not thinking about "post" life at all; I am thinking about what I have seen in war myself. They have these things in the French and the British Armies, and the men are more comfortable

by reason thereof. You don't find their men living for 50 weeks in the year on the ground or on these cold metal cots that are as cold as the ground. You don't find them eating in bunches out in the rain from their tins and canteens, with no place to go to get warm when they are cold or chilly. You find them sleeping in iron bunks, with sheets and pillowcases; and you will find there everything a well-regulated hospital should have, and there is no reason why you shouldn't as long as things are quiet. If you can get an instrument case with beveled glass, get it. If it is white enameled, so much the better. The whole supply for field hospitals will have to be revised; it is being revised right now. We have a great many things we don't need, and there are a great many things we will have to have. As it is now we have a field hospital per our Manual for the Medical Department that if taken into the field with the name field hospital attached to it, when it is only a fake hospital, we are not going to do for our soldiers the things we ought to do for them; we are not supplying to the soldier what he has the right to expect when he is in hospital. They are not hospitals; they are merely temporary shelters, with dressing station equipment, and we have got to supply a very different sort of thing for the future. Where everything heretofore has been sacrificed to mobility we have got to make a distinction between those things which we will leave behind in a move until things are quiet, and our absolute needs to provide an emergency hospital of modern type in the field of battle.

Another thing: There has been a tendency in our Army to discourage the equipment of hospitals at the front with certain comforts and certain things that please the eye and soul of the soldier. The Red Cross has been anxious to get these things in, but owing to a good many different conditions they haven't done it yet. This is the hospital where the Red Cross should be allowed to bust itself. They can furnish a lot of things that we can get in no other way, and every one would make a soldier better off. Do you remember what Crile said about the predisposing causes of shock? Cold, lack of comfort, that little by little take away his percentage of safety? And you have the answer right there. These Red Cross people should be allowed to furnish wicker chairs, games, all kinds of medical comforts, including commissary stuff; they should be allowed to decorate wards, to paint, to whitewash, to provide tables, writing materials, magazines, books, tennis balls and rackets, footballs, baseballs, bats, physical culture men if you want them for that period of inactivity. Now when the field hospital is ordered to the front in an advance, the corps medical supply depot can take over all that property not possible to carry and hold it for the unit. In fact the best way is to have a corps field hospital move into and run it as a stationary hospital. It might be possible to simply put a guard over it. A triage tent, a preoperating tent, and 12 Bessonneaus should go with the field hospital into combat. They should go on the same principle that you would transport a heavy gun, and if this augmented equipment is lost it should be viewed in the same light as the loss of big guns. You have got to have the gun to kill boches, and you have got to have your equipment to take care of wounded men so you can fix them up and get them promptly into shape to kill more boches. Your mobile surgical unit, with its equipment and, of course, your operating team goes, and your resuscitation team goes, and your personnel goes. Then you should carry on with you all those things that you know you are going to need in that battle, and somebody has got to sit down and say what should be carried forward and what should not go. For instance, you should carry gauze and cotton and Thomas splints up with you, but you needn't carry any atomizers up with you. Any of you nose and throat men know that, while it might perhaps do some good, it doesn't do enough good to warrant loading yourselves down with such things. Lots of medicines need not go.

We have got to have more of certain things; more and better instruments—no question about that part of it. They ought to have portable deshoeking apparatus, and a number of other things we haven't to-day. Now, that goes forward on the trucks that you have. You get to the place where you are going and you unload. You are going to use these trucks, perhaps, for the transportation of wounded. You don't know how long you are going to be there. The other surgical hospital behind you eventually moves ahead of you when the advance takes place. When there is such an advance the one behind moves ahead and jumps over the one in front of it and establishes itself in front in the same relative position to the fighting troops as the first one had. Then it opens and takes the wounded coming to the

rear off the hands of the first. The wounded in the first hospital being evacuated to the evacuation hospital, that hospital in the rear then moves forward to a point in front of the field hospital which preceded it, leap-frog fashion. This tandem work has been tried out in the 32d Division and has given good satisfaction in the second Battle of the Marne. It seems to be a very sensible proposition. In retreat the process is reversed. Now, when stationary warfare comes on again you can build about you with the aid of the corps surgeon the things you left behind when you were inactive.

In a war of movement the surgical hospital farthest to the front should conduct the whole triage. If your corps surgeon or your division surgeon insists on triage at one place, this is the place to do it. The triage should never be done where you can not apply the remedy to the cases that desperately need it. Otherwise it is an utter loss of time and a destruction of that man's limit of safety by exposing him to cold, to fear, and to chill. The cases that should always be detained at this advance surgical hospital are chest cases, abdominal cases—chest cases will die if you send them back with open wounds—severe compound fractures, shock and hemorrhage. That is taken directly from M. Okinezye's estimate of what this hospital ought to be used for. Here is one of the great arguments for this place: You never have assurance that you can get to the casualty clearing station, to the evacuation hospital, because, as we have seen in this last push, they are left far behind over crowded roads, with scanty transportation to get at them, and desperately wounded men at the front are utterly deprived of the proper sort of help. You have got to provide for that on the way back.

Now we come to the gas hospital. The gas hospital is rapidly taking form under the excellent administration of Colonel Gilehrst. He has an outfit, a portable degassing outfit. There are two of them to a division. It consists of a large 1,200-gallon tank of water, which is really a portable bath, and all the material necessary to do the bathing and degassing of these patients. Therefore the gas hospital should contain 10 Bessonneau tents for the accommodation of your patients—300 by crowding them in on litters—you are not taking beds with you this time—1 large old-type ward tent for stores—got to have that; 1 for a dining room; 1 hospital tent for kitchen and one for kitchen stores; 10 pyramidal tents for men, and 6 more tents for officers and nurses. You may have to cut some of that tentage down especially that for personnel, but you should hang on to your ward tents and receiving tent to do triage in, and the portable degassing outfit. Now when you get settled and things quiet down, that becomes a place where you can send men from time to time for rest, and as a rest station this field hospital should take on all the characteristics we have described for the others, with its cobbler shop, carpenter shop, etc. The number of men is the same, and the Red Cross here should be especially active to provide recreation, games, theatricals, music, comforts, etc. Now in regard to gas, remember what happened in the 26th Division—that only 10 to 15 per cent of the people supposed to be gassed really were, and the rest were only exhausted, mentally and physically. You see the gas hospital is the natural place to have a rest station, and a rest station in the strict sense of the word.

Now we come to the medical hospital. They should have 11 Bessonneau tents—1 for triage and the rest for wards; 1 for kitchen, 1 for stores, 10 tents for the men, and 6 for the officers. Same as the outfit for the gas hospital and the surgical hospital minus the degassing outfit and the surgical equipment, but it should include baths and be equipped to run skin and venereal wards. You can delouse these skin patients, but you want them separated from the others if you can. The medical hospital should have its division consulting physician, and the gas officer should have his headquarters here at the gas hospital. In that way you have within the division the head of the evacuation system offering real hospital conditions of a temporary emergency nature to men desperately needing it and who can get it only with great difficulty otherwise. I believe that is the situation as far as we can develop it in our army to-day in France. I don't believe all of these things are going to be carried out, because I am sure somebody will develop much better ideas than I have; but I believe in general the plan should be followed because it seems to me to be built on facts in this war, and it seems to me to be something which the conditions imperatively demand.

Now that finishes the consideration of the field hospital as far as I am able to give it to you, but one thing should be made very plain. Whenever nearness to the line, good roads, and a quiet sector permit, practically all wounded should go direct to the evacuation hospital

where the triage can be made. To stop a man on the way there is never an ideal; it should be only done in time of stress. Just as an evacuation hospital in a push can not operate on slightly wounded as a rule, which they send to the stationary hospital in their rear, so the desperately wounded when the roads are clogged should be taken care of farther to the front, and here triage must be done to prevent them from being carted to the wrong place or dumped in a confused heap on an overworked central hospital, such as the evacuation hospital comes to be. In fact, in a war of movement and severe operations from intrenched positions, triage is necessary, but it must not be done as it has been done. It needs an experienced officer of the best type to facilitate and not hinder the prompt delivery of the patient to his final destination for definitive treatment. The full 90 per cent of slightly wounded can be sent clear to the general hospital, 150 kms. in the rear, suffer there, from 24 to 36 hours thereafter, a surgical removal of devitalized tissue and the foreign body and a closure by retarded suture from three to five days thereafter, and their wounds will heal by primary intention, but to relieve evacuation hospitals of these cases needs a good triage officer to make it a success.

Army Sanitary School, No. 146.

THE EVACUATION HOSPITAL

A lecture by Col. Bailey K. Ashford, M. C., commandant.

All that has been said yesterday of the dependencies of the field hospital, its shops, baths, recreation huts, amusements, comforts, and ornateness apply in a still higher degree to the evacuation hospital. In fact the field hospital while stationary in inactive periods is a small evacuation hospital, differing chiefly in its portability, its size, position, and limitation to emergency surgery and medicine. The field hospital stands at the head of that system of evacuation through which alone the man can be salvaged. It is the emergency hospital of the battle field.

The evacuation hospital is the real theater of our professional effort in the field of battle. What is to be done must be done and must be done quickly, and under modern medical and surgical conditions in so far as the terrible stress of war will permit. This evacuation hospital is the pivot upon which the man's life, limb, and future usefulness turns. Here is done the urgent surgery of war, the kind that won't wait—the vital part. It must meet the demands of medical science—words, a show of sympathy, and a spiritless, ignorant imitation of the efficient technique of modern methods of treatment are worthless. They are worse than worthless, for they delude the soldier into believing that he is being handled according to the latest tenets of our profession, when, as a matter of fact, what he would be getting under such circumstances would be a poor substitute. Remember that every poorly run military hospital is a defilement on the field of battle of an ancient and honorable profession and a future menace to our standing as serious-minded, practical scientists among our own people. One is apt to forget that the war of to-day is made possible by the application of the sciences by men who possess every other quality that has gone to make successful military men in all time. If we can not apply the medical sciences to war in such manner that our results will tell against our enemy we shall fall behind all other arts and sciences and be limited to a colorless part in the victory, be limited to that function of saving life and preventing suffering in the individual which is the life of the doctor in times of peace, leaving untouched that great task—the prompt return to our fighting line of men who can be saved for future usefulness to our arms. We are not falling behind the others; we are well in the advance, but we don't want to fall behind. Even in antbellum days we were far on our way to taking an active part through sanitation in the life of the state. To do this we must be something more than doctors, we must apply the medical sciences as military officers, remembering, however, that it is the medical sciences and not the art of war that makes us officers.

The evacuation hospital used to be a mere forwarding depot to the rear. It is still, so far as that considerable number of cases fit to be forwarded is concerned, but to-day much of the surgery that would have been done back at "base hospitals" has moved up here.

There are three great departments to-day in every evacuation hospital: (1) The triage or sorting; (2) the hospitalization of those who have to undergo immediate treatment; (3) the evacuation of those who can be safely sent farther to the rear.

This has been the basic plan of most of the evacuation hospitals in the French and English Armies, but two factors have entered quite suddenly to make it perfectly plain that the organization and scope of this important unit can be modified for the better working of our medical service. These two factors are: (1) The change from trench warfare to a war of movement; (2) the possibility, in a large number of cases, of postponing the removal of foreign bodies and dead tissue to a later date.

Upon the original conception of the evacuation hospital, both of our allied armies were constructing, very near the front, larger and larger centers bearing the name evacuation hospital. The French had units of this sort accommodating 2,000, 3,000, even to 5,000 patients, and the English even went them one better by grouping "casualty clearing stations," their name for evacuation hospitals. These huge plants, equipped not only with the necessary instruments and appliances, beds, etc., but with many comforts and conveniences, were near the front, a distance of 15 to 20 km. They were totally helpless as far as possibility of moving was concerned and were exposed to the normal ebb and flow of a battle front. There was, of course, as there should be, a professional reason for their employment in this fashion, and this was the accepted doctrine that the wounds of this war were all infected and that they should all be operated upon as soon as possible to remove damaged tissue and foreign bodies before infection should get a foothold. It was argued that while humanitarian instinct leads us to give priority of treatment to the graver wounds, the slightly wounded are far more important, inasmuch as they require not only one-fifth the time for their operation but they are in this manner saved to the army and in most instances can be returned to the lines in class A condition without leaving the immediate front, thus shortening their convalescence by primary healing and vigorously reinforcing the fighting troops. The result of this reasoning was (1) an attempt to do as much operating as possible on the less severely wounded cases at the evacuation hospital and (2) the consequent very prompt overwhelming of this unit by force of numbers, inasmuch as there were never enough operating teams nor, for that matter, an adequate hospitalization section matériel to handle such a large number of cases. To complicate matters, it was better to treat these wounded by the Carrel-Dakin technique, as the time had passed for the application of Lemaitre's primary suture. But as time went on it became evident that removal of devitalized tissue and foreign bodies could be successfully accomplished in slight wounds back at the bases and that in a few days thereafter, with the check of the laboratory, these cases could be sutured and would heal by primary intention. Now came the abrupt change to a war of movement. The allied armies lost thousands of beds and many of these evacuation hospitals in the rapid advance of the enemy, and they were all at sea again with all wounded being piled pell-mell back over great distances to the base. It was here discovered on a large scale that less severely wounded men were susceptible of this same operation, which Lemaitre had insisted should be done within 12 hours, 24, and even 36 hours after this reception of their wound. It is now clear that the evacuation hospital should not attempt to operate upon all, but only upon selected cases which experience has proven should not be delayed to reach a base, and that the majority can be safely salvaged farther back. This relieves an impossible military situation for the evacuation hospital, gives it a definite part of the surgery of war to do, and takes a load from it which was daily becoming more burdensome.

Therefore, where previously an evacuation hospital was considered to be insufficient with two or three thousand beds, to-day 1,000 to 1,500, 10 per cent of which serve for hospitalization, can be considered ample in the majority of cases. However, the constantly shifting military situation demands that whatever be the bed capacity and type of construction of these hospitals, their organization must be sufficiently elastic to enable their adaptation to any tactical situation with which we are confronted. It must be borne in mind that every inch of ground in the zone of the army is at a premium, and the nearer the front we get the more valuable it becomes for purely combat purposes, especially in the vicinity of railheads. In consequence our aim should be to reduce to a minimum the amount of space we require for evacuation hospitals—throwing the burden of hospitalizing the wounded as far to the rear as possible without sacrificing the results of treatment. Thus in the case of a rapid advance ordinarily we should push forward at first evacuation hospitals of reduced size, say 400 to 500 beds. However, it is conceivable that a situation might arise, as was the

case at Chateau Thierry, where, owing to the state of roads and the degree of devastation existing, it was better to push forward larger groups of 2,000 to 3,000 beds. This elasticity can be accomplished by establishing somewhere in the rear of the armies a mobile reserve where all medical units are held up on reaching France unless needed for work at some particular place. The question of treating the very slightly wounded at a corps field hospital to which they can be directed, thus preventing their loss from their own units, should always be given the preference provided the military situation admits of such a solution.

Position.—An evacuation hospital should be on the spur of a railroad, away from towns, ammunition dumps, depots, aviation fields, and troop cantonments. It should be off by itself, well marked with large crosses and communicating by a good road with the front. Upon its isolation depends its only real chance for safety against avions, its most formidable enemy. From 20 to 30 km. now is the normal distance from the front lines for an evacuation hospital, the second in the echelon of hospitals in the zone of operations.

Capacity and composition.—It should have from 1,000 to 1,500 beds. It should be portable, a tent hospital, of Bessoneaus and Bessoneau hangars, or their full equivalent (double-walled tents). At this hospital should be packed and ready to move the nucleus of another evacuation hospital with a capacity of 400 beds. This should be complete in every particular; and when the evacuation hospital begins to fall away to the rear of the advancing army, this nucleus should be moved forward toward the advancing railhead by means of truck companies or by rail.

One truck company, or fifteen 10-ton railway cars, or one standard troop train will carry this nucleus, and 100 men can set it up at its new site, as an advance party. In fact, this nucleus can begin to functionate in one or two days from the time its first elements begin to arrive, if the distance is not over 15 to 30 km.

In the meantime the original evacuation hospital can clear itself of cases and gradually move toward the new site, building up on the nucleus to form a complete new evacuation hospital. According to Gen. Cuthbert Wallace, of the English Army, an evacuation hospital in a push can not hope to operate on more than 25 per cent of the wounded that pass through it, at least. Let us consider that 25 per cent of casualties on any one day, excluding dead and missing, will be the maximum per division of 25,000 for which we should prepare hospital accommodations. From the classification of these casualties into (1) wounded, (2) gassed, (3) sick, we have per the recent casualty list of an American division, $54\frac{1}{3}$ per cent wounded, $21\frac{1}{4}$ per cent gassed, and $24\frac{1}{4}$ per cent sick. In the last operations around Verdun the number of gassed was considerably less. This gives on this basis of 25 per cent maximum casualties of this sort a total of 6,250 divided as follows: Wounded, 3,396; gassed, 1,333; sick, 1,521. Calculating 30 per cent of these wounded as recumbent, we have 1,132. The number of recumbent cases which should be operated upon, therefore, will not be far from 400. The decision as to who shall and who shall not be operated upon admits an individual factor so variable as to be unsafe for accurate figuring, but in general we can class these cases as 120 seriously wounded, requiring 6 tables and 18 teams; 180 less seriously wounded, requiring 6 tables and 18 teams; and 100 moderately wounded, requiring 2 tables and 6 teams. Total 14 tables and 42 operating teams, an ideal not yet attained.

We are now prepared to consider the function and equipment of an evacuation hospital.

I wish particularly to harp on the fact that an evacuation hospital should provide for a certain number of cases to be kept there; because if there is one thing that the French and British have both learned in this war it is that a hospital purely for the purpose of evacuation is a failure. It is really the point where most of the big surgery of the war is conducted, and General Wallace is father of that idea in the British Army. This is not so with us; I have been through some of our evacuation hospitals where they would like to carry that out and where they haven't been able to do it, and I fear that some of them don't know that it is really necessary. Now, the rest station is a sort of a buffer for the casualty clearing station or gas hospital; if the latter isn't too full of gas cases it can take up some of these exhausted fellows and keep them off the casualty clearing station. The evacuation hospital is a sieve and can treat all kinds of cases. It should have a separate gas quarter; some think that all gas cases should be treated at the field hospital, but that isn't always possible; many of these fellows will go to the evacuation hospital of their own accord. All that I have seen have had

a quarter for gas cases, with adequate provision for their treatment—all the evacuation hospitals, British and French. As to the number to be hospitalized, it depends entirely on how much of an attack it is; on how many of these cases that are operated on stay there the full time. The more serious cases operated upon ought to stay there two weeks, or until the stitches can come out. But owing to the tendency to operate on too many, they stay there sometimes only four or five days. In general, in a chest case, and abdominal case, a knee joint case, if they stay five days you might take a risk and send them back—it certainly is not recommended. Brain cases, if they are operated upon, where they should not be, at the evacuation hospital, require a long time before they can be transported. The minimum is 10 days. The compound fractures of the thigh should stay there as long a time as you can keep them, of course. But in evacuation hospitals men have often operated on chest cases and abdominal cases and have had to send them away in 24 hours owing to the enormous throng of wounded. Of course, this isn't right, but in such a case you have got to make room for the people pouring in. Now, as I have told you, an evacuation hospital ought to hold about a thousand cases—I am speaking about the evacuation hospital of the second echelon of the evacuation system, the one that receives the general wounded, not the one that receives the slightly wounded. Tuffier has shown that a French division will have from 400 to 500 casualties the first day, 200 or 300 the second day, 200 to 150 the third day, and so on. As our divisions are so much larger, a thousand beds are not too much. At Vimy Ridge they had 8,500 go through the casualty clearing station in 5 days. We have seen that the English tend to group these casualty clearing stations together—three or four in a group. I saw one of 10,000 beds at a Canadian center, and they are a good deal like us. It was a nice hospital, first class, a hut hospital, but too large and too near the lines. They can be either of huts or Bessonneau tents. I think they should be Bessonneau tents in the second echelon and huts in the third. The English combine them because they say they economize on railroad service; they economize on X-ray equipment. But it isn't equipment so much as operators. They have had a hard time getting them. Sometimes one radiologist will actually serve two hospitals. It saves laboratory equipment; one laboratory will do for three or four hospitals. It saves on water, fuel, and light, of course.

THE ENGLISH CASUALTY CLEARING STATION

The approach to an evacuation hospital for the reception of patients.—The approaches are by hard roads, as I have said, and the hospitals are within easy reach of main metal roads and railroads. The entrances are in the form of an arc, entering by one side and going out by the other. When an attack takes place the ambulances arrive in convoys. When they get to the triage of the casualty clearing station, which is generally three long tents, one for "sitters," one for "lyers," and one for "pack store," as the English put it. The entrance is often double, triple, or even quadruple in width. This is so that four of them can get up in one line and unload at once. There is usually a big electric light with a reflector there to facilitate the unloading. At the gate as the ambulance passes out the driver hands the little receipt which the receiving sergeant gave him stating how many blankets, litters, hot-water bottles, etc., were left with the patient, and as he passes out the gate this amount of property is loaded on, so that when he goes out he is refurnished the things he brought in; in this way the front is not depleted of its stores. The driver's word is taken for it without receipt in our Army, a better way.

Now, the sitters. They go into the reception room, which must be well heated, and the field medical card which should have been begun at the A. D. S. is examined. If it has not been begun there, it is begun here. This is the place where the man gets antitetanic serum, if he hasn't gotten it already—only about 1½ per cent of the men that come in have not had it. There should be a buffet here with both hot food and drink. The bureau of admissions of the evacuation hospital makes out a slip which differs in detail for the different armies, but in general they are the same. They give the name, organization, and diagnosis, and always a serial hospital number, which is a local affair. His kit is taken away and sent to the pack store, and that number goes to the pack store on his equipment. In the English Army they make identical notations on the stub. The stub they pin to the man's field medical card; the slip itself goes to the record office of the hospital and is entered in the admission and discharge book.

The sitters are divided into those needing dressings and those needing only food and heat before being evacuated. Those men that can go out right away are not given a bed at all, but the former have their kit taken away and are given a bed until they are ready to go.

The dressing room.—That is just beyond. There is a good practical surgeon here, and on him devolves the duty of saying whether a man stays or is evacuated at once. It takes a man of keen judgment and quick perception; he must be a good diagnostician. In this dressing room they dress all small wounds. Those needing operation are sent across to the recumbent side. The patients whose condition is bad are sent to wards.

Now, the recumbent. The recumbents are admitted to a somewhat larger reception room, which holds 50 or more, but never less. I have seen these places overflow with men lying on the ground. Just at the beginning of the fight before Amiens—we were up at Choque—they were commencing to receive a lot of wounded and we saw the advantage of having a large reception room. Here his kit is sent to the pack store. On the other side, you will remember, it was sent to the Thresh sterilizer and brought back to put on. Blood-stained or irreparably damaged clothing is destroyed. The officer here should be fully as capable a man as the other on the "sitter" side. If operation is not needed the man is dressed and sent to the ward for evacuation, because many of these lying wounded can be sent on farther. If operation is needed, he is sent to the preoperating room; if he is in shock or his condition is desperate he is sent to the resuscitation ward. That is near by.

Now the preoperating ward. The English have a nursing sister in charge of it. There the man is bathed and the wound prepared for operation. Of course, this man has been badly wounded; his clothing is taken off; they heat him; and then a team on duty here—generally the team that has just come off operating-room duty—directs his preparation and decides when the man is ready for operation, or it may be left to the receiving officer. If morphine is necessary it is given here; also gum arabic solution. Blood transfusion is usually done in the resuscitation ward, but it can be done here. First the case goes to the radiologic room and gets his shell fragments localized; then he goes to the operating room. The operating team consists of 1 operator, 1 assistant (it should generally be a nurse), 1 anesthetist (also preferably a female nurse), 1 clerk, two orderlies, and 2 stretcher bearers. Remember what Crile says: The best anesthetist he knows is a neurasthenic female with a high sense of responsibility. The English have three teams in a room, working at the same time. This English system is very good. If you understand this you have something to work on. They have a compartment in that room for each team. There are 2 tables; 1 case for dressings; 1 case for instruments; and an anesthetist table; and an instrument table between the operating tables. They have a screen between each two tables; while you are operating upon one man the other is being anesthetized—he can't see the operation and get a psychic shock. As soon as you finish you transfer the screen over to the other side of the instrument table and another patient is brought in and anesthetized. They keep alternating in that way.

Three teams working by day and two by night can handle 120 cases in 24 hours. In times of activity they are reinforced by extra teams which bring equipment with them if necessary. Each English team operates 12 hours, at a stretch, spends 4 hours visiting the cases, and sleeps 8 hours. Pretty strenuous. When a man goes into an operating room he goes in there with his boots tied to a litter and his Dorothy bag. The man who takes the notes—the recorder—is responsible that nothing is taken from that Dorothy bag while the owner is under the anesthetic. They never know the extent of the wound they are going to handle until they operate. A man may have an abdominal, a chest, or a thoracic-abdominal wound. You never know exactly where the man is going until they get through with him in the operating room, but in general they try to fill up the farthest evacuation ward first if the man is liable to be evacuated; only here are beds for hospitalization assigned, not in the reception room. All wards in an evacuation hospital for English wounded are divided into bed wards and litter wards. The litter wards are for those that are operated upon and can be evacuated. The bed wards are for those who can be hospitalized. The officers' ward is separate, of course.

Ambulances coming in from the front are to be loaded with 4 recumbent and 2 sitting; there should be 2 sitting wounded sent with the recumbent cases to render help in case of necessity, and besides utilize the extra room.

THE BRITISH CASUALTY CLEARING STATION

Casualty clearing station 18.—This was a Marquee tent hospital well laid out on the banks of a canal in a well-shaded park. It was very orderly and the grounds were in excellent condition. The tents were joined together in sets of 3, making wards holding 30 bed patients and 50 stretcher cases. Wards were joined by covered passageways, heated by stoves and lighted by electricity, but were dark by day. The floors were of wood, covered by linoleum. The beds were of enameled iron, with wire springs, and well made up with mattresses, pillows, pillowcases, blankets, and sheets; they were clean and smart. Each ward had one end which was a lounge, with easy chairs, books, and many comforts. Each bed had a bedside table. Plenty of fire buckets were seen, as the danger from fire in tents is great. Tents are much warmer than barracks it is said, but Nissen huts cost £50 and accommodate 20, while the marquee tent costs £120 and only houses 10; besides, they last only one year and a half.

There was a delousing outfit with a horse-drawn Thresh disinfector, bath, and a drying room. The kitchen was in excellent condition, a frame building with brick floor and open on one side. It was well whitewashed weekly, tarred outside, fitted with Soyer stoves and an improvised range with 16 ovens, the ovens being simply metal containers about the size of a bread box of fair proportions, with a door. They were issued as part of the field equipment of the old British field ambulance. This entire range was improvised of brick and mud. They had roast meat twice a week and stew three times. All utensils, like knives, ladles, etc., were perfectly clean and hung up; all utensils and appliances not in constant use were stored. The cooks wore white uniforms and caps. Most of the garbage was generally given to farmers; any excess was burned in an incinerator, which was used for this purpose in common with the latrine not far from the kitchen.

The latrine was of the MacPherson type. It was said here that its working was perfect, but it was only good for small commands constantly under supervision. A pail was kept here reserved for men with diarrhea.

The operating theater was in a barrack with white enameled walls and exceedingly neat. It was furnished from the Cowell-Wallace operating team equipment carried on a truck and was lighted by electricity, but had acetylene fittings for emergency.

The pack store was at the side of the receiving tents. It had 100 complete changes of clothing; the equipment and rooms were kept in order by an ordnance sergeant and were very clean.

The method of loading a train depended on the entraining officer, who was usually a dental officer. Ten minutes before the train left its commanding officer was given a correct list of patients. They were loaded in the following order: Carrel cases, serious recumbent, sitting, mental diseases, and infectious diseases, which were isolated. They were loaded rapidly in bunches of six, the best of care being taken not to load a man that might die en route as the responsibility fell directly on the hospital in such cases and was judged with great severity.

Casualty clearing station 23.—This was also an old-style casualty clearing station modified for use in this war and was in tents. As it was not on a railroad and they therefore had to evacuate to casualty clearing station 18 by ambulance 4 miles, it had become practically a rest station and a hospital for ophthalmic and gas cases. It was a perfect model of good administration, was clean and attractive, and in grounds of an old château on a high hill. Its commanding officer was Lieutenant Colonel Safford, who lectured to us on casualty clearing stations at the British school for instruction of medical officers at the first session of this little board with a school.

The clerk taking the "particulars" had a little board with a strap for his wrist to facilitate his rapid writing.

On the side of the dressing room for lyers was seen what Colonel Safford calls his "fire-alarm box." This was a biscuit tin with one side removed and replaced by paper pasted over the opening. It was hung up on the wall and served to furnish at all hours of night and day sterilized instruments and dressings for immediate use. These biscuit tins contained: (1) Tourniquet, (2) rubber gloves, (3) tracheotomy tubes, (4) hemostats, (5) scalpel, (6) scissors, (7) trocar, (8) hypodermic syringe and needles, (9) surgical needles, (10) silkworm gut, (11) dressings. When this box was needed the hand was simply

shoved through the paper and the instruments needed were removed, thus avoiding the confusion of hunting for instruments and dressings separated by distance and confused with a large amount of material for other operations. As soon as used, the hole in the paper attracted the attention of the orderly who was in charge and he replaced it immediately by another and similar biscuit tin.

The preoperation room accommodated 40 to 50 patients. Here, they were washed, put in pajamas and warmed. The operating room was white painted and clean, and was furnished with a Cowell-Wallace operating-room equipment with its furniture. All of this equipment was put on a trailer, within an hour, when the team was called to operate in some other casualty clearing station in an emergency. Among things noticed in this room were enameled iron tables with glass tops, folding operating tables, a separate operating table with a compartment underneath the table top for heating by means of electric lights in case of operation involving shock. There was a traveling tank filled with an irrigating solution swung overhead on a wire, with a trolley which served all of the tables.

There was a department set aside for the 60 cases of chronic gonorrhea which had been sent here to do the rough work around the hospital. They were housed in tents, had their own bath, latrines, and dispensary, and constituted practically a venereal camp within the hospital. We noticed an open shed with tables for the passing of sounds and irrigations of urethra by permanganate solution. It was most cleanly and well whitewashed.

The latrines here were also of the MacPherson type. The pack store was in charge of a quartermaster who was commissioned in the Medical Department and had been a hospital sergeant of long service. Here, only 50 changes of clothing were kept. All officers leaving the hospital were required to sign a statement that they had received all of their property. The laundry was given out to civilians. The ward beds were furnished by the British Red Cross, as were most of the comforts. We noticed chairs, tables, and reading material, etc. The officers' ward had 18 beds, a good stove, a lounging room, a washroom, and other things connected therewith. We were told that stretcher wards held 24 patients.

There was here a large shed well whitewashed, with cement floor, and open on one side for gassed cases. This held 54 stretcher and 8 bed cases. The beds and stretchers were arranged in clumps of 4, with the head turned toward the Haldane oxygen apparatus. This was only used in the summer time, a barrack being used for this purpose in winter. All gas cases were treated as recumbent cases.

The following casualty clearing stations were large, modern, and generally of wooden barrack construction.

Casualty clearing stations, Canadian sector.—Here they were building three enormous casualty clearing stations chiefly of Nissen tents. Each one was to hold 2,500 cases.

Group of two casualty clearing stations near Arras (Casualty Clearing Stations 57 and 30).—These were British and represented the most advanced type of casualty clearing stations. One was chiefly of Nissen huts; the other was partly composed of tents. Their capacity was a thousand apiece. There was a large number of machine dumps and repair shops in the immediate vicinity which had been recently grouped near it. Here, we found that the Marquee wards held 44 patients and the Nissen 20. The Nissen hut was hard to heat, and in one we saw a very good stove of the old Franklin type built of cement. This hospital was excellently built and the wards were lined and floored with tongue and grooved lumber, as well as being well painted. They were models of cleanliness and comfort, had linoleum on the floor, and a louvred window ventilator the length of the building.

The baths were excellent. While tubs were used, the main dependence we placed upon the shower baths, which were furnished each with a large rose shower head. The water was heated by a very substantial upright boiler with a hot-water reservoir above and cooling tank arrangement on the side. It was far more substantial and better than the French system, but more bulky, heavier, and required more water. There were 12 separate shower heads, "secours aux soldats"; four could bathe under each shower head at one time, giving a capacity of 1,000 in two hours. This was a bathing center for the corps, and the British make a "parade" of it, or a "formation" as we call it. Every soldier in the British Army was said to have a bath every 8 to 10 days. The outer clothing was disinfested at the same time and fresh underclothing issued. There was a separate bath for skin cases.

The latrine used here was of the bucket and incinerator system.

The laundry was taken by civilians and gave a great deal of trouble.

The operating group was in Nissen huts, well lined with tongue and grooved lumber, well painted, well furnished, heated, and lighted. Surgeons operated 12 hours, spent 4 hours visiting their cases, and slept 8 hours. They counted on having two teams for every 100 admitted, which meant that they operated on slight and nervous cases at this hospital. There are six such teams here at present. They keep three medical officers in the reception and dressing room, two in the resuscitation room, and one in training. The personnel have a ward, one nurse, and three orderlies. The two hospitals had one radiologist and one bacteriologist in common.

The kitchens were models of cleanliness and their capacity was 500 meals apiece. They each had a Nissen stove which bakes for 500 men. This model is found in a detailed description of this hospital ("Visit to English casualty clearing stations Army Sanitary School"), and it heats, in addition, 120 gallons of water a day. Another kitchen range has pipes running through its fire box to supply a hot-water tank tapped for the ablution benches. The incinerator for the latrines was near the kitchen and heated water for the washing of dishes in the same manner. The Thresh sterilizer was housed and its smokestack laid across the ceiling and heated the drying room.

COMMENTS ON THE ENGLISH CASUALTY CLEARING STATION

I have not seen the casualty clearing station since the change to open warfare, and it is said that certain changes of a radical nature have been made, but is very evident that in general such a hospital would be defined as a stationary hospital as described in our antebellum literature. It is not portable enough, generally too close to the lines, and seems to be usually a collecting point for adventitious groups of war supplies for which the Medical Department can in no way be blamed, but which must have been the excuse for the terrible bombing expeditions of casualty clearing stations which horrified the civilized world.

Another comment, in the line of what we know to-day as self-evident, is that such a hospital operates on too many cases; and the converse of this, that these operating groups are much too unwieldy. The Marquee tent is strictly inferior to the Bessonneau. No practicability can be considered without a tent installation. It is unnecessary to testify to the evident excellence of these hospitals in their administration, equipment, comfort, decency, and good surgical personnel, as well as to call attention to self-evident schemes which improve the efficiency of these institutions, such as Colonel Safford's fire-alarm box.

THE FRENCH H. O. E. (HÔPITAL ORIGINE EVACUATION)

H. O. E. 32.—At Mont Notre Dame. This hospital fell into the hands of the enemy a few days after we visited it. The nearest point to the firing line was 15 km. It received its patients direct from all formations to its front, battalion aid posts, G. B. D., special surgical hospitals on the battle field, as well as field ambulances. Its capacity was 3,380, expandable to 5,000. It was a barrack hospital in excellent condition and built on the ruins of its predecessor destroyed by fire only five months before.

The water supply is from the abbaye of Mont Notre Dame on a hill near by and is piped to four large tanks in the center of the cantonment, where it is centrally hypochlorinated.

All huts are revetted up to about 3 feet, the roads are macadamed and well guttered and the place is cheerful and attractive. We understood it had a twin hospital near it.

Triage: This did not differ from the accepted plan in all armies except that there was a secondary triage in all three quarters of this hospital; that for the wounded, that for the gassed, and that for the slightly wounded.

The operating groups: There were 4; 2 were for the hospitalization quarter with 880 beds, 1 for the slightly wounded, and 1 small but complete one for prisoners of war. Each hospitalization group comprised three barrack buildings for triage and preparation for operation, a hollow square of buildings for operating, and a group for personnel, laboratory, stores, etc. All were connected by protected covered ways.

The preparation of the patient consisted in a general bath and removal of clothing in one room; here the wound itself was not touched. Next to this was a large room with beds

for the storage of cases preliminary to their reception into the preoperating barrack placed between the two. The clean patient is now transferred by a covered way to this latter barrack, where the wound itself is prepared. The preoperating room proper is connected directly with hot shock rooms elaborately fitted up with electric-lighted hoods, transfusion apparatus, etc. They divide their shock cases into those with nervous shock and those with shock due to hemorrhage. The first receive saline solution, the second blood.

Once prepared the man is carried by litter bearers by means of wheeled litters to the waiting room for prepared patients and from there to the X-ray room, which also has its reservation for waiting cases. In the center of this operating group and communicating with it directly by windows was the sterilizing room, fed by the sterilizing truck of the auto-chair, backed into the opening cut in the wall for this purpose. At the time this sterilizing truck was an auxiliary to the central sterilizing plant which did the main part of the work of sterilization for the entire hospital. On either side are 3 operating rooms, each with 2 tables; 1 of each 3 was kept for septic cases.

In the far end of this group was the X-ray photograph plant, storerooms, rooms for personnel, laboratory, pharmacy, etc. The laboratory was a field mobile affair, very practical, and presided over by an efficient bacteriologist. His equipment was packed into six small chests, but he nevertheless kept a bacteriological numerical chart of organisms per field of the microscope for each patient as well as an accurate qualitative description of the principal organisms in each wound, anaerobes as well as aerobes. His procedure was simple enough and consisted in sowing from each case at the first operation and thereafter p. r. n. He sowed one single agar slant for aerobes, one Veillon agar tube for anaerobes, and a third Vignal capillary tube filled from a diluted Veillon agar tube. His charts for each case looked like fever charts and were kept with great precision and detail. Attention is invited to the fact that the radiologist and bacteriologist form part of the operating group. During a push the bacteriologist was utilized in the operating room. There were two such groups practically exactly alike.

The central sterilization plant: This has proved to be a great time and personnel saver and has been adopted in the French Army to unburden the overloaded operating groups. The main essentials are:

1. A large Geneste-Hercher steam sterilizer with cages holding a large amount of dressings.
2. A preparing room for dressings where nurses make packages of gauze, cotton, sponges, abdominal pads, etc.
3. A place for the assembly of sets of instruments for "ephussage," scalpels, scissors, rubber gloves, glass syringes, needles, etc., with their distribution into small tin boxes ready for sterilization.
4. A place for the sharpening of knives and scissors, repair of rubber gloves, etc.
5. The store of raw material for dressings.
6. A store and distributing room for the sterilized material.

Instruments and gloves are sterilized in the same box with 200 gm. of formal sprinkled in gauze over them and at a temperature of 80° for 45 minutes. Compresses of cotton, dressings in general, and operating-room linen are subjected to 134° C. for 1¾ hours in the autoclave. Sealed capillary glass tubes filled with sulphur containing a trace of methylene blue are wrapped into the center of each package and if the desired temperature reaches the interior this fact can be evidenced in using the dressing by the beautiful ultramine blue this mixture makes on reaching a sterilizing temperature.

This plant was remarkably efficient, neat, and quick.

Gas quarter: This was of Bessonneau tents and wooden barracks, with a capacity of 550. They were sorting here into the asphyxiated and the vesicated. The asphyxiated were taken direct to a barrack ward with 40 iron bunks. Running along the whole length of the tent on one side was a pipe system connected with a large oxygen tank which was tapped at the head of each bed for a rubber tube controlled by a Mohr clip and terminated in a rubber funnel. Each patient on this side thus received oxygen; the other side was for those not needing it.

The vesicated were admitted to a long barrack building floored with cement. In the first room they were rapidly disrobed, the clothing thrown out of the window on a cement dump outside through a flap door. They were then sent to the next rooms for their alkaline shower bath and their hair cut. Here there were 16 showers. The next room was devoted to alkaline sprays for eyes, nose, mouth, throat, and sitz baths for the genitals. Gomenol oil (10 per cent) was used as a spray for the nose and throat. In the next room patients were dried and given clean clothing; here was a shock room. In the last room, a rest room, the history is taken and they are sent to wards.

Section for salvage of dressings: This was in a concrete-floored hut. There was a room for bloody and muddy litters, cleansed by hose. Another room contained a series of tubs for gauze. Soiled gauze was soaked in cold water 24 hours, then 24 hours in a solution of 1 to 1,000 chloride of lime, then 24 hours again in water, then boiled in a large stew pot, then laundered and folded, and finally sterilized in a Geneste-Hercher at 134° C. for 1¾ hours.

Cotton was picked over, the soiled portions burned and the rest sent to a salvage depot for recarding, sterilization, and issue.

Advance medical supply depot: This supplied all medical organizations in front. It held 20,000 gas masks as a reserve and supplies for six months.

Hospital garden: This yielded 20,000 francs a year.

Quarter for prisoners of war: This was complete and extremely neat, and consisted of Bessonneau tents, a Bessonneau hangar, and a small operating group.

Quarter for slightly wounded: This consisted of a Bessonneau hangar and an operating group from which patients were stored in evacuation wards as attended to. The arrangement of this hangar was the most complete and the best I have ever seen, and all medical officers should possess a plan thereof. It is furnished in the description of this plant (H. O. E. 32) issued by our school. Here the slightly wounded were all gathered, made to sit on benches in an orderly manner, and were bathed, given hot drinks, dressed if necessary, and booked in. It communicated with the operating group adjoining, where such as needed operation before evacuation could be handled. The hangar held from 300 to 400, as per diagram, and the operating group could handle 450 operations in 24 hours. Considering 15 per cent as needing operation, this means that about 3,000 could be put through in 24 hours. Slightly wounded were defined here as were all those (generally able to walk) in whom there was no wound of a large joint, or fracture of thigh, leg, humerus, or skull, or wound involving any of the splanchnic organs. As soon as these slightly wounded receive attention, they were sent for evacuation to the evacuation wards near the railway siding. There were wards with litters and the wards with beds and Bessonneau hangars for sitting wounded in which to await the next train. But the French do not leave a recumbent patient to await a train on a litter for any length of time. They put him to bed and shortly before the train is due they transfer to a litter and fill these litter wards. In active periods they have at least two trains a day, which report automatically.

Other details of this hospital: The latrines of the hospital are inadequate. The kitchens are orderly and the food good. In fact a cooking school was in session here at the time of our visit.

They had an excellent Red Cross recreation hall. There was a group of centers, one each for a stomatologist, ophthalmologist, and otorhinolaryngologist. All had dispensaries, operating plants, and wards in the hospital.

The mobile evacuation hospital: In one large Bessonneau hangar was stored one complete reserve evacuation tent hospital, which it completely filled, with accommodations for 400 patients. There are four of these per field army. They are complete down to the last pin, with Bessonneau tents, iron bunks and bedding, X-ray apparatus, instruments, etc., all packed and ready to go at a moment's notice. The hospital consists of 4 Bessonneau hangars and 32 No. 2 Bessonneau tents. The personnel is 200, which in a move is split into a group of 100 to forward the hospital and 100 to receive and set it up. It requires for transportation thirty 10-ton railway cars or 100 motor trucks, and the time required to transport it 15 km. and set it up is 8 days. The hospital thus transported could functionate in one or two days from the arrival of the first element.

In a push, 120 medical officers were needed, but only 40 during quiet periods.

GENERAL DATA CONCERNING H. O. E. 32

This hospital was one of the best we have seen, the most complete, the best administered; but it would have been termed "a stationary hospital" in our Army. In fact the French so consider it, and it is really the last échelon of their evacuation hospital system; or to put it more correctly, it is an evacuation hospital of the third echelon, the first being a divisional one, the "field ambulance"; the second, the H. O. E. of the corps. It retained for hospitalization the nonevacuable, all who can be returned to the front in four or five weeks, and certain gassed cases.

The hospital stands alone, no ammunition dump or depots being near. There are large black crosses on a white background, marking it against avions, whose dimensions are 30 m. from tip to tip.

There is a barrack for the triage of sitting and another for the recumbent and a hangar near by in case of a rush, accommodating 200 lying or 500 sitting.

Composition of the hospital

22 wards, 40 beds each, for hospitalization.....	880
Evacuation lying, 20 wards, 40 beds each.....	800
Evacuation sitting, 20 wards, 50 beds each.....	1,000
For écloppés and vesicated, 5 wards, 50 beds each.....	250
3 Bessonneau hangars, vesicated and prisoners of war, 50 beds each.....	450

Personnel.—Three auto-chirs (39 officers and 102 men), 20 surgical teams (40 officers, 60 enlisted men, 10 field ambulances (80 officers, 380 enlisted men), section of evacuation hospital (12 officers, 52 men); reinforcement H. O. E. (12 officers, 250 men). Specialists: Stomatologist, otorhinolaryngologist, and ophthalmologist, 3 radiologists. To these add, for litter bearing, 240 territorials. Automobile transport, 60 enlisted men; supply train, 42 chauffeurs; female nurse, 104. Total about 1,500.

Service of an operation table provided for by 2 teams: Team No. 1, 5 a. m. to 1 p. m. and 9 p. m. to 5 a. m.; total, 16 hours. Team No. 2, from 1 p. m. to 9 p. m.; total 8 hours. Next day team No. 2 takes the 16-hour day and team No. 1 the 8-hour day.

Average number of patients operated upon per table per 24 hours: Badly wounded, serious, 20; lying wounded, 30; sitting and slightly wounded, 100. Six tables for hospitalization yield 120 operations, serious, in 24 hours. Six tables for lying wounded to be evacuated yield 180 in 24 hours. Six tables for sitting wounded, slight cases, 600.

They could thus operate upon 900 wounded in 24 hours.

The commanding officer of the hospital, in liaison with groups of field hospitals of the corps and with the fourth bureau of the general staff, requests mixed trains in case of necessity for élopés, or permanent trains for wounded (here used in sense of slightly wounded and sick). He also establishes liaison with the regulation station, through the "commissaire sanitaire" regulating center, and with the centers to which he must evacuate in the line of communications when the operative capacity of this hospital is exceeded. In addition he confers with the chief surgeon of the army.

Triage means reception and inscription of these patients admitted and their distribution to different quarters for hospitalization or evacuation. The medical officer in charge of these services sorts them into:

First. Sick: (a) Those with acute diseases not contagious; (b) tubercular; (c) venereal and cutaneous diseases; (d) contagious.

Second. Nonevacuable cases, sitting and lying.

Third. The écloppés.

Services of evacuation.—Ward surgeons decide when a man is to be evacuated. They may be sent: First, to formations in the zone of the interior, (ZI) or zone of the army (ZA); second, evacuated on special sanitary formations in the vicinity (contagious diseases, venereal diseases, fractures, etc.); third, may rejoin their units at the front after treatment.

Evacuation by sanitary train.—a. Permanent sanitary trains (T. S. permanents). All the gravely wounded are transported to Paris.

b. Semipermanent sanitary trains (T. S. semipermanents). For wounded and sick, sitting and lying, to ZI or ZA.

c. Mixed improvised sanitary trains (T. S. improvises mixtes), sitting or lying; only for intensive periods.

d. Ordinary commercial trains for *éclopés*.

The semipermanent trains ZI receive all who can not be returned to the line within five weeks, either French, foreign, or prisoners of war.

The semipermanent trains for the zone of the army carry all sick or wounded, sitting or lying, French or foreign, that can go back to the line within five weeks.

The commanding officer of the H. O. E. requisitions trains from the regulating medical officer and the regulating station of the army. The call states: First, the category of train desired; second, its composition (number sitting or lying); third, its destination—ZI or ZA.

Except in a push the evacuation hospital does not make special requests for trains, but sends to the regulating medical officer by telephone every day at 4 o'clock p. m. a statement as to the number of evacuable patients.

When the bureau of evacuation of the H. O. E. receives announcement of the next arrival of a sanitary train, they advise the ward surgeons to prepare their sick and wounded which are to be evacuated from the wards by the bureau of evacuation and conducted to the evacuation wards near the railway. There a medical officer sorts these cases as follows:

First. According to destination: (a) Sick, (b) wounded, (c) cases requiring a specialist's attention.

Second. According to mode of transport: (a) Sitting, (b) lying.

Third. According to character of patient: Officer, foreign, Mussulman, native.

Evacuation on sanitary formations of the army to special ophthalmological, orthopedic, contagious, psychopathic, or venereal hospitals, accomplished by automotive ambulances, the motor ambulance convoy, the "S. S. A." of the French.

The pharmaceutical service has charge of the central sterilizing plant, general hygiene, salvage of cotton and gauze, manufacture of ice, superintendence of gardens, and the proper distribution of drugs and medical supplies in general. It runs three separate services: (1) The central pharmacy of the hospital; (2) the special pharmacy for the specialists and infirmaries; and (3) the reserve supply of drugs.

H. O. E., BOULEUSE

This was a hospital of the third echelon and the seat of the French Army medical school for officers at the front.

The capacity was 3,000, capable of expansion to 4,000. It was an Adrian barrack hospital, isolated from dumps, etc., on a spur of the main railroad. There were two operating groups, one under Le Maître and the other under Leriche.

The bureau of admissions.—They received no gas cases, but had a service for wounds of soft parts, chest, genitourinary wounds, and medical cases. One of the most interesting features of this hospital was its triage, which is a type of the triage of these H. O. E's. The personnel consists of a triage officer, one sergeant in general charge, 2 sergeant secretaries, and 4 litter bearers. They kept two sets of admission books, one for odd and one for even numbers, to economize in time. The book called the *carnet de passage* is composed of sheets perforated to give 10 slips, one for each of 10 men, and the entries are triplicated by carbon paper. These slips, when torn out, contain the man's hospital number in series from hospital enumeration, his name, organization, diagnosis, etc. One slip accompanies the man, one goes to the office of the bureau of admissions and one to the War Office.

A register of entrance, taking up a whole page, is also made in triplicate as above; one goes to the man's regiment, another to the surgeon general of the army, and the third remains on file at the hospital.

In this barrack was a dressing room for emergencies and a buffet serving hot food and drinks, but usually the man was simply booked in and sorted by his diagnosis tag or "*fiêche*." No other sort of triage was desirable nor possible, as the main object was to get him promptly on the operating table where the real and final triage was done.

The bureau of evacuations.—This was in the main office building and occupied adjacent quarters to the central bureau of admission. The personnel consisted of 1 medical officer

1 officer of administration, and 2 teams consisting each of 1 sergeant and 4 men, 1 for day and 1 for night work. This personnel checked all patients in the hospital at 8 a. m., at mid-day, and at 6 p. m. They determine the total number present and the number of evacuable and nonevacuable patients. The evacuable are further classified into recumbent and sitting. Only patients who can not recover in four weeks are sent back in times of inactivity. In time of activity all are evacuated that can be; in time of inactivity, they keep all they can.

Specifically, these are, in time of inactivity:

1. The transportable sick and wounded not possible to hold and curable in less than four weeks—to the zone of the army (Z.A.).

2. The sick and wounded needing more than four weeks for their cure—to the zone of the interior (Z. I.).

3. Those cured at the hospital—to rejoin their corps directly after a leave of 10 days.

At the time of our visit the period was one of exceptional activity and all were consequently evacuated into the zone of the interior, except (1) those who can be cured in 10 days, (2) the nonevacuable, (3) those having venereal or other contagious disease. This hospital could evacuate 3,000 cases a day. The information concerning the state of the hospital was transmitted by telegraph to the chief of staff, fourth bureau, headquarters, and a duplicate sent the regulating officer of train.

A large blackboard was displayed in the corridor of the bureau of evacuation giving particulars of the actual state of the hospital since the last census taken by the evacuation administration staff, as just described. The headings on this board are as follows:

ZIELA. Meaning zone interieur eloigne legers assis (zone of the interior, distant, slightly wounded, sitting cases).

ZIELC. Same as last meaning, except last word, which is couchés (recumbent).

ZIESA. Same but last two words, meaning "serious sitting" (serieux assis).

ZIESC. Same as last, except last word meaning recumbent (couchés).

ZIRA. Last two words mean near by (rapproches), sitting (assis).

ZIRC. Last word meaning couché (recumbent).

T. B. Signification not known.

G. Guéris (cured).

Éclopés. All those suffering from sickness or injury not a battle casualty.

Scabies.

On leave of absence.

All from T. B. generally are evacuated by motor ambulance, save those cured and on leave, who go by train to their units or homes.

Finally there is a recapitulation of the evacuable and nonevacuable arranged according to whether they are French, allied troops, or prisoners of war.

From all this the entraining officer makes up the train. This train is made up on a folder in which is pasted the carnet de passage of each man furnished the bureau of evacuation by the bureau of admissions. This is given the commander of the train, who receipts for it and sends back the slips with the destination of each man entered thereon. Thus the completed record at last rests at the hospital. Patients carry their envelopes, with the field medical card of "billet de hospitalization" plus clinical notes, X-ray pictures, sketches, and recommendations for further treatment.

Patients are sent from the wards to the train shed an hour before train time. It takes about a half hour to load sitting patients on a train holding 150 to 200 patients and one hour and a half to load lying patients.

Other notes.—In this H. O. E. there are 800 beds for hospitalization alone, 800 for those to be evacuated sitting, 775 for recumbents, and 900 for éclopés. There is a fine ophthalmological center here, central sterilizing plant, and X-ray laboratory. Otherwise it is the same as H. O. E. 32, but not so well situated or kept up. A feature of this place is a group of 18 portable laundries.

H. O. E. AT TRAMERY

Also an H. O. E. of the third echelon, composed of 80 Bessonneau tents and 4 hangars. There are 3 operating groups in this hospital with 4 tables for serious and 2 for light cases each; 12 teams work in each group. We learned here that a Bessonneau hangar is set up only

by army constructing teams and that it takes them three days to do it. Bessonneau tents are set up in three hours. The Bessonneau tents hold from 15 to 20 patients, using iron bunks, or 30 litters. There are 42 evacuation wards and it was said that they can handle 1,200 surgical cases a day of 24 hours.

At this hospital we saw the best pharmacy and the best central sterilizing plant it has ever been our pleasure to inspect.

H. O. E. DE LA VEUVE

This is a large evacuation hospital of the second echelon, 18 km. from the front, with a capacity of about 3,000 patients.

There was a beautiful gas quarter, remarkably complete and permanent, in which on one occasion 600 were received and cared for in 8 hours. Here we were informed that for outer clothing impregnated with gas 10 minutes at 90° C. in an autoclave is sufficient if the pieces are aired for 3 hours thereafter. They can perform 120 major operations a day here. They also have one operating room set apart for septic cases.

The following is a statement sent me by le medecin principal de 2 classe Bechelonne, the 30th of May, 1918, just before the German offensive:

Capacity of the H. O. E.

Different services	Beds	Auxiliary beds with mattresses and blankets	Space on plank platform with mattresses and blankets	Seats in double benches with backs	Total
Hospitalization.....	617				617
Gassed.....	240				240
Evacuable recumbent.....	352				352
Evacuable sitting.....	190	360	510	510	1570
Total.....	1399	360	510	510	2779

The hospital can be divided into four sections:

- (1) Gas quarter composed of 3 Bessonneau tents, 2 Bessonneau hangars, and 4 barracks.
- (2) The section for the evacuable—(a) recumbent (4 barracks); (b) sitting (in 2 barracks, 2 Bessonneau hangars). In this subsection barracks 23 and 24 are used by the otorhinolaryngologist and barracks 28, 29, and 30 by the ophthalmologist.
- (3) The section for hospitalization (severe, intransportable wounded), found in barracks 2 to 15, inclusive, and the operating groups 1 and 16.
- (4) The section for the personnel barrack P. P. and T——. In addition there are storehouses, a tea house, a pharmacy, baths, douches, etc.

In Bessonneau hangar 42 is a reserve of medical supplies.

COMMENTS ON THE FRENCH H. O. E.

The recent practice of placing them in echelon is certainly a great advance over their previous habit of one large one in the immediate rear of fighting units and the still more recent provision of a mobile tent evacuation hospital, packed and ready to move forward should be the basis for our future plans.

The French are also quite consistent in separating them from depots, towns, and troops cantonments. In addition they place them boldly in the open and still provide against a savage enemy avion attack on defenseless wounded by revetting each barrack and providing at least splinter-proof dugouts.

The practice of washing up a patient before preparing his wound for operation in the preoperating room is worthy of emulation.

There is a general approval also of the central sterilizing plant separate from the over-worked operating groups.

The salvage of dressings is another hint to our own hospital administration.

One of the very excellent provisions of H. O. E. 32 was a quarter for prisoners of war. The American soldier is unduly excited shortly after his wound, and he thinks and acts like a plucky boy with a bloody nose. The sight of a boche is apt to throw him into a state of mind at variance with that peaceful tranquillity of mind and body which it is necessary to secure in the hospital in order not to use up the remaining resistance against shock upon which we count to tide him over. A man who has just lost his right arm can not rest peacefully in a bed alongside of the man who represents the force that crippled him for life. There are many other considerations that make quarters for prisoners of war a real necessity.

In brief, the French, as do the English, demonstrate their dominating desire to make the soldier in hospital happy and comfortable and their innate love of all that uplifts the man's spirit takes form and substance here. But their evacuation hospitals are too large, too immobile, and too much surgery that could be done at the rear is exacted of them.

THE AMERICAN EVACUATION HOSPITAL

No attempt will be made to describe a regulation equipment well known to all of our medical officers. It needs no argument to prove that the original evacuation hospital as provided by our Manual for the Medical Department is utterly inadequate not only for hospitalization and the surgery of this war, but for rudimentary comfort.

However inadequate this hospital equipment may be, it is mobile and, with the equipment presently to be described, will obviate the most serious defects of the evacuation hospitals of our Allies. A few notes may be made on such as have been seen in operation to date, especially those functioning in the recent drive of our First Army in the Verdun sector.

With few exceptions they were placed in intimate confusion with large military centers right at or near the main depot and railroad loading platforms for military supplies. This was beyond our control, as there was no time to seek isolated places and we had to take preexisting cantonments of the French.

There was a group of two hospitals at a main military advanced base where a representative of the general staff (himself a medical officer), a representative of the chief surgeon of the army (also a member of the general staff), a director of all evacuation hospitals in the army, and a director of all evacuation were centralized. This most excellent and practical scheme worked like a charm, especially the provision for a director of evacuation from the front to the evacuation hospital and loading for hospitals to the rear. This latter officer had pooled all evacuation hospital transportation and was accomplishing in a systematic manner as to leave divisions quite free to meet their local difficulties without detaching their precious transportation to make the long trip back to the railhead.

Evacuation Hospital 6 (Colonel Baker's hospital).—He stated that he believed an evacuation hospital should be prepared to hospitalize 10 per cent of all wounded passing through, which would provide about 400 beds per hospital of 1,000 capacity.

He has 6 men and 4 clerks in his admission barrack with a 12-hour shift; 5 constantly on duty. In addition there is a triage officer.

Mobile Hospital No. 39 (Lieutenant Colonel Flint).—This is functioning as an evacuation hospital of the first or second echelon. It was a model of good administration, clean and neat and scrupulous in providing comfort and amusement for the men. It had the inestimable advantage, however, of having remained fixed for a considerable time and of not having been driven from pillar to post. It had also been for this reason especially favored by supplies of all kinds.

His scheme of apportioning beds was noteworthy. Behind each of the operating pavilions he had a little room for 6 litter bearers and between the two a booth for a regulating officer of admission to wards (a sanitary officer or a sergeant). When the operation is completed, the surgeon designates the ward and calls the litter bearers, who carry the patient directly to it, receiving from the nurse a slip giving the man's name, organization, ward, and number of bed. This is taken to the regulating officer who card-indexes it and fills the ward bed on his ward diagram. Thus, at any time he can give the number of empty beds or inform anyone where such and such a patient is.

He also has an artist in his triage team who sketches the point of entrance and exit of the projectile. These sketches at the close of day are charted with the number of the case on a 6-foot figure of a man, front and rear view, seriatim. This forms a composite of all wounds of a determinate number of patients in series and is most valuable in determining the relative frequency of wounds of regions as well as giving a chart form from which histories of wounds of these regions may be looked up and made instantly available for scientific analysis. Otherwise one would have to wait until after the war to draw conclusions of vital importance for current treatment, comparison of method, etc.

The evacuation desk is provided with a sergeant in telephonic communication with the central office. Men are checked out here by telephone as they leave for their destination. They carry with them their field card, sketches, and a brief statement of the case. Here also are locked in a long box the man's valuables which have been collected from him on his arrival and are now returned to him on his departure. Every surgeon initials the history of each operation he performs and is thus made responsible for the operation.

This hospital takes only nonevacuable theoretically. It is a great credit to our corps.

American Red Cross Hospital No. 110 (Major Morehead).—This fortunate organization inherited a very complete and handsome French evacuation hospital, but while it had only been here three days, during which time it was receiving the wounded from the Verdun battle, it was as neat, clean, and orderly as though it had been here a year. This was particularly so of the gas quarter, which was very nearly perfect and installed in Bessonneaus. Its reputation for rapidly reaching a state of cleanliness and efficiency is made, as this hospital, thrown suddenly into a filthy little hamlet evacuated by the Germans near Coincy on the Marne battle field, was a model of cleanliness and comfort only a few days thereafter.

Its capacity is 1,100, and it is acting as an evacuation hospital. There is a tremendous danger from fire in Bessonneau huts, as Colonel Flint tells us that these tents are impregnated with paraffin and everybody is usually burned to death before they can get out in case of sudden fire.

COMMENTS ON THE AMERICAN EVACUATION HOSPITAL

Evacuation hospital ambulance companies.—In widely distributed evacuation hospitals each should have for a period of activity not less than four of these companies. No divisional units should ever be called on to send their patient back from field hospitals, especially in a war of movement. The ideal would be to replace every ambulance leaving the divisional area by another. This would prevent unnecessary hauling around of patients and might make possible a transfer direct from the ambulance head to the evacuation hospital.

Colonel Grissinger, corps surgeon, states that he believes that mobile hospitals (the so-called auto-chir's) should be used at the rate of two per corps and sent up for nontransportable to the battle field. Major Poole, M. C., insists that it is necessary in evacuating to evacuation hospitals for the director of these hospitals to keep the director of evacuation informed of the numerical state of each one, to the end that each hospital receive its equal share of wounded. They would be there so dealt out, as it were, that every evacuation hospital should be at the same time fed with cases to the point where each is six hours behind in its work. Then when a flood of wounded comes their wounded can be evacuated into anteoperating trains and moved to the interior.

The matter of relieving the strain on these surgical hospitals and evacuation hospitals is best met by insistence upon the sound principles enunciated by our own teachers, Colonel Munson and Colonel Straub particularly, with regard to the establishment of stations for slightly wounded. These stations can be manned by 1 officer, 1 sergeant, and 5 men, who would act as a dressing and forwarding party. The position of such a station should always be cited in the battle order and these wounded should be sent back in trucks furnished by the corps surgeon to a surgical field hospital in the rear on the railroad paralleling the battle front. According to Major Poole about 15 per cent of these slightly wounded, no matter how carefully culled, need X-ray localization and operation, and he calculates that 3 teams would clean up 300 in 24 hours, doing 50 operations. He also calls attention to the self-evident fact that very slightly wounded men do not need a hospital bed but could even be quartered around the town or cantonment, provided they were always under surgical surveillance. Colonel Grissinger also acceded to the proposition that slightly wounded should be cared for in a corps field hospital.

COMBAT EQUIPMENT OF AN EVACUATION HOSPITAL

Admission and operation, sitting cases: Bessonneau hangar, groupe complementaire de chirurgie (mobile surgical unit).

Admission and operation, recumbent cases: Bessonneau hangar (arranged for recumbent with stands for litters, holding 4), mobile hospital complete.

For hospitalization: Bessonneau tents (mobile hospital) as per equipment, Bessonneau tents, extra, 10.

For evacuation: Recumbent cases, Bessonneau tents, 10; sitting cases, Bessonneau tents, 20.

Gas quarter: Bessonneau hangar (triage, bath, treatment for mustard gas); Bessonneau tents, 10.

This would provide accommodations comfortably for 1,200 cases, expandible to 1,500.

One degassing outfit (which would also provide a bath).

Wall tents for officers.

Wall tents for nurses.

Pyramidal tents for men.

Old-style field hospital wards for dining rooms, 2.

Old-style field hospital ward for pack store.

Old-style field hospital ward for commissaries.

Old-style field hospital ward for medical and surgical supplies.

Hospital tent for kitchen hospitalization area.

Hospital tent for the evacuation area kitchen.

Hospital tent for nurses and officers' kitchen.

Hospital tent for replacement stores (to be sent back to divisions by returning ambulances in exchange for articles brought with patients).

Hospital tent for dispensary.

Hospital tent for pharmacy.

Hospital tent for linen.

Section de hygiene corporelle for bathing and delousing.

In time of inactivity and relative permanence the following dependencies are believed necessary:

Garden.

Portable laundries.

Chapel and morgue.

Guardhouse.

Baggage room.

Central sterilizing plant.

Laboratory (bacteriological).

Radiographic laboratory.

Theater.

Canteen.

Library and reading room.

Amusement hut.

Central office.

Electric plant.

Auto park.

Repair shop.

Electrical shop.

Carpenter shop.

Tailor shop.

Cobblers' shop.

Tinsmiths' shop.

THE ORGANIZATION OF A CONVALESCENT CAMP

By Maj. Alfred E. Cohn, M. C., senior consultant in general medicine, A. E. F.

The convalescent camp in the British and the American Armies is no longer a theory and a pious wish. It has become an indispensable institution. Whether for return to the line or to civil life, it performs a function which is relatively speaking new in medicine. But convalescent camps or hospitals, the name matters little, have for a long time been the hope and despair of physicians in civil practice, especially in great cities. The war has forced the solution of this, as it has of so many problems. Of the medical activities, it has become for the Army as important as any of its branches. As reckoned by numbers, its value is estimated not by thousands, or tens of thousands, but literally by hundreds of thousands. And it is not only the line which the convalescent camps will supply and benefit, it is also the Services of Supply.

What is the convalescent camp, and what are its purposes? In the first place the camp is not a hard-shell stereotype institution. It is an institution with a spirit. A powerful and inspiring personality must pervade its life, and the source from which the spirit flows is the commanding officer. The other officers who are his assistants must be imbued with it. Its direction is toward stimulating renewed endeavor, the will to do new things with which the camp should fire the imagination of its inhabitants. In no place should the spiritual and intellectual causes of the war receive more thorough and adequate treatment than here. To understand them is to want to contribute to victory.

The conditions of life in the American Army are so unusual in comparison with those in the Armies of France and Great Britain and of the Central Powers that new and possibly different facilities are required for it. It is more nearly like that of the Canadians, Australians, and New Zealanders. A separation of 3,000 miles renders the chance for the best kind of convalescence, that at home, impossible. The usual sources of cheerfulness are wanting; sympathetic interest in the individual is supplied as well as it may be in a thin and pale form by organized well-wishers. These are scarcely substitutes for the real contacts with live people which the home furnishes to which the British and French can go. It is idle to pretend that an adequate substitute for America can be found in France. But a substitute for it we must nevertheless try to provide; a spirit and method for the whole plan must be found. Unless the spirit is correct, a dull and soulless thing will result. Has it ever happened that a man has been made content with a form, when the form was divorced from the spirit? The men in charge of camps must supply the spirit; they themselves must be men of spirit. Such men have succeeded in making the British convalescent camp the success it is. The officers must be able to play on equal terms with their men at games and at the same time be leaders having the respect and confidence of the men—cheerful, resourceful, just, intelligent. If the leaders are worthy and have the strength, they will set the spirit for their camps. They will set the spirit anyway, for good or ill. No two leaders will be alike. Uniformity need not be expected of them. Uniformity would be in fact undesirable. Every stimulus to individual initiative that is possible should be given. The real fruits in this work will undoubtedly spring from originality; and originality should be recognized and rewarded.

Models are unquestionably useful. The British convalescent camp as a model is in point of fact wholly admirable. Undoubtedly it expresses thoroughly and adequately the spirit of the British nation. It breathes a sense of order, a love of form, and presents the marks of what in Great Britain is decent living. Its growing flowers, its games, its music are all peculiar to the British spirit. If another nation were to imitate it slavishly it might do an unprofitable thing. It would result in adopting the expression of a spirit it does not possess. In the American Army, no doubt much of the machinery useful to the Britisher will be adopted; undoubtedly its uses will be given a somewhat different turn, adapted to our needs. Can anyone say what these needs are? Does anyone really understand the requirements, the psychology of the American soldier under these conditions? Has anyone studied the matter so that use may be made of the study? The information which is required is not available. But we have certain tools we are able to bring to the hands of the workers in our camps. These we must leave there for each one to manipulate as his native genius will dictate. Confidence in the successful use of them is so strong within us that we may go on, assured that we shall find the proper use of the means at our disposal.

We expect and require certain results to flow from the convalescent camps. We expect to make men well. That is the duty of the medical officer. If our work is well done, we shall make soldiers fit for front-line service, and we shall recognize those who are not. This does not mean that men fit only for front-line service will result from the convalescent system. That is far from the truth. The Services of Supply will likewise benefit constantly from having supplied to it both unskilled men and men of high training. Many adapted to such service will be found.

In this sense the convalescent camp is in effect a sorting station. It is called upon to decide what service a man can render. It bases its judgment on what it has observed that a man is actually able to do. The method is different from the old hospital method. There, judgment of efficiency was a mere guess and was accompanied by the hope that the judgment might be correct.

The new method leaves little to chance. While the work of sorting the fit from the unfit is going on, the convalescent camp fulfills another important function. It attempts to elevate morale. How does the camp do these things? What means has it at its command?

Of the qualifications desirable in the commanding officer and his staff, a description has already been given. The general appearance of the camp is a matter of great importance. The camp should not be luxurious; but it should not be uncheerful. To obtain cheerfulness, the camp should be laid out not with wasteful, but with liberal, use of space. Crowding must be avoided. Color can be given to it and cheerfulness by generous use of growing flowering plants. In France success in gardening can be secured and a good show obtained in the first season.

The entire grounds should be attractively laid out and the planting suitably arranged. If barracks are available, the use of black and white paint is suggested, or substitutes for them. The attractiveness and cleanliness and tidiness of the place is much enhanced by the use of these simple devices. They are not unimportant things, as a matter of fact. The use of them adds immeasurably to the work of improving the mental background of the men. To bring this about is one of the chief things for which the camp exists, just because deterioration in mental background or morale is one of the principal ailments of the men. There is therefore excellent ground for laying emphasis on this aspect of the organization of the camps.

The camp is naturally an intermediate station between the hospital and the line. There must consequently obtain in it an approach to military discipline. The day should be occupied with drill and work and play, all supervised more or less rigidly by medical officers and non-commissioned officers. There must be entertainment as well. The men must not be permitted to be bored. To prevent this, occupation for the body and mind is required. These are the elements, work and play, with which the object of the camp is accomplished. They can be arranged and varied in endless variety. But the arrangement and variety must be left to the genius of the officers in charge. The means are slight and the successful working with means such as these depends largely on the spirit which animates the work.

But these means do not exhaust the possibilities. A great aid is music. Each camp requires at least one brass band; possibly other organized musical units are desirable. The band is especially useful in route marches; it diverts, it stimulates, it encourages. And then there ought to be connected with each camp the kitchen garden or farm. Experience must teach how many men can benefit by the use of the farm. But it will probably be found that an acre for one to five men, so employed, is required.

Trades must be provided for in the camp; a tailor shop is required and a barber shop and perhaps a shoemaker's shop as well. But aside from these shops, means for carrying on vocational training might well be instituted. Articles for use, not so much in the Army as in the hospitals, could be made. Whatever is made should be thoroughly useful. Men should not be permitted to get the impression that they are tinkering. It should be apparent that whatever they are making is seriously required. Men at war do not want to be played with. Manufacture should be confined to such articles as are, in the first place, indispensable and, in the second place, capable of being made in such quantities as can supply the need for them. Articles that can be made probably include splints, bedside tables and chairs, bedpan racks, hot-air cribs, dressing carts; printing, especially with moveable type, might be undertaken to supply the medical department with its various forms.

And, again, a large amount of work in caring for, developing, and enlarging the camp will constantly want to be done. As much of this work as possible should be done by the convalescents themselves. They will do it, not as fatigues, but because they will be stimulated by the desire of living in decent and reasonably attractive surroundings. Experience has shown that fatigues do not as a matter of fact constitute the most salubrious method of carrying on convalescence.

In addition to the equipment for the camp which has been suggested, a gymnasium and a partially protected shed for drill and exercise should be provided. The gymnasium should of course be equipped with apparatus and all necessary appliances. Both the exercise shed and the gymnasium must naturally be of requisite size.

The organization of the camp itself is a vexed question. The principle that men in camp are not sick is correct and is now established. The arrangement of the men in the camp is,

however, difficult. If men are admitted into the camps directly from base hospitals they will be found in all stages of convalescence in the camps, some having been out of hospital for rather a long period, possibly three weeks; others having recently come. The two classes naturally can not be managed as belonging to the same class. In practice, the difficulty can be obviated in one of two ways.

In the first place, men can be divided on admission to the convalescent camp into three classes, according to their physical ability. In the first class the amount of exertion required is limited and small; the second is an intermediate class; and in the third class the amount of exertion expected is equivalent to the maximum required in the line. A soldier is advanced to a higher class as soon as his abilities, in the judgment of the medical officer in charge, permits; he will be discharged from camp as soon as he is capable of doing the amount of work required in the line.

The convalescent camp, on the other hand, might be arranged so that preparation is made for one class only, all convalescents being managed in a single group. If this were done, the work of sorting and the bringing of men to a single standard of fitness must elsewhere be provided for.

This work could be undertaken either by the intermediate camp or the base hospital. If intermediate camp were provided, patients would proceed to the convalescent camp only for stage three of their training. This alternative has been adopted by the British in the Rouen district. The intermediate camp acts as a clearing station for patients discharged from base hospitals, for sorting into classes sent before medical boards or sent to convalescent camps. Those who are detained in this camp are of the skin cases and the D. A. H. cases (effort syndrome cases in the American Expeditionary Forces). The care of the latter cases is especially important.

The same preliminary work would be required if work of grading and initial stages of exercise were carried on in the base hospitals. In this case it would no doubt be advisable, as the chief surgeon has recommended, to detail officers to see to the sorting and training. A certain portion of the hospital would then be set apart for this purpose, as much of it, indeed, as the service requires for carrying on this work. In this case, one medical officer with assistants, if necessary, and properly trained noncommissioned officers would devote their time to this department. In any case it must be pointed out that there can be no escape from graduated retraining, whether in the convalescent camp itself, in the base hospital, or in the intermediate camp. Convalescents can not profitably be regarded as all equally able physically.

The question of the amount of medical attendance required is a matter of open discussion. Provisions for illness must no doubt be made. In the single class convalescent camp it has been found that 11.7 per cent of cases return to hospital. At one of the camps in England (Eastbourne), 4 per cent of the beds were kept in the camp itself as sick beds, quite apart from the fact that the seriously ill are sent to near-by hospitals. But medical officers are needed in addition, in order that judgment may be available as to whether fitness for duty has been attained. The making of such decisions is not a simple matter. Medical officers especially trained for this work should therefore be provided in such numbers as are necessary.

What variety of disease or disability should be sent to the convalescent camps? Men ill of certain diseases, especially, have been found to benefit from such treatment. These include trench fever, pneumonia, gas poisoning, rheumatism, effort syndrome. Only those diseases of interest to the medical sections are enumerated here. The section of neuropsychiatry has found it advantageous for certain of its cases to manage their convalescence independently. However, the surgical sections very likely will want patients for whom they are responsible to benefit by the advantages to be gained from the camps.

The convalescent camps are, then, for America, new institutions. They bridge over for patients that often mismanaged interval between illness in hospital and restoration to health. The special circumstances which attend the conditions of the war have made it necessary to consider, in addition, other aspects of convalescence more closely associated with the psychology of the sick. These subjects have been discussed in this paper. The attempt has likewise been made to point out how the purposes of the camps can be furthered, both from the point of view of the kind of personnel likely to be most serviceable and from that of the

organization of the camp itself. At the present time there is little doubt that the spirit which is infused into the life of the camp is the first essential, and for this spirit the commanding officer will be responsible.

Army Sanitary School No. 151.

THE APPLICATORY METHOD OF TACTICAL INSTRUCTION

By Col. P. S. Bond, C. E.

There is no form of human endeavor where more skill, intelligence, application, and care are required than in the military art. In spite of this fact, it is a rather curious thing that a great many people imagine that after coming into the Army one never has to use his head or think because everything is already thought out and provided for in the regulations. I am quite satisfied that a large proportion of our soldiers have the idea that everything is governed by orders and regulations which relieve one of the necessity of thinking. That is as wide of the truth as it could be. The regulations do indeed serve a purpose and it is this: That in the large body we have to control they aim to secure a certain minimum of service from everyone. They certainly were never intended to hold back a man able to do more than the minimum. It is well to bear this in mind in interpreting the regulations. If your motives are pure and you are producing results, you need have no fear of the regulations. They are intended to help and not to hamper you.

The elements of a military situation are exceedingly complex, numerous, and uncertain, and they are, moreover, all of them, subject to kaleidoscopic changes sometimes without any previous warning; and man, the principal element with which we have to deal, is unquestionably the most complex and difficult of all. You gentlemen deal with the physical nature of man and you have probably found that very complex. His psychological nature is yet more complex, and that is the one we have to deal with in war.

In science we proceed logically from one proven fact to another, but in war we have to make a pretty good guess and discount the chances of failure; and the difference between the difficulty of scientific investigation and of tactical investigation is indicated by the fact that history records many great scientists but only one really great commander.

The mistakes of a commander in war are rather expensive; they are paid for usually in blood. No matter how great a man's native intelligence, it must be trained in this profession the same as in others. War is a profession, and we have found that all great commanders were deep students of their profession. Napoleon was a great student of the military profession.

The position of the inexperienced man in the face of an unfamiliar military situation is nothing short of pitiful, and it is by training and practice only that his embarrassment and helplessness are overcome. I saw many examples of this in the National Guard before the war. I have seen officers who in civil life were aggressive and successful business men, yet when confronted with the simplest tactical situation were perfectly helpless so far as giving orders was concerned. Of course, I am referring to tactical situations as distinguished from drill, which they understood.

The highest degree of character, initiative, judgment, and courage are necessary to meet a situation where the lives of other men depend on your decision—not only the lives of other men but the honor of your country, perhaps. These traits are best developed by placing responsibility upon the shoulders of a man. That is true not only in our profession but in every other one, as you know. The knowledge that he has responsibility resting upon him strengthens a man who previously has been weak. So our problem is to find some means of putting responsibility on the shoulders of the officers, and I wish to give you to-day an outline of the methods that have been developed for accomplishing this purpose.

The system of instruction that has been developed is just as applicable to your branch as it is to every other branch of the service. You have the same situations to meet, the technique is different, but the fundamental principles are the same. You will sympathize more with the efforts of your instructors if you understand the methods that are followed, how these methods have been developed from crude beginnings up to their present state of efficiency, what they aim to teach and why.

In a practical profession it is necessary to have practical experience and training—and war is intensely practical. In civil life when a man wishes to follow a practical profession he enters that profession, starts at the bottom, and follows the practice through to the end and sees it under all conditions. Take, for example, your own profession. I do not suppose you have learned it from books alone. No one would care to trust himself to a surgeon who had derived all his knowledge from books. This is quite as true in war as it is in surgery. You can not learn surgery from books alone; nor can you learn war from books alone—you must have experience.

When a surgical operation is to be performed all the usual conditions are present. But in training for war, in tactical training, we must simulate our conditions, and we have found this a very difficult matter. In a technical way we have been able to simulate conditions, such as artillery and rifle fire. But the most important condition in war is an enemy opposite us filled with a desire and equipped with means to kill us, and we have found it extraordinarily difficult to provide a safe and satisfactory substitute for that enemy in time of peace. One attempt was the "sham battle," which was in vogue as late as when I was a cadet. Its name is a sufficient commentary upon it. There was one European government, I think it was Russia, which attempted to give a touch of realism to the sham battle. It was announced that 1 ball cartridge would be issued in each 1,000 blank cartridges, the idea being that each soldier would believe he was opposite that thousandth cartridge and this would induce him to take the cover of the ground and otherwise act naturally, the same as if an enemy were really shooting at him. The idea was not a bad one.

The most usual form of outdoor practical instruction is what is called maneuvers. It means the exercise of a body of troops—not drill, but tactical exercises carried out on the ground. These vary in size from the exercises of a company to those of a division or army corps, and they may be one or two sided; that is, one force or two forces, acting as belligerents. But there are difficulties with maneuvers. One is finding sufficient ground available within a reasonable distance of the stations of the troops, another is the difficulty of assembling troops, who often must come from a great distance. The cost is considerable, the amount of time lost very great. There are property restrictions and damages to interfere. If we cut a barbed-wire fence we find it was made of gold. The weather interferes very much. So that if maneuvers can be had for as much as one month in two years this is doing very well in the face of so many difficulties. The men do not take the matter seriously in time of peace. Nevertheless, maneuvers on both large and small scales were excellent forms of instructions, but on account of their limited application we found it necessary to employ other kinds of indoor training.

An officer is supposed to study his profession, to read military history, and follow the battles of the great commanders—and some do. But, as in surgery, study alone is monotonous and insufficient and a good many officers do not study if left to themselves. And then, too, the study of history and tactics alone did not develop those traits of character, initiative, judgment, and decision of which I have spoken.

When a man reads a book on the subject of the art of war the responsibility for the facts stated and the conclusions drawn rests upon the author; the officer who reads it obtains a certain amount of knowledge, but he certainly assumes no responsibility and thus loses the most important feature of training. It became necessary, therefore, to find some system that would cause officers to use their wits and make decisions; we needed a peacetime substitute for the actual conditions of war. The first effort to provide anything of this kind was in the form of games, and some of our old games are of military origin or were used for military instruction. Chief amongst these was the game of chess. Now chess certainly does make a man think and estimate situations, but at the same time a chess board doesn't look much like a modern battle field. The games, of course, were played according to arbitrary rules and bore very little resemblance to the warfare of their own day; certainly none at all to the warfare of the present.

When maps had been developed to such perfection that they actually represented the ground and presented a picture of the terrain to those who understood how to read them, it was found that a map was a very much better board on which to play out military games than the chess and checkerboards. And so the development of maps marked the dawn of

intelligent tactical instruction. For the arbitrary rules were substituted certain imaginary tactical situations, and this was a great advance on what we had before; and finally the applicatory system of instruction was developed, and even before this war it had come into vogue in the armies of all countries.

In this system the student is furnished with a map which is a correct picture of the terrain, provided he knows how to read it. He is then given a tactical situation; he is told that a certain body of troops are at such and such a place in certain circumstances and that they have been ordered to accomplish certain things. With these data the student proceeds to study the situation and come to a decision as to what he is going to do with the imaginary troops of which he is the commander. Having done this, he is required to prepare the plans and write the orders for his imaginary subordinates. There are a number of variations of this system, each one supplementing the other and varying the interest somewhat, some bringing out points that others do not bring out. One form is called the "map problem," which is a solitaire game. The student works alone with his map. He is given his data, he estimates the situation, comes to a decision, prepares his orders, writes it all out, and hands his solution to the instructor. He works all alone, the responsibility is entirely on him; he does not receive even moral support from anybody else. Another form of this instruction is the war game or map maneuver. It was the first form that was developed, and is a true game played on a rather large map, drawn to scale. The players are divided into two sides representing the two belligerents—very much as the boys play baseball. The leaders are selected by the instructor, and they in turn choose their men. Each side is then given a situation. Instead of writing out their orders, they confer amongst themselves, make their preliminary decision, and pin it out on the map. They are then sent out of the room. The other side is called in and carries the game to a certain point, stating their moves, after which they in turn retire; the other side comes in and carries the game to the next stage. In the interval the pins are removed, unless there are two maps in separate rooms, one for each side, because, of course, one side must not be allowed to know the disposition of the troops of the other prior to the time when in the natural course of events the other side would find this out for themselves. This is playing according to common sense. One commander says, "I would send an airplane." "Where would you send it?" asks the instructor or umpire. "To such and such a place." An airplane at that place would see certain hostile dispositions. The umpire says "Your airplane reports so and so. What are you going to do?" This is stimulating and considerably less of a strain on the mind than the game of solitaire. One does not feel so utterly alone when playing the war game.

In order to give the touch of nature, we have also outdoor games. One of them is called the tactical ride or walk. The instructor rides out with his students and gives them an assumed "situation." "What would you do in such a case, Captain Jones?" "Now, Captain Smith, what criticism have you to make of Captain Jones's decision?" and so on. There is also the terrain exercise. This is the same as the map problem except that it is solved outdoors on the terrain instead of indoors on a map. Terrain exercises are limited to small forces. It is impracticable to solve a problem with any considerable force (larger than a battalion) on the ground because of the impossibility of seeing and comprehending a large area. Therefore, even in actual operations, the problems of large forces are virtually map problems, or at least solved with the aid of a map. We have also one or two sided maneuvers, as I have explained before.

You will observe that the important feature of all these forms of instruction is that the student is compelled to make a decision. That is the vital feature of them all. He is required to make an independent decision; he is not allowed to ask somebody else what to do; he must come to his own conclusions from the information furnished him.

When the student has completed his solution, or when the war game is over, the instructor reviews the situation, calls attention to errors that have been made, and impresses them upon the mind of the student. Now it is a fact that to play games like this and to be shown your mistakes (and to acknowledge them) has to some extent the effect of practical experience. The game impresses itself upon the student's mind somewhat as an actual experience; not as strongly as actual experience in the field, of course, but certainly much more strongly than the reading of a problem which somebody else has solved, for in the latter case the student

reads but does not think. Another advantage is that the experience is cheap; it is cheap for the student, and cheap for the soldiers who might have lost their lives through his mistakes. The student must candidly acknowledge his mistakes and resolve not to make the same mistakes again.

This form of instruction simulates actual conditions very much better than the formal games and is a considerable advance over them. It is the best form of tactical instruction ever devised except the actual experience of warfare. It was developed to a state of high perfection even before the war. We had some difficulties in the way of creating plausible situations. It used to be the custom for students to take the situation presented by the instructor and pick flaws in it, pointing out where the situation was not realistic. These situations were based on the experiences of former wars. The latest war of any importance prior to this one was the Russo-Japanese War, and so prior to this war our situations for problems were based on the situations of that war. But as we progressed weapons were improved and new weapons invented, new conditions arose, and during peace, when there is no chance to see any real situations, it is difficult to keep up to date or predict what the course of the next war may be. However, this is only a detail, because, as you have been informed a number of times, the fundamental principles of war, like the fundamental traits of human character, are not subject to progressive change, it is only the manner of application that changes. Therefore the methods that we followed developed the judgment and power of decision of the officer, even if the situations were sometimes a bit forced; and through the application of this method we have been able to build up efficient armies even in time of peace.

I might say that, speaking strictly from our professional and not from a humanitarian point of view, we should look with enthusiasm to the next great war. We have developed the interesting warfare of to-day from a state of crude combat with clubs; we have made it a highly refined and delicate, if excruciating, art. In the next war we will start right, from the beginning, and it will be a wonderful fight.

All of our knowledge of war is, of course, based on practical experience, but this practical experience does not suffice for the individual. It is too costly; we can not afford to let him learn his duties at the cost of the lives of men. One man actually sees very little of the war, and the little that he does see is apt to give him false ideas and a one-sided development. I have seen many examples of this in the French, British, and American Armies. I could tell you many instances of it, but I will mention only one. I came across a British machine-gun officer somewhere in France. The approved method of machine-gun defense, as you probably know, is by the development of enfiladed fire at short ranges. Now this officer had a field of fire of about 3,000 yards, and he said to me, "This planning business is all tommyrot. What's the use of waiting until the enemy gets up to 50 yards when you can shoot hell out of him at 2,000 yards?" I said, "What would you do if he started at 100 yards from you; what would you do if he laid down a smoke barrage, or came on you in a fog or at night?" He said he would shoot anyway. He had a one-sided idea; he had never seen a situation where the lines were close together, he based his ideas on his own limited experience, and the result was dangerous. Even Napoleon, who knew more about the art of war than any other man, made the statement that no one man's experience could be trusted, but that the collaboration of other men was not only valuable but necessary. We can draw a problem in such a way as to bring out and illustrate quite a number of tactical points, and it is possible to give instructions over a very wide field. So we find that this system is still applicable in war, still useful, and in fact better now than it was in peace time, because for imaginary situations are substituted real situations based on experiences of the present war. Instead of guessing what the situations might be, we know what they actually are. We can show you things that you probably never could learn from your own limited practical experience.

Now as to the details of this method of instruction. We first have what we call the "general situation." For example, the United States and Germany are at war, the line of battle is at such and such a locality and the circumstances are these. Then follows the "special situation," presenting in some detail the situation of a particular command. This situation will include a deal of testimony or "intelligence," and from that testimony you are supposed first to determine the truth. Some of the testimony will be conflicting, some will be unreliable, some positively false. You are supposed to weigh the evidence and, like a judge,

determine the truth from this mass of conflicting and contradictory evidence—the “fog of war.” The requirements of the problem are that you assume the military situation, come to a decision as to what you are going to do, and prepare your plans and orders.

Decisions on military situations are not the result of inspiration; they can result only from hard and painstaking labor. There may be exceptions, possibly there are some commanders who act by intuition, who jump to their conclusions; but Napoleon said he never did, and if he could not I do not think it is safe for any lesser intellect to attempt it. For the average man we may take it as quite certain that he must study the situation and examine all the evidence before coming to a decision. There is no short cut, and it is lazy and criminal to make a decision on which the lives of men depend without thoroughly examining the evidence. You must learn to do that here in your course of study, because if you acquire the lazy man’s habit of taking the short cuts to decisions, you will not lose that habit when you are in the field, but men will lose their lives because of your habit.

The estimate of a situation is no innovation; it is something that we do in every walk of life, military or otherwise. When you are confronted with any situation you think over the conditions that bear on the situation, you examine the different courses open to you, and come to a decision as to which is the best of those courses. This estimating a military situation is nothing more than that; it is exactly the same as in the affairs of everyday life, except that we go into it a little more systematically, a little more thoroughly; it is an application of common sense to war.

I will read something on this mental process written by a German officer—I am sorry to present anything from German sources, but this was written before the war, and it does give a good idea of the mental processes of the estimate. He says, first, that you must read over the problem very carefully several times:

After we have gained in the above manner a correct insight into the details of the problem, we get to the main task, which is to think ourselves completely into the spirit of the problem and to arrive at an estimate and decision for our future course.

By repeatedly and quietly reading the problem, paying due regard to the map in front of us, we gain, just as in focussing a telescope, a clearer and clearer conception of the situation. The more we succeed in placing ourselves mentally in the given situation and recognizing all the details in their relation to the general problem, the more we succeed in thinking ourselves into the soul of the leader, in conceiving the magnitude of his task—and in sharing his responsibility, the more eager we shall become to take over his duties and play an active part in the operations.

The longer we pore over the map, the clearer will be our conception of the measures which the situation demands. And in this it is important to hold and consider carefully; that is, to follow out to their furthest effects, all the thoughts and ideas which come to us, often passing like lightning through our brains, and suggesting various lines of action. Often it is precisely these fleeting thoughts which lead us to the right path. But ideas which are not fully thought out and thoroughly weighed can not have a decisive influence on our judgment and decision. A head which has a hundred thoughts, but which can neither hold fast nor think out a single one, will always remain undecided and irresolute in tactics.

Only by intensive reflection is found in the confusion the Ariadne thread which will lead us from the maze. However, although attention to details is to be recommended, yet the larger points of view which we have gained must not be lost in the consideration of minor details—a mistake often made and naturally often leading to false conclusions. It is rather our chief duty to find just these main points, and attention to minor details is but a means to this end.

Character and intuition unconsciously weave their thread into this labor of comprehension. To that which our mind devises is added, with good or bad effects, that which our intuition presents; and from the combined activity of both come as a product judgment and decision.

It is a delicate psychological process which takes place in the head and breast of the tactician, and without doubt this inner effort is one of the most stimulating and interesting of activities.

A tactical question awakens all our spiritual and mental powers. It demands keenness and understanding, common sense and imagination, firmness and patience, caution and daring, sense of locality and memory, judgment and the power of decision. The whole character, the whole disposition, the whole individuality of a man finds its expression here. Thus the solution of a tactical problem reflects the spirit of its author, since it is based on the peculiarities of his own individual character. A hesitating character will, in doubtful cases, prefer the defensive to the offensive. Kindred natures will follow similar trains of thought and in the majority of cases reach similar solutions.

That, I think, is a very good presentation of the nature of these mental processes.

The first item that we take up in making this estimate is your own mission, because that is the basis of your subsequent thought. What do you want to do? What do you seek to accomplish? This might appear to be very simple, but it is not always so. Your mission may be directly stated in the orders you have received. On the other hand, it may have to be deduced from these orders and it may require considerable skill to make the deductions. Often you find that the situation has quite changed since the orders were issued, and with it your mission. You must have the sense and the spirit and the judgment to see what your mission is, and that is not always so simple as you may imagine. In making this estimate it is well to have a form—not to be slavishly followed but to insure that no important points be overlooked. There are many different forms for different classes of problems, and the man who solves problems usually devises some form of his own. Here is one merely to exemplify the idea.

1. The mission, of which I have just spoken.
2. The resources at your disposal. Do you need any more? If so, where are you going to get them.
3. The tactical plan on which your plan will be based.
4. The general conditions. Roads available, shelter, enemy fire, nature of the terrain, and how it affects your problems.
5. Eventualities. What emergencies may arise and how do they affect your plan.
6. The various courses open. There will be a number of such courses which suggest themselves, some of them radically different.
7. Comparison of these courses and weighing the advantages and disadvantages of each.
8. Decision on the best course to follow. Does it best meet the probable course of events? Is it sufficiently elastic to cover the contingencies almost certain to arise?
9. A plan based on this decision and, finally,
10. The orders necessary to translate this plan into action.

A few general suggestions on the preparation of estimates, plans, and orders may be of some help. They are mostly of a practical nature. One of the first, however, is that you must be able to read a map. Colonel Ashford told you that yesterday, and I wish to add my testimony to his. The modern war game is played on a map; for all commanders it is a map problem, and if you can not read a map you will be almost helpless when you are confronted by a military situation; the map is absolutely indispensable. You must also know your matériel, its nature, capacity, and limitations, including transportation.

You must avoid dispersion; don't scatter your forces all over the terrain. This does not mean you can not distribute them, but do not scatter them so that they can not be assembled when needed to meet emergencies. This depends on liaison to a very great extent. The importance of liaison can not be overstated. The course of events in warfare requires constant attention by the commander, and the only way to do this is to have a perfect system of liaison. Find out the systems of liaison available and use them to the utmost, and as a last resort have some good trusted runners. You will undoubtedly have need of them.

Simplicity is the keynote of sound tactical procedure and should characterize all decisions, plans, and orders. In the stress of combat only the simplest plan has a chance of success. A complicated plan is poor tactics and is extremely dangerous in war.

The nature of the terrain may be of vital importance. Fortunately the terrain is not subject to change, but the roads may be blocked, bridges or culverts destroyed by enemy fire, congested by other traffic. Times and distances are matters of vital importance. You might think these very simple matters, yet we have known time after time cases where a student solving a map problem would assume that he could reach such a place at such an hour, when if he had taken the trouble to measure the distances and calculate the times he would have seen that he could not arrive there in twice the time or that the enemy would certainly reach the locality first. Times and distances are likely to be matters of vital importance—make no mistake about them.

Do not spend too much time on unimportant matters, except to satisfy yourself that they are unimportant. Your form will probably cover a great many of these, in fact it should, but you must acquire what we call a "sense of proportion." It is the ability to distinguish the things that count from those that do not.

Learn to do your work fast, but not hastily; learn to travel the right road at high speed, but do not take the short cut. Don't pile one contingency on top of another; the pile will be very unstable. Don't jump violently from one idea to another or allow each new conception that enters your mind to upset all your previous ideas. That is one of the characteristics of the untrained mind, the irresoluteness that allows it to be thrown completely out of gear by each new idea that enters.

Jot down each idea that enters your mind, think out each one to its logical conclusion, and then take up the next one.

You should go over the situation several times on the map. Each time it will be clearer. The first time over there may be five or six points you do not understand; the next time over two or three of these vague points will have disappeared. On the third reading the situation will be perfectly clear. And each time you read over your problem you discover something you have overlooked in former readings. I will not try to explain the psychology of this. I tell you only that it is true.

Do not seek too long for the absolutely ideal. A good plan, promptly prepared and vigorously carried out, is better than the best plan too long delayed and not vigorously executed.

As a result of your study you will find a number of methods by which you might accomplish your mission; perhaps there will be one or two, perhaps there will be seven or eight. Usually the more skillful you are the fewer and better will be the plans you evolve. You must select the best of these courses, and you should first arrange them in groups according to similarity if there are many. One group contemplates one general method, another group quite a different method. You consider the groups as a whole and perhaps discard an entire group. This saves time. You finally select the best group and from this the single plan that appears to be the best, or you may perhaps combine the best features of two or three. But do not try to straddle every situation; you must come to a clean-cut decision; you must decide between two different courses, but do not straddle them. I remember a situation in a problem given out at Leavenworth: A student, whose solution I read, was not quite sure what he wanted to do. The first time I read his problem I thought he intended to attack, but it was not perfectly clear. I read it over again. The second time it appeared to me that he intended to take up a defensive position. I read it a third time. "No; he is going to take up a position in readiness—for advance or retreat." I read the problem a last time. "I have it now; what he intends is to retreat." This was a case where the student had been unable to come to a decision. He was lost in a maze of possibilities and he attempted to straddle them all.

It is quite manifest that these are not problems in arithmetic. Similar minds will reach similar but never identical solutions. The fact that two solutions are different does not prove necessarily that one of them is wrong. Either of them might accomplish the results if vigorously carried out. But do not get the idea that any solution will do. There is always more than one solution, even more than one good solution.

For a beginner at least it is a good thing to write out the estimate of the situation. A lead pencil seems to stimulate the mental processes, and we have made it a rule to always require students to write out their estimates. You need not write for publication, but you should write out or at least jot down notes of your ideas, because if you don't put them down they will escape you; you must pin them down. This, moreover, gives you the best form of practice, and practice is the only means of becoming perfect or of approaching perfection in tactics, the same as in surgery or any other practical art.

As a basis for estimate and decision, you must be acquainted with what we call "good practice." There are certain people in every profession who make great discoveries and thus we have progress in science. But the average practitioner should seek to learn good practice, to become acquainted with the methods of the great surgeons or great engineers; and being fully acquainted with that practice, with which he keeps in touch by reading, observation, study, he can apply it to the situations which he meets himself. This is the case in war. One must know the methods by which efficient commanders accomplish their results and apply them to one's own problems.

You must learn to work against time. You have always a certain limited time to meet situations, and you must learn to make the best use of that time. That is something the beginner finds it hard to appreciate, and he will spend hours of his time going over some matters of no vital importance and will have no time left for matters that really do count.

Don't fail to be thorough in your work and don't trust to luck to bring you out right. It may be that the Lord occasionally saves the fool from his folly, but as a rule He helps only those who help themselves. When you have made a thorough and careful estimate of the situation, and only then, you are able to make an intelligent decision.

When your decision is made have the courage to carry it out unflinchingly. Do not let doubts begin to assail your mind the minute you make your decision. Your plan may not be perfect, but if you carry it out vigorously and forcefully you will succeed, and if you vacillate and retract you commit the gravest of military crimes and you invite disaster.

Having made the decision, you will prepare the details of the plan of action which are based on this decision, whereupon you reach the very critical stage in which you are called upon to prepare orders for your subordinates. Your decision, however wise, is useless, perfectly useless, unless you can translate it into action through the medium of good orders. Having cleared Seylla, be careful that you do not wreck the enterprise on Charybdis. So I want to give you a few suggestions in regard to orders. The first one is: Don't attempt to write an order until you are perfectly sure what you want. Your orders will reflect your state of mind. If you are not sure what you want, you certainly can not make it plain to your subordinates. You can only communicate your indecision to them.

The orders should be expressed in professional language. I believe you, being professional men, will sympathize with this. Every profession has its language, and when we talk with our professional confreres we like to have them use that language. When you are talking with a man who professes to be a surgeon you can soon tell from the language he uses whether he is really a surgeon or not. If he does not speak your language you know he doesn't belong to the profession. The military profession has its language. We use certain terms and certain modes of expression, and your subordinates will be used to this language. If you do not use it they will think you do not know the game, and probably they will be right. As a consequence they will lose confidence in you, if, indeed, they ever had any. You must learn the language and use it.

Orders, to be easily translated and readily grasped, should also be according to form. For your tactical orders we have a very excellent form and we stick closely to it. In administrative orders, such as you will have to give, there will be more elasticity, but at the same time you should have forms for your orders, and these forms you will learn here. Use them, because if you do not you acquire the habit of giving orders in a haphazard way. Those who obey the orders learn to look for certain matters in certain paragraphs. If they do not find them in the usual place they may not look farther, and the orders are not carried out. The form and arrangement should be professional and characteristic, like the language. If you do not use a systematic form your subordinates will again lose confidence in you.

Orders should be brief and should contain no unnecessary words. Brevity is the soul of wit and the soul of tactical orders. These orders should above all be clear; but you will generally find that brevity and clearness go hand in hand. Learn to express yourself in brief, simple language. This is a characteristic of military parlance. Long orders indicate laziness. It is harder to read a long order than a short one. A long order arouses hostility on the part of your subordinates. If any of you has ever belonged to a division, as no doubt you have, and has seen the amount of literature that comes from that infernal machine called a mimeograph you can sympathize with those who are the victims of over-many orders, especially when they never know the people from whom these orders come. They live in the infernal regions and simply grind out orders.

There should be only so much detail in an order as is necessary to secure results. It requires a good deal of skill to determine just what that should be. The amount of information, as distinguished from instructions, that is contained in an order, should be just sufficient to enable an intelligent subordinate to understand the situation and the mission. This is necessary so that in case he meets an emergency unforeseen in the order he will be

able to act intelligently and do what you would have him do—in other words, carry out the spirit of the order. He can not do that unless he knows the situation, and unless you have made it clear to him what you are trying to accomplish. The amount of detail that should be included is largely dependent on the training and efficiency of your subordinates. In our map problems we make the assumption that each subordinate knows his duty and is fully competent in his own sphere, but, of course, in actual practice this may not be the case. You may have green, untrained men, and it may be necessary to give them more detailed instructions than would be necessary with highly trained men who understand their work. If there is time and opportunity, you may assemble your subordinates and discuss with them certain matters which it would not be proper to include in an order, and make perfectly sure that they understand what is wanted. But there will not always be an opportunity to do this.

Reasons, conjectures, arguments, discussions, guesses, have no place in an order. Don't argue—command. That's what orders are for. Ambiguity, of course, is a fatal mistake. It nearly always results from a lack of decision. If you don't know what you want, of course your orders will be ambiguous.

The orders must agree with the decision and you must check them and see that they cover every essential point and insure performance of what you want done.

In a combined order for the entire command you should see that you have given every one of your subordinates his task and that you have covered the disposition of every item of your equipment. You should make lists of your personnel, or of all who are to receive orders. If you are not to give orders direct to certain men, make sure that they are under the control of other men to whom you do give orders, and that both parties know it.

Written orders are preferable, but if obliged to give a verbal order use the same language and the same general form, and don't speak until you have decided what to say. It is a common fault to speak without just deciding what to say, and it always produces confusion. Your subordinates will perceive at once your state of indecision, which is communicated to them. Make notes of what you intend to say, and unless it is very simple cause your subordinates also to make notes.

Do not invade the province of your subordinates by detailed instructions as to how they are to perform their duties. Tell them what to do, but not how to do it. If you put no responsibility on them they will feel none, and the man without responsibility has nothing to hold him steady in a storm. If you are satisfied a subordinate does not know his task, it is better to send him to Blois and put in somebody that does. If the men are new and green you have to teach them, of course. They can not be competent in the beginning. Train them.

Do not divide responsibility with your subordinates or "pass the buck" to them. Avoid such expressions as "If possible," "If you think best," "If conditions warrant." Shoulder your own responsibility and put your subordinate's strictly up to him. If he has to carry your responsibility you are plainly superfluous, and might better be disposed of yourself, and, on the other hand, if you give your subordinate no responsibility he will take none, and it is the feeling of responsibility above all else that compels us to do our duties.

Do not discuss contingencies in an order or look too far ahead. It isn't safe in war. Conditions are very unstable, very subject to change. War resembles a kaleidoscope; you can not predict what is going to happen too far ahead. You must have the future in mind yourself; be prepared, but do not include plans looking into the far-distant future in your orders. Let the situation develop; it will then be clearer and you can give intelligent orders at the right time. If your orders dip too deep into the future you run a tremendous risk of having to retract them, thus destroying the confidence of your subordinates in the commander who has too plainly guessed and guessed wrong.

If you have seen fit to omit from your orders certain items which are usually included and which your subordinates expect to see, it will be well to explain that orders on these matters will be given later when occasion demands. This shows you have not overlooked or neglected some important point and relieves the minds of your subordinates.

There is only one method of becoming perfect in order writing, and that is practice—practice. So make the most of what practice you will be given here. If you acquire a habit of laziness at the start, you will probably continue that habit in the field.

The elements of success in war are simple plans, based on good judgment, and painstaking study, and carried out with unwavering determination. Do not allow apparent emergencies arriving after the promulgation of your orders to stampede you into a violent disruption of your carefully prepared plans. This will produce more confusion than the emergency you seek to evade.

These data I have been giving you are applicable of course to larger problems, but they are equally applicable to the smaller ones. There is no decision you make that is too small to be worth your care and attention. Be honest in all you do. Make prompt decisions but never snap decisions. It is not the length of time required for the solution that determines the importance of the problem. An important decision may be made in an hour, or in five minutes. Do not think that because a decision must be made promptly you are relieved of the necessity of using your wits and giving it careful study. All these precautions apply to the little matters just the same as to the big ones, and, as you know, the big ones are made up of little matters after all.

As our forefathers said, "We hold these truths to be self-evident and fundamental." I make no apologies for my subject, for its importance can not be overrated. I only hope I have been able to present it in such a manner as to convince you and to stimulate your interest in the excellent course of instruction you will receive at this school.

Army Sanitary School No. 153.

PLAN FOR EVACUATION OF SICK AND WOUNDED

By Col. J. W. Grissinger, M. C., chief surgeon, First Corps

REGIMENTAL SERVICE

1. *Battalion aid posts.*—Battalion aid posts and relays of litter bearers, when the latter are necessary, will be established at such times and places as may be determined by regimental surgeons under the supervision of the division surgeon.

It will be the duty of the regimental sanitary personnel, and the attached litter bearers detailed from line troops to apply first aid, including splints when needed, to the wounded as they find them. They will then litter them to the battalion aid post, which is simply a collecting point for wounded. One of these collecting points for a regiment will frequently be all that is necessary. It should, if possible, be placed in a sheltered spot.

The regimental litter bearers must pass no farther to the rear, but must return at once to their organization in the line and continue their search for wounded. They must not lose contact with their command. They will also direct walking wounded to their proper destination.

At the battalion aid post (collecting point) will be stationed two battalion medical officers with one sergeant and eight privates, Medical Department. It will be the duty of these officers to see that the wounded are given the necessary attention and to maintain liaison with the ambulance company personnel who are charged with evacuating wounded from this point to the ambulance head. The more highly trained permanent sanitary personnel of the regiment should be utilized as much as possible for the application of dressings, including splints to the wounded, while the attached litter bearers from line troops are used for the actual littering of the wounded to the collecting points. Antitetanic serum will be given at the battalion aid post when practicable.

The responsibility for the care and evacuation of the wounded ceases for the regimental sanitary personnel the moment the case leaves the battalion aid post en route to the ambulance head.

DIVISIONAL SANITARY TRAIN

Ambulance company section

1. It will be the duty of the litter bearers from the ambulance company section of the divisional sanitary train to litter the wounded from the battalion aid posts (collecting points) to the ambulance head. One officer from the ambulance company section of the divisional sanitary train will be detailed with each regiment. His station will be at the battalion aid

post and he will be responsible for the evacuation of wounded from this point to the ambulance head. If there is more than one battalion aid post he will supervise the evacuation from each. He will maintain close liaison between the regimental and ambulance company service.

2. *Ambulance head.*—The ambulance head is the farthest point forward to which ambulances can go with reasonable safety. It is the point to which cases are littered from the battalion aid posts and where they are first placed in an ambulance. It should be on a good road if possible. From the ambulance head, patients will be carried by ambulance to the triage.

3. *Ambulance dressing station.*—An ambulance dressing station will be established about midway between the ambulance head and the triage. With the narrow front usually held in open warfare, one ambulance dressing station will usually be sufficient. Before an engagement opens, however, it may not be possible to forecast with certainty which path the stream of casualties will follow. In this event, it will be wise to send enough equipment to two or three points to establish nuclei of dressing stations. If later it is found that these stations are not needed, they should be withdrawn and only those retained which are really necessary. At the ambulance dressing station, only those cases will be removed whose condition requires attention. Shock tables will be installed so that cases needing shock treatment may be cared for. Cases which do not need attention at this point will be immediately sent on to the triage. Shock cases as soon as sufficiently recovered will be sent on to the triage.

There are times when only Ford ambulances can operate in advance areas; roads are in such condition that the heavier ambulances can not get through. In this event, the Ford ambulances should be used to bring cases to the ambulance dressing station, and at this point they will be transferred to the heavier ambulances. This will necessitate, of course, the establishment of the ambulance dressing station at a point which the heavier ambulances can reach.

The ambulance dressing station should be on a good road if possible. It must be on a return road and should have shelter if such can be procured.

4. During active operations, when the number of casualties becomes very large, it will be found that the available ambulance transportation will be entirely insufficient to carry all wounded and gassed to the rear and to prevent congestion in the front areas. It therefore is necessary for division surgeons to keep in liaison with the division motor transport officer and to secure the use of as many trucks as possible to carry back lightly wounded, lightly gassed, and lightly sick cases. Severely wounded and severely gassed must be carried in ambulances only. The corps surgeon will give every possible assistance to division surgeons during such periods of stress and will utilize for this purpose all available ambulances within the corps. Motor transportation (trucks) of sanitary train will be utilized to their capacity in transporting lightly wounded, lightly sick, and lightly gassed.

5. Close liaison must be maintained in the division between the director of the ambulance company section and the director of the field hospital section of the divisional sanitary train. The commanding officer of the sanitary train under the supervision of the division surgeon will see that this liaison is constantly maintained. It is particularly important that the director of the ambulance section know immediately when any change is made in the location of the triage so that ambulances may be properly directed. Otherwise much confusion and loss of valuable time will result.

6. The station of the division surgeon, commanding officer, sanitary train, and director of field hospital section, divisional sanitary train, will normally be at the place where the field hospitals are grouped. The division surgeon must be in close liaison, however, with the division post of command. This may be accomplished by stationing a subordinate medical officer at that point to keep the Division Surgeon informed as to changes in the tactical situation. The station of the director of ambulance section, divisional sanitary train, will normally be at the ambulance dressing station.

7. Roads in the vicinity of all divisional sanitary formations will be plainly marked so that ambulance drivers may locate them without trouble. The divisional assistant provost marshal will be kept advised of the location of all sanitary units and of any changes made so that the military police will be competent at all times to give necessary and intelligent instructions as to their location.

Field hospital section

1. Field Hospitals will be utilized as follows:

- | | |
|---------------------------|-----------|
| (a) Hospital for wounded. | } Triage. |
| (b) Hospital for sick. | |
| (c) Hospital for gassed. | |
| (d) Hospital in reserve. | |

Wherever possible the field hospitals will be grouped in one place. They will be placed at a point far enough from the front line as to be reasonably safe from enemy shell fire. This will ordinarily be from 10 to 12 km. from the front. They will be plainly marked with the red cross. They will not be placed near an important crossroads, ammunition dump, important bridge, or a battery position. Any one of the above places are subject at any time to enemy shell fire. In order to avoid interference with traffic, it is better to place them on a side road rather than a main road. In either case, a cut-out should be constructed so that ambulances will not stop on the road but will be directed into the cut-out. They must be on a return road, which should, of course, be as good a road as can be found. There is no advantage in placing them so far forward as to be subjected to shell fire; on the other hand, the disadvantages are obvious. It can not be hoped, of course, to invariably escape shelling, of back areas. Shelter in buildings is most advantageous if it can be secured. If such can not be secured, the field hospital tentage will be utilized for that purpose.

2. *Triage*.—The triage, therefore, is a group of three field hospitals. All cases come to the main receiving tent, from which they are at once diverted in three streams—all wounded to the hospital for wounded, all sick to the hospital for sick, and all gassed to the hospital for gassed. At these three places the real sorting takes place.

The saving in ambulance transportation and in general efficiency is administration that results from having these hospitals grouped in one place at once becomes evident.

All cases from the front must pass through this group of field hospitals.

3. *Hospital for wounded*.—At the hospital for wounded, in addition to the personnel of the field hospital conducting it, will be stationed the following medical officers: Division orthopedist; a medical officer with good surgical experience and judgment.

The division orthopedist will examine all fracture cases and cases having joint injuries and will see that all cases are properly splinted before being sent to the rear. Insistence must be laid on the fact that fractures and joint injuries should, whenever possible, be splinted where they fall. In all events, they must never pass through the hospital for wounded without having this properly done.

The medical officer with good surgical experience and judgment who is selected for duty at this point will examine all wounds and direct to which hospital each case will be sent.

4. All wounded will be examined, dressings adjusted, and hemorrhage controlled if necessary, antitetanic serum administered if not already done, food and hot drinks given where permissible, and shock treated when the patient's condition makes it necessary. They will be sorted and placed under shelter while awaiting transportation to the rear. They will not, however, be disturbed any more than is absolutely necessary. Unnecessary handling of cases causes much suffering to the patient, increases his shock, and multiplies enormously his chances for infection. There has been too much tendency in the past to renew dressings when such was not actually necessary.

Shock tables will be installed, so that cases needing shock treatment may be properly cared for. Cases in shock will be held, if military conditions permit, until their condition permits transportation to the rear.

5. All wounded will be divided into three groups: (a) Transportable lying; (b) transportable sitting; (c) nontransportable.

The transportable cases will be held in two groups (lying and sitting), under shelter, until ambulance or truck transportation is available for their removal to the rear. This will be done as quickly as possible and should be direct from the field hospital for wounded to the evacuation hospital. Cases, especially those showing shock symptoms, must be kept warm during transit. Canteens make excellent hot-water containers. An ample supply can usually be obtained from salvage. They should be placed around each shocked case that is to be transported by ambulance to the rear.

Nontransportable wounded will be sent direct to the hospital designated for such cases.

This hospital should be as near the triage as possible, preferably in the same plot, so that the time and handling from triage to hospital will be reduced to the minimum.

At this hospital will be finally held only those cases whose transportation farther to the rear will mean death. These cases should not represent more than one-half to 1 per cent of the total casualties. Not more than two surgical teams should be required. The cases which should be operated here will resolve themselves very largely into bleeding abdominal wounds and badly shocked extremities. Head, chest, and nonbleeding abdominal wounds will ordinarily stand transportation farther to the rear without greatly compromising their chances.

After operation, nontransportable cases will be sent to the evacuation hospital as soon as they are able to stand transportation.

6. In transportation by ambulance, it is essential that cases be not mixed—place sick in one ambulance, gassed in one ambulance, and wounded in one ambulance. It is easily seen that a wounded man may be also gassed by placing him in the same ambulance with a gas casualty. Likewise a wounded or gassed man may be infected with influenza by placing him in an ambulance with one suffering from that infection. A man who is both gassed and wounded will be placed in an ambulance for gassed cases.

7. In times of activity, when wounded are coming in rapidly, transport the wounded first, allowing the sick and gassed to wait until the rush has subsided. Delay for wounded men is more dangerous than it is for sick or gassed. Segregation of sick, wounded, and gassed in groups as outlined above renders this procedure a simple matter.

8. Each division surgeon will name a medical officer of good judgment and experience who will have charge of and be responsible for the shock work at the field hospital for wounded. This is a most important function which, if properly performed, will save many lives. In order to insure, however, that it be properly done it is necessary that one man be held responsible for the work. He will be responsible for the collection of necessary supplies and apparatus and the training of enlisted personnel. He will determine when the shocked patient is fit for further transportation. When the triage and the hospital for nontransportable wounded are adjacent, all cases in shock will be sent to the latter place. Here they will get the necessary shock treatment and final decision made as to whether they shall be operated on here or transported to the evacuation hospital. If there is a division internist, he will be the officer designated to take charge of shock treatment. Careful blanketing is a most potent means for preventing shock.

9. *Hospital for sick.*—All sick of whatever character will be sent from the receiving tent immediately to the field hospital for sick. In this field hospital, in addition to the personnel conducting the hospital, will be stationed: Division internist; division psychiatrist.

10. The division internist will see that all cases are as carefully examined as time and circumstances permit. He will separate cases, except those of a nervous character, into the following groups and dispose of them as indicated:

(a) Those fit for duty at once will be returned to their organization immediately.

(b) Those who will be fit for duty in two days will be retained at this field hospital and returned from this point to their organization when they have recovered. Any of these cases later showing serious symptoms will be transferred at once to the evacuation hospital. This refers to times of activity, with many casualties passing through. In quiet periods medical cases who will be ready for duty within four or five days may be held. No really sick man, however, such as dysentery, influenza, pneumonia, etc., must be held under any circumstances longer than is necessary to secure transportation to the rear.

(c) Those who are not seriously sick, but who will be incapacitated for from two to seven days, will be sent to the corps rest camp when such is established. If not established, they will be sent to the evacuation hospital.

(d) All others except contagious will be sent direct to the evacuation hospital.

(e) Contagious diseases to contagious hospital.

(f) During active operations, venereal cases, except those having disabling complications such as orchitis, epididymitis, or infectious stages of syphilis, must be retained for full duty at the front.

11. The division psychiatrist will examine all cases of concussion, suspected simulation, and other nervous conditions that are sent to this hospital. He will group the cases coming under his observation in the same way and make the same disposition as directed above for other medical cases by the division internist.

12. *Gas hospital (divisional).*—To this field hospital will be sent immediately from the receiving tent all gas casualties. The division medical gas officer will be stationed at this hospital. He will supervise the sorting of the cases and their proper treatment. Facilities must be provided to give the necessary special treatment—a proper bathing, alkaline treatment, administration of oxygen, and, if necessary, venesection. A shock table will also be provided for the treatment of such cases as need shock treatment.

The gas hospital must be located near a satisfactory water supply.

All cases will be divided, under the supervision of the division medical gas officer, into the following groups and disposed of as indicated:

(a) Those fit for immediate duty, who will be returned at once to their organization.

(b) Those who will be fit for duty in 24 hours. These will be retained at this field hospital and returned to their organization when they have recovered.

(c) All others, who will be sent to the evacuation hospital.

13. In past experience during open warfare it has been found that large numbers of men return from the front diagnosed as concussion, suspected simulation, or other nervous disorder or gas casualties. The great majority of these men present neither of the above conditions, but are simply exhausted, mentally and physically. They are disabled for the time being, but should not be sent to evacuation hospitals. They must be held in divisional or corps sanitary organizations, given the necessary food, bath when possible, and an opportunity to thoroughly rest. It will be found that within one to three days they will be able to return to full duty at the front, thus saving a very marked loss of man power when the maintenance of the man power of a division at its full strength is most important. Any such cases subsequently developing serious symptoms will be at once transferred to an evacuation hospital.

14. *One field hospital in reserve.*—This will be utilized to give assistance whenever needed, both in personnel and equipment. When necessary to move sanitary formations farther to the front, this field hospital will be sent forward to establish the new triage. When it is ready to function, the other units will be brought up as quickly as possible.

15. In each division should be established a hospital for nontransportable wounded. The following equipment and personnel will be all that is necessary:

- 1 small Bessonneau tent for operating room.
- 1 or 2 ward tents for wards.
- 50 cots.
- 150 blankets.
- 1 field operating case (large).
- 6 dozen quarter-pound cans ether.
- 2 gallons alcohol.
- 2 dozen hemostats.
- 1 instrument boiler.
- 4 hand basins.
- 1 dozen small operating sheets.
- 4 dozen towels.
- 1,200 gauze sponges, 4 by 4.
- 100 gauze pads, 9 by 9.
- 100 chest or abdominal binders.
- 100 chest or abdominal dressings.
- 100 4-inch bandages.
- 100 6-inch bandages.
- 2 5-yard rolls adhesive plaster.
- 1 dozen intestinal needles, straight.
- 1 dozen intestinal needles, curved (Mayo No. 12).
- 2 dozen packages intestinal silk or linen.
- 1 dozen tubes No. "0" chromic catgut.

- 1 dozen tubes No. 1 chromic catgut.
- 1 dozen tubes No. 2 chromic catgut.
- 1 dozen tubes No. "0" plain catgut.
- 1 dozen tubes No. 1 plain catgut.
- 1 dozen tubes No. 2 plain catgut.
- 1 dozen rubber gloves, No. 7½.
- 1 dozen rubber gloves, No. 8.
- 2 operating tables.
- 1 bolt unsterile surgical gauze.

This is in addition to the regular equipment for treatment of shock.

The linen and dressings can be obtained from the nearest evacuation hospital already sterilized.

The personnel should consist of two operating teams, composed of operator, assistant, and anesthetist. Two medical officers and 20 men from the personnel of the field hospital section, sanitary train, will be necessary for pre and post operative care.

The above equipment can all be carried on two 3-ton trucks.

Care must be taken that these organizations be kept absolutely mobile at all times. The tendency is to accumulate too much material and to attempt entirely too much surgery. The proper location for a hospital for nontransportable wounded is in close proximity to the triage so that these cases may be carried by litter from the triage to this hospital. This saves ambulance transportation and, further, saves time and much jolting with the consequent increases in shock for a class of desperately wounded men whose only chance for life rests in immediate skillful operation.

Two surgical teams will be sufficient to care for all cases that should be operated here. Experience has shown that two groups will cover practically all real nontransportables—(a) bleeding abdominal wounds, (b) badly shocked extremities (tourniquet). Ordinary abdominal wounds, head and chest cases will stand transportation farther to the rear where the increased facilities for operation and after care, particularly the latter, will more than compensate for the earlier operation.

In case this operating unit is located adjacent to the triage, all shock cases coming to the latter place should immediately be sent to this field hospital. After shock has been combatted, final decision will be made as to the necessity for operation. If a real nontransportable, operate; if the case will stand transportation to the rear, make ample provision to keep him warm in transit and send him to the evacuation hospital.

Cases will of course be evacuated to the rear just as soon after operation as their condition will permit.

In case there are not enough surgical teams to furnish two teams for each division in the corps, six teams for the corps will be sufficient to carry on the work inasmuch as there are rarely more than three divisions in the line at one time. These teams could then be shifted from one division to another as occasion demanded. In case the divisional triage with the hospital for nontransportable moved forward, it would be necessary for the corps sanitary train to take care of any cases remaining in this hospital who were not in condition to be evacuated to evacuation hospitals.

It will be noted that no X-ray equipment or sterilizing equipment for dressings is provided in the list furnished. This reduces the bulk to be transported by a considerable amount. X-ray equipment and equipment for sterilization of dressings is not necessary for this hospital.

The above equipment and surgical personnel should be attached to and operate with the field hospital for wounded.

16. It must always be borne in mind that divisional hospitals must be as rapidly cleared as is possible in order that they may be mobile at all times.

17. *Exchange of supplies.*—It is of utmost importance that a systematic exchange of supplies—as litters, dressings, splints, blankets, hot-water bottles—operating from the front line all the way back to the final hospital to which the patient is delivered be instituted at once. When a patient is placed in an ambulance, the ambulance orderly must return to the litter bearers a duplicate of all supplies furnished the patient. Similarly, when the ambulance delivers the patient to a hospital he must get from the hospital a duplicate of all supplies furnished the patient. This must operate at every point where a change of transportation

is made. Otherwise, the supplies at the front-line positions will soon become exhausted and unnecessary delay and suffering result. If this system of exchange is enforced, there is a constant steady stream of all necessary supplies going forward and there need be no interruption in the care given to wounded or other casualties.

If casualties are evacuated in trucks which do not return to division hospitals, blankets, litters, and other supplies should be returned by evacuation hospitals to the first ambulance which will return to the division.

18. For the purpose of securing proper records it will be wise to have placed at each triage an intelligence officer and an officer from the statistical section, with sufficient clerks. By this arrangement all necessary data can be obtained by these officers immediately upon entrance of cases at the triage, thus saving much time and subsequent paper work.

CORPS SANITARY TRAIN

1. Corps ambulance companies will be utilized under the direction of the commanding officer, corps sanitary train, to evacuate corps field hospitals and to lend all possible assistance in evacuating sick and wounded from divisional sanitary formations.

2. Corps field hospitals will be grouped at a central point, with good road facilities to all divisions in the corps. Three of these field hospitals will be utilized to form a corps rest camp. The fourth field hospital will be held in reserve for such use, both of personnel and equipment, as may be required.

To the corps rest camp will be sent the following class of cases:

(a) All sick from divisions and from corps troops who will be incapacitated longer than two days. The corps rest camp will hold all those who will be fit for duty within 10 days and will evacuate all others to an evacuation hospital.

(b) Return of cases fit for duty from evacuation hospitals.

Arrangements will be made with all evacuation hospitals draining the corps area to return to the corps rest camp all cases who are fit to return from the evacuation hospital to duty. Particular attention will be paid to gas hospitals in order to prevent the large number of pseudo or slightly gassed cases from getting farther to the rear. This will prevent the loss of those men to combat divisions who through error or by reason of slight illness or injury got into evacuation hospitals instead of being treated in divisional or corps sanitary organizations. It will amount to many hundreds of cases during a period of activity and is therefore a most important function. The commanding officer, corps sanitary train, is charged with keeping in liaison with evacuation hospital authorities in order to assure that all such cases are turned over to the rest camp instead of being evacuated to base hospitals or other formations in the rear. He will also keep in liaison with the proper divisional authorities in order to make satisfactory arrangements to have these men returned from the corps rest camp to a specific point in the division and thus avoid their wandering about the country looking for the organizations. He will make the necessary arrangements to assure that these men are properly equipped. (G. O. 111, sec. 7, par. 2, c. s.)

In order that these men may return to their organizations in good physical condition, the commanding officer, corps sanitary train, will institute a program of physical training sufficient to keep the men well occupied and so graduated as to insure a gradual return of full physical strength before returning them to full duty at the front.

(c) In case the hospital for slightly wounded is located a long distance from divisional triages, the corps rest camp may be utilized as a relay point for slightly wounded. To this point will be brought from the divisional triages all sitting wounded. From this point the sitting wounded will be evacuated by the corps ambulance or truck transportation to the appropriate evacuation hospital. No operations will be attempted.

3. In order to assure that ambulances get to their proper destination, the commanding officer, corps sanitary train, will station enlisted men at such road points as may be necessary, whose duty will be to direct ambulances to the proper hospital. They will be supplied with illuminated signs at night (an ordinary box with the lid replaced by sheeting and illuminated by candles will be sufficient). This will be under the immediate supervision of an officer of the day appointed by roster from the corps sanitary train.

The commanding officer, corps sanitary train, will keep in touch with evacuation hospitals, who will inform the former at regular intervals how many vacant beds are in each hospital. The commanding officer, corps sanitary train, will transmit this information to the enlisted men at the road points mentioned. These enlisted men will then be able at all times to properly direct all ambulances. Road congestion is frequently so marked and telephone service so unreliable during active operations that it becomes impossible to keep the evacuating officer at the triage informed as to the vacant beds in various hospitals. Unless such guides as noted above are placed, much time is lost and transportation wasted by peddling cases from one hospital to another hunting for one that has vacant space.

A medical officer from the corps sanitary train will be placed at the triage of each division in the line. He will be responsible for the evacuation from the triage and the proper instruction of ambulance drivers and orderlies as to routes and hospitals.

A medical officer from the corps sanitary train will be stationed at each evacuation hospital draining the corps area, if these hospitals are grouped. If not grouped, then at as many of the more important hospitals as is possible. His duties will be to supervise the unloading of ambulances, the exchange of supplies, instruction of drivers and orderlies as to their return, and any other points concerning the ambulance service that may arise.

With the corps sanitary train officers at the triages and evacuation hospitals and with road guides under the supervision of an officer of the day at properly selected road points, there should be no difficulty in keeping ambulances properly directed.

EVACUATION HOSPITALS

1. These come under the supervision of the army.

For efficient and economical evacuation, evacuation hospitals should be grouped. For a corps area, two groups should be provided, each of course on a railroad.

At each group should be accepted all cases without a question that are brought to it. There should be a gas section, a medical section, and a surgical section, to each of which are sent the appropriate class of cases immediately upon arrival.

The need for a medical service at each evacuation hospital is obvious.

In the surgical section a careful triage of all wounded will be made. Separate surgical services for slightly wounded and severely wounded will be provided, each with its own personnel and each concentrating exclusively on one or the other class of cases.

Close attention should be paid to the slightly wounded, for this class represents a valuable military asset. Early and expert surgical service assures their return to the line at an early date, and represents, therefore, a very decided saving in man power.

The present method of having evacuation hospitals scattered widely over an area is very unsatisfactory for the following reasons:

- (a) Drivers of ambulances have great difficulty in locating the various hospitals.
- (b) They learn the way to one hospital and concentrate on it. The result is congestion there, while another equally well-equipped institution but less accessible will have little to do.
- (c) Much time is lost, with resulting suffering and damage to the patient.
- (d) Great increase in ambulance transportation required.
- (e) It has happened quite frequently that a hospital does not agree with the selection made at the triage and will therefore not accept the cases, or will accept only a portion of those in the ambulance. The others are directed to another hospital and from there perhaps to a third. Grouping of hospitals with acceptances of all classes of cases would remove the possibility of this peddling of cases.
- (f) Increased economy in utilizing available hospital space. If hospitals were grouped, it would be a simple matter to utilize all available space. When widely separated, it frequently happens that one is crowded while the other is almost empty; and with the difficulty in telephonic communication and the lack of transportation, it is not always easy to get the stream properly diverted. It is true that close liaison between the army and corps should largely obviate this, but in any event grouping of hospitals would absolutely eliminate the difficulty.
- (g) Grouping of evacuation hospitals would also greatly facilitate the evacuation of cases from this point farther to the rear.

2. If the evacuation hospitals can not be grouped, the only alteration required in the above plan would be that a more careful sorting of surgical cases would be necessary at the divisional triage.

3. It is felt that mobile hospitals should be under the control of the corps surgeon—two to a corps. They should be placed as far forward as possible and should receive the very seriously wounded who do not fall into the class of actual nontransportables as previously noted.

Being under the control of the corps surgeon, who is in close touch with actual conditions at the front and has better knowledge of roads and terrain, they can be moved forward more advantageously and with much less delay than when the corps surgeon does not exercise control. It would make decidedly for efficiency.

Army Sanitary School No. 155.

ARMY HOSPITALS

Lieut. Col. Howard H. Johnson, M. C.

It has been the object of this paper to collect in one communication some of the principal points covering the establishment, regulation, and function of mobile and evacuation hospitals as they have been seen in operation in four areas of our army activity from August 4 to November 11. Many of the good features are perhaps not included through failure to appreciate them all. Many of the weak points and reasons for inefficiency are likewise omitted. It is hoped, however, that this presentation of the subject will serve in a measure to direct attention to a very definite and important area of our activity as medical officers, which, in the experience of most of us is new, peculiar, and lacking in definite regulations.

The subject has been dealt with under the heads of: I. Instructions to commanding officers of evacuation, mobile, and special hospitals, covering the points (a) location and establishment, (b) collection of patients from triages, (c) admission of patients to hospital, (d) the receiving ward, (e) triage, (f) evacuation, (g) professional work, (h) mess. II. Regulations. III. Function of mobile and evacuation hospitals. IV. Standard types of evacuation and mobile hospitals. V. Ground plans. VI. Army hospital centers.

Some of these subjects have been covered in a way as they would be covered in regulations or by an army chief surgeon in his memoranda to the commanding officers of hospitals. In this form, definite and at times dogmatic statements are made to cover ideal conditions in order that those concerned may, as it were, "have a mark to shoot at," and critics may agree or disagree. It is hoped that with the outline presented, subtractions and additions may result in a fairly definite plan for the establishment, regulation, and function of these hospitals.

I. INSTRUCTIONS TO COMMANDING OFFICERS OF MOBILE, EVACUATION, AND SPECIAL HOSPITALS

The work to be performed in these hospitals in so far as it has to do with the professional care of patients is presumed to be fully understood by the commanding officers and personnel. Consultants in the various branches of medicine and surgery on duty in the chief surgeon's office will be sent to the hospital for the purpose of inspection and instruction of the members of the staff. In addition to the proper surgical and medical attention required by the patient, there are other features particularly administrative which require careful attention and regulation.

(a) *Location and establishment.*—(1) Mobile hospitals, where practicable, will be established in a field located on a good road, which, with other roads, will drain a particular portion of the line which it is desired this hospital shall serve. In general, an attempt will be made to place this hospital from 2 to 3 km. back of the area of normal artillery fire, protected if possible from overshots by hills or ridges. In winter, these hospitals should be so located as to prevent their being subject to prevailing winds. This protection may be had from woods or hills, or in emergency a windbreak may be constructed by the personnel or by the camouflage service. Good ambulance roads to the receiving ward and through the evacuation area will be constructed by the engineers at the earliest practicable moment. Distribution of tentage, corridors, and latrines, together with the internal arrangement and function, will be made to conform to circumstances found to exist.

(2) Evacuation hospitals will be established along a standard-gauge railway where a siding suitable for loading is at hand, or where such siding may be put in. Specifications regarding sanitary sidings will be given under "ground plans." It will be the endeavor of the chief surgeon to establish these hospitals as near the front as is possible. Such establishment, however, will depend upon existing railways or railway construction, so that evacuation hospitals will be established, in the main, a short distance back of railhead. The establishment of special hospitals will be avoided, except perhaps those for the treatment of neuropsychiatric cases. In some instances, gas hospitals will be established as departments of established evacuation hospitals.

(b) *Collection of patients from triages.*—This work will be under the control of the corps surgeon and, in general, will be performed in the following manner:

An officer of the evacuation ambulance service will be placed in charge of ambulance evacuation for one or more divisional triages. He will be given a suitable number of ambulances, with instructions covering proper triage evacuation. He will be supplied, from time to time, by the corps surgeon with information regarding roads to the rear; bed capacity available in the various hospitals; changes in location of hospitals and triages. This officer will be held responsible for the proper transportation to mobile, special, or designated evacuation hospitals, as the requirements of the situation demand, sending cases designated "mobile hospital" to the nearest mobile hospital having available beds; gas cases to the nearest hospital having facilities and bed space for gas cases, etc. This officer will see that signs are placed along all roads leading to the hospitals in the rear. He will personally direct the placing of these signs and will see that they are of such size and character as to clearly indicate the route to be followed. Particular attention will be paid to crossroads. Each sign will give the following information: "Evacuation Hospital No. —, Seully (with an arrow pointing the direction to be taken), 5.5 km." These signs will be illuminated at night. He will furnish the ambulance driver a slip containing the following information:

Date -----

----- Triage. (10 a. m.) Departed. (11 a. m.) Arrived.

1. -----

(Maximum speed allowed)

2. -----

(Name, number and location of hospital)

3. ----- splints; ----- blankets to be returned.

A space will be available on this slip for the initial or stamp of the receiving hospital which will indicate that the patients have been received. The evacuation ambulance officer will take the necessary precautions to assure himself that cases dispatched to the various hospitals are being received and that they are not diverted to other hospitals by ambulance drivers without authority; as in the past, ambulance drivers have shown a tendency to deliver cases to hospitals other than those to which they have been directed, with the result that certain hospitals have been overcrowded, while others have not received their share of the work.

(c) *Admission of patients to hospitals.*—Information will be furnished corps and division surgeons regarding the location of hospitals and the work to be performed by them. This information will be found in army, corps, and division orders. Corps and division surgeons will be responsible for the proper selection, classification, and loading of cases at triages and for the information regarding their classification and the hospital to which they are to be delivered. The commanding officer of each hospital will receive instructions in writing covering the work to be performed in his hospital. When the hospital is established and ready to receive patients, a soldier of intelligence will be placed at the entrance to the hospital with instructions to supply information to ambulance drivers regarding this hospital or other hospitals in the area. Upon arrival at the receiving ward of the hospital, the ambulance driver will present his "destination slip" to the noncommissioned officer in charge of the entrance. This noncommissioned officer will make certain that the cases have been designated by the evacuation ambulance officer for this particular hospital. Cases designated by the evacuation ambulance officer for delivery to this hospital will be received regardless of minor differences of opinion on the part of receiving officers and others. After their admission and examination in the

hospital by a competent officer, other disposition may be made of them by the chief surgeon. Officers responsible for classification and selection of cases at the divisional and corps triages often work under very great difficulty and it is expected that disagreements in classification will occur. Again certain cases will combine two or more classifications; for example, as where a wounded man has also been gassed.

One of the most frequent and serious causes of embarrassment and inefficiency in evacuation and mobile hospitals has resulted from inefficiency in the receiving ward, the result in most instances of a lack of definite information or instruction on the subject of "admissions" and "receiving."

The capacity of a given hospital at a stated time to receive and properly care for patients is fixed and should be definitely understood by the commanding officer and the receiving officer; for example:

Bed capacity	-----beds.
Patients in hospital	-----
Patients awaiting operation	-----
Operating teams on duty	-----
Operation rate for heavy cases	-----
Operation rate for light cases	-----
Average operation rate	-----
Evacuation time required for transportation of preoperative cases to base hospital in the rear	-----hours.

With this information at hand it will be apparent that 500 cases requiring operation should not be received without the chief surgeon's order if the operation rate of this hospital is 100 cases in 24 hours where a base hospital prepared to care for and receive preoperative cases is located two hours to the rear. The evacuation time required for preoperative cases to base hospital being known, the number of cases awaiting operation which should be allowed in any hospital can be definitely stated if the operation rate of the hospital is known. When any evacuation hospital has received 75 per cent of this number of preoperative or "cases awaiting operation," notice should be given the chief surgeon's office of the fact, when redistribution from the front may be ordered through the corps surgeon, added teams and personnel may be sent, or preparations may be commenced for preoperative evacuation of cases which have been carefully selected according to definite regulations covering this class of evacuation. The most careful and painstaking attention should be taken in this matter of receiving cases, as complete demoralization with unnecessary suffering from lack of attention and surgical care result when hospitals become overcrowded or filled beyond their operating or bed capacity. This condition has been known to exist in hospitals where other hospitals in the immediate neighborhood have been relatively idle. The remedy is simple and apparent and commanding officers will be held strictly to account for efficient administration covering the details of admission rate and timely notification of the chief surgeon regarding the status of their hospital.

(d) *The receiving ward.*—The receiving ward of a 1,000-bed evacuation hospital should be large enough to accommodate 150 sitting and 30 litter patients. It should be well heated and lighted and should have a good floor. Benches and litter racks for this number of patients should be installed. A safe or strong box for safe-keeping of valuables and decorations is necessary. Provision for the administration of hot drinks should be made. Experienced clerks with typewriters should be located at desks where the field medical card, Forms 52 and 22, are made out. There should be sufficient litter bearers to properly litter and assist patients from the ambulances into the receiving ward and to distribute them from the receiving ward to the various departments of the hospital to which they may require distribution.

(e) *Triage.*—This consists of prompt separation in the receiving ward into surgical, medical, and gassed. These are again separated into walking, litter, contagious, noncontagious, seriously wounded, slightly wounded, shock, and urgent. This work is done by the triage officer, who is responsible for prompt designation of the various classes mentioned. He is also charged with the proper conduct of the receiving ward and care of patients until their arrival at the various points of distribution from the receiving ward. He may require

the assistance, especially in rush times, of trained medical officers; at other times and after sufficient training, experienced noncommissioned officers may be competent to perform the work of assistants in the triage or sorting. Cases in shock among the surgical patients should be sought out and sent to the shock ward at once. Medical cases, on account of possible contagions, should be promptly segregated and masked if necessary. The medical cases should be distributed soon after their arrival. Walking medical and surgical groups are conducted past the deck, where the three clerks prepare, at one reading of the diagnosis tag, the field medical card covering the points of triage and subsequent course of the cases through the hospital. This might be termed a provisional triage, as these cases are subject to redistribution should this be found necessary in the slightly wounded, severely wounded, or medical sections of the triage, operating rooms, or wards. Thus the triage officer will designate medical by capital "M"; "C" following the "M" indicates contagious; "S" severely wounded; "O" slightly wounded; "SH" shock; "U," or a red paster, indicates urgent operation. Here also the date and hour of the injury, with date and hour of admission to the hospital, are recorded. If A. T. S. has not been given, a yellow paster is attached to the F. M. C.

Cases are then distributed to (1) shock ward, (2) severely wounded section, (3) slight and walking wounded section, and (4) medical section, contagious, noncontagious, and gassed. Where large numbers of gassed cases are being received, a special gas section should be arranged outside the general receiving ward. In each of the triage sections and wards the patient is placed in the most favorable position to receive quickly the special examination required by the case, as facilities are there at hand for the treatment or examination of these classes especially. In these wards with more careful examination further triage is directed, as, for instance, a shock patient is marked "X" for X ray; "OP" for operation, or "W" for ward. In the severely wounded triage he may be designated "S" for shock, or any of the designations previously mentioned in the case of shock patients. In the slightly and walking wounded triage, the patient may be marked "DR," dressing room, or any of the previous designations mentioned. In the dressing room the patient may be marked "EW," evacuation ward; "X," X ray; "OS," slightly wounded operating room, or any of these combinations as found necessary to cover the distribution or triage of the cases. Further triage may be directed in either of the operating rooms, where the patient may be marked "EW," evacuation ward; "H," hospitalize, and a note on the field medical card may even direct deferred evacuation upon reexamination. Further triage of medical cases may be done in the wards, after leaving the medical section of the triage. This applies especially to the evacuable or non-evacuable status of the case, though the case may be sent to contagious wards or convalescent camp from here.

Valuables, including decorations, should be carefully guarded, especially where the patient is to be operated upon; records should be kept accurately and receipt for them obtained upon evacuation of the case. Small bags such as the Dorothy bag are convenient and should be furnished for valuables and small articles which accompany the patient to the ward. Officers' clothes and those of the Allies accompany the patient through the hospital. Removal of clothing, its disposal or salvage, bathing and dressing in pajamas, and proper forwarding of cases occurs at the four points after preliminary or provisional triage; namely, in the shock ward, severely wounded section, slight and walking wounded section, and medical section. Special care should be taken in all of these wards and triage sections that exposure and chilling is avoided. Hot soups, cocoa, sufficient blankets properly applied, and hot-water bottles should be used judiciously in order that the patient's condition may be improved, if possible, prior to operation if required.

At intervals during the day the number of beds available in the various wards is recorded by a noncommissioned officer, and as patients are assigned an attempt is made to keep account of available vacant beds and their distribution. It is in this location—that is, in the receiving ward—that the status of the hospital is constantly kept in mind with a view to the prevention of overcrowding and with a view to the prevention (or at least notification of the chief surgeon) of inability to properly handle or digest surgical cases requiring operation.

(f) *Evacuation.*—Mobile and evacuation hospitals are not intended for and will not perform elective operations, nor will they retain evacuable medical cases for complete hos-

pitalization in time of battle or where action may occur at any time. The function of these hospitals is to prepare cases of all descriptions for evacuation at the earliest practicable moment, with assurance that evacuation will not result unfavorably for the patient or others. Retention of evacuable patients in either of these hospitals is in direct violation of the most essential feature of their function and will result disastrously sooner or later. For this reason, patients will be divided into evacuable and nonevacuable at the earliest practicable moment. Responsibility for this early division will rest with the commanding officer of the hospital, who will arrange the details and determination by properly selected officers along the following lines:

Where an operation is performed the operating surgeon will indicate on the field medical card, diagnosis tag, or by other means that the case is evacuable at once, or will be at the expiration of certain number of hours or days; or that he is not evacuable. The same note or notes will be made in the dressing room if operation is not performed. Cases in the surgical wards will be recorded as shown under regulations, at the earliest moment practicable. Medical cases will be decided for evacuation or hospitalization under the direction of the chief of the medical service or designated medical officer. Subsequent changes in designation for "hospitalization" or "evacuation," specifying whether the case is to be evacuated, "lying" or "sitting," as contagious or not, will be made by ward surgeons or operating surgeons responsible for the case in the wards, if necessary. A system of ward records which will show the number of cases evacuable, by name, location, and method, is described under "Regulations." Cases to be evacuated without operation must be selected with the greatest care, in accordance with definite rules and specifications laid down by the chief surgeon, and the decision will be recorded in writing on the field medical card or other record and will be signed by the officer making the decision.

An evacuation officer, with an entraining officer, a suitable number of assistants, and a "loading detail," should be designated in each hospital of sufficient size to require one or more of these details.

The commanding officer of the hospital will receive instructions regarding the total number of cases to be entrained, also the classification into "lying" and "sitting" cases, whether postoperative, preoperative, medical, gassed, contagious, or other classification. He will be held responsible for an accurate and recent check of patients loaded, in order that patients unsuited for evacuation for any reason may not be evacuated. He will not load more cases than he has been given authority to load, and he will see that classification of cases loaded conforms accurately with the authorization given him. Great inconvenience, unnecessary suffering, and death have resulted from careless and inaccurate evacuation.

The evacuation area, so-called, meaning the portion of the hospital situated along the loading platform, is from the standpoint of the evacuation hospital an essential department. In this area are collected the cases from the hospital to which the area belongs, and in addition it collects, for evacuation, cases from mobile and other hospitals not located on the railway. The various tents for wards for surgery, medicine, gassed (lying and sitting) are designated and used for these cases, as far as practicable. These wards and the area are under the direction and control of the evacuation officer. He will be responsible for systematic arrangement, attention to feeding, inspection of cases therein to detect shock, for inspection of dressings, splints, and clothing, to see that they are sufficient and properly applied. When an evacuation is ordered, a trainload will be made up by the evacuation officer from selected cases conforming to the requirements and specifications of the train to be loaded. In favorable weather, litter cases may be placed on the loading quay, head outward, shortly before the arrival of the train. Walking cases should be collected and placed under the direction of a none commissioned officer, who will see that these cases do not wander away or cause confusion in the loading by wandering about the platform. Upon the arrival of the train the evacuation officer will receive from the train commander his designation of cars for sitting, lying, contagious, medical, and other classes, and will proceed to mark the designated cars with legible signs indicating class of cases to be loaded therein. Litter cases are loaded first and sitting cases afterward. American trains are standard as a rule in so far as number of patients accommodated and uniformity of equipment are concerned. The average American train carries 480 sitting cases, with 120 lying

cases at the same time. This may be considered a typical load. Variation from this is necessary as a rule, and can be figured according to the following rule: For each additional lying case above 120, 2 sitting cases must be subtracted; example: With 150 litter cases the number of sitting cases which may be accommodated is figured as follows: 150 minus 120 equals 30; 30 multiplied by 2 is 60; 150 minus 60 is 90; 90 therefore represents the number of sitting cases that may be accommodated with 150 litter cases. American trains carry a contagious section which has been found to be exceptionally useful. By the use of the personnel car on short trips and the placing of patients on litters and benches in aisles and doorways, some trains have carried over 700 patients.

French trains are of various types and their capacity can not be intelligently figured so that information regarding their capacity must come from the regulating officer. These trains are not nearly so comfortable or well equipped as American trains and should not be relied upon for use if American trains are available, as difficulties in loading, feeding, and care of patients are numerous.

(g) *Professional work.*—The current dictum regarding professional work should be a matter of written orders based on the written memoranda of surgical and medical chiefs or special consultants of the chief surgeon's office. Frequent inspections of each hospital will be made by army consultants, who will inform the chief surgeon after verbal report to the commanding officer of the hospital concerned of necessary changes in personnel, technique, additional supplies, or other facilities for the care of wounded and sick. Sample memoranda from some of the hospitals are given herewith for use as a guide in framing similar regulations for surgical and medical services. Regulations for gas service should be similarly defined and published.

GENERAL PRINCIPLES GUIDING THE TREATMENT OF WOUNDS OF WAR

1. Speaking generally, every wound of war should be regarded as either contaminated or already infected.

2. The aims of treatment should be (a) to prevent the development of infection if the wound is merely soiled, or to sterilize it if infection has already developed; (b) to close the wound secondarily by suture when "clinical" sterilization has been obtained.

3. The general rule governing the treatment should be free opening up of the cavity, combined with resection of all contused and contaminated tissues, and removal of all fragments of clothing or other foreign bodies. No deviation from this rule is justifiable.

Pathogenesis of gas gangrene.—Under this heading the predisposing causes are considered.

For a moment, and from a surgical point of view, the most important rôle must be assigned to predisposing causes, because certain of these are more or less amenable to therapeutic measures. They may be divided into two classes: (a) General; (b) special.

(a) General causes: (1) Geographical distribution. The frequency of the clinical entity known as gas gangrene is to a considerable extent dependent on the locality in which patients may be wounded.

(2) Wounds inflicted by fragments of shells and bombs are the most dangerous variety.

(b) Special causes: (1) Localization of the injury in the fleshy parts of the limbs, especially in the lower extremity.

(2) The special characteristics of the wounds, such as narrow orifices associated with serious deep lesions.

(3) The impaction of foreign bodies, especially débris of clothing, which may carry soil, with all its contaminations or fecal material, with them.

(4) Extensive contusion of the tissues leading to mortification. Other predisposing causes, although of inconstant occurrence, are none the less frequent.

(5) Severe comminution of bones, or of fractures implicating joints.

(6) The ischemia dependent on injury to large vessels, obliteration of large vessels by ligature, or the prolonged application of the tourniquet.

(7) Multiplicity of wounds.

(8) The presence of a hematoma.

(9) Traumatic shock.

(10) The risks of gas gangrene diminish in direct proportion to the efficiency with which surgical measures are carried out, and the promptitude with which these measures are undertaken.

(11) Even when surgical intervention has been both prompt and efficient, the occurrence of gas gangrene may be favored by the employment of unsuitable methods of treatment, especially dressings which allow the wound to rapidly become dry.

(12) Attention should be directed to the investigation of certain factors in the toxemia accompanying gas gangrene, especially acidosis, local and general. Researches in this direction may result in the establishment of indications for treatment.

Bacteriology of gas gangrene.—(1) Researches carried out since the commencement of the war have confirmed the infectious origin of the process, and the anaerobic nature of the organisms that give rise to it.

(2) Amongst the organisms met with, special importance should be attributed to the *Vibrio septique*, *B. bellonensis* (the exact relations existing between *B. bellonensis* and *B. oedematiens* are not yet determined), and *B. perfringens*.

(3) The anaerobic infection is often aggravated in its effect by the association of other microorganisms, especially the streptococci.

(4) In consonance with the general principles of bacteriology, attempts should be made to obtain sera active against the organisms enumerated above, with a view to serum therapy. Such sera have been prepared and used with great effectiveness.

Treatment of gas gangrene.—(1) Gas gangrene is most often the consequence of delayed or inefficient primary surgical intervention.

(2) Prophylactic treatment is of the first importance; it includes rapid evacuation to a surgical unit in order that proper measures may be promptly taken, free exposure of the wound cavity in its whole extent, excision of contused or sloughing tissue, removal of all foreign bodies, incising facial planes to relieve subfacial hematomæ, and careful hemostasis.

(3) When the process is localized, whether the tissues are already infiltrated or not, the curative treatment consists in (a) complete exposure to the air of all deep recesses of the wound; (b) excision of all tissue already gangrenous or even open to suspicion; (c) free incisions in the zone of infiltration, and at the limit of that zone.

(4) Amputation is imperative; in the presence of acute massive gangrene, especially when complicated by lesions of the bones, or serious injury to the vessels; also in instances of very rapid extension with threatening general symptoms (rapid fall in tension of the pulse is a valuable symptom in this respect). The method of choice is the "flush" amputation.

When the amputation is carried through infiltrated tissues, additional incisions should be made in the infiltrated zone, extending upward to the limits of the limb or even on the trunk.

Shock.—It should be remembered that the soldier before his injury is in good physical condition, and if given rest, warmth, morphia, etc., will react remarkably well. Patients with a blood pressure much below 100 mm. Hg. should be considered as poor surgical risks, and may suitably be treated, where the opportunity offers, by additional methods, such as transfusion, etc. In these cases a local anesthetic (novocaine) or nitrous oxide is to be preferred to ether. Chest cases should be operated on under nitrous oxide anesthesia when available. This anesthetic should be one of choice when operations are performed on gassed cases.

Examinations.—One of the first duties of the chief operator is to examine thoroughly the entire surface of the body for all possible wounds and make note on the field medical card.

Débridement.—Wounds that are necessary on account of surgical interference should be thoroughly débrided, whereby the devitalized skin and muscle tissue and bone detached from periosteum is removed. This should be done in case of extremities under traction, in order to bring the parts as nearly as possible into the position in which they were when the wound was received. In wounds over three days old and with abscess, drainage of free pus should not have an extensive débridement for obvious reasons (opening up nature's inflammatory area of resistance). Through and through wounds from rifle bullets with punctiform entrance are not to be débrided or opened up, unless some contraindication for the above management is present, which has been made evident by great tension of the overlying tissues from hemorrhage or infection, made evident by marked tenderness, usually occurring in a wound three days or more old. In this case incision and exploration is demanded.

Nerve and blood vessel injury.—In all severe wounds of the extremities the operator should examine for possible nerve lesion before anesthetization and note preoperative as well as operative findings on F. M. C. when making operative note. If nerve is found severed, draw ends together with single fine silk suture and note fact. Ascertain whether pulsation is present in vessels beyond injury.

Tendons.—(a) Tendons should have a primary suture; (b) care as to undue freshening of the ends; (c) if not a primary suture, silk run into each end of the tendon. Above measures will facilitate the surgeon in finding tendon in any secondary operation.

Closure of wounds.—All wounds, except those noted below, should be left wide open. In dressing wounds, avoid packing with gauze, which prevents drainage and necessitates anesthesia for removal. The sides of the wound should be protected from contact with gauze by using gutta-percha tissue, cellophane, cellosilk, or other similar material, and when one of these is not at hand the gauze may be prevented from sticking by using vaseline. In no instance are wounds to be packed with gauze, or large drainage tubes inserted. In only exceptional cases are the wounds to be Dakinized in evacuation hospitals, owing to the inability for the proper moistening of wounds during the rush and transportation. Therefore, Dakin tubes are to be used conservatively in evacuation hospital service. The leaving of a skin wound open is a matter of choice in evacuation hospital service, as a large percentage of skin closures have been found infected at the base, destroying results of preliminary surgical procedures. If a wound is found clean, the delayed suturing of the skin is done at the base.

Head cases.—It is the policy of this institution to transfer head cases to the "head hospital," as they stand transportation better before than after operation. After operation they should be retained for at least 10 days. If operated here, entire head should be shaved (preferably dry) and they should be operated under local anesthetic, if possible. Every scalp wound conceals a possible penetrating wound, and many are found among the walking wounded. Drainage of wounds involving the brain is to be avoided. Primary closure and thorough cleaning of the tract, daily dressing, and prompt removal of a few sutures over the immediate tract on the first sign of infection.

Fractures.—(a) Simple fractures with soft part wounds not extending to bone: Remove foreign tract and clothing; débridement; treat bone as a simple fracture.

(b) Bone wounds: Débridement, with removal of foreign body and tract. Removal of infected layer of bone (do not close in evacuation hospital service).

(c) Compound-comminuted fractures: Débridement; removal of foreign body and all detached fragments; retarded primary suture; proper splinting.

(d) In general, fractures by machine-gun bullets do not require operation. Treat as simple fractures. About 90 per cent will not be infected.

Fractures will be evacuated here as soon as possible, as they stand transportation early if primary operation permits, better than late, and early transportation gets the patient to the base for more definite treatment than can be given at an evacuation hospital. Before evacuation, the splints should be carefully examined to ascertain their proper application and position.

Joints.—(a) Capsule of all joints to be closed when possible. No primary suture of soft parts unless cases can be kept in hospital one week. Postoperative aspiration if necessary. Immobilization with extension for 48 to 72 hours, then voluntary motion.

(b) Suppurative joints. Free incision without irrigation, with voluntary motion begun in six hours and repeated every two hours; no drainage into joints.

(c) Resections of joints are deprecated, except in exceptional cases. If resection is necessary, owing to extensive bone wounds or fracture of atypical resection is preferable. In the knee the operation should be primary, whereas in the elbow and shoulder secondary operation is preferable.

(d) In general, machine-gun or pistol wounds of joints should not be operated upon, unless definitely infected. Aspiration if necessary.

Amputations.—(a) In all cases of amputation or complete resection, a signed consultation with the chief of the surgical service, or his representative, is required.

(b) Preserve all skin.

(c) Preserve as much bone as possible.

(d) Preserve gliding surface of muscle for future cinematization.

(e) Traction to be made on skin.

(f) Preserve all muscle and tendons possible.

1. Amputation is indicated only when conservation of the limb would lead to the death of the patient, or if eventual loss of the limb is inevitable.

2. The two chief indications for amputations are (a) extent of the injury; (b) infection.

3. Amputations for infection are always the more dangerous.

4. The indications for primary amputation are found in the nature and extent of the injury—pulverization, crushing, partial avulsion of the limb, and especially rupture of the main blood vessels.

5. The indications for secondary amputation are found in massive gangrene, either ischemic or infective. Other extending infections (superficial gangrene) may be treated by conservative measures.

6. In primary amputations, especially those indicated by infection, the wound should be left widely open. Care should be taken not to open up the intermuscular planes. With this object the vessels and nerves should not be followed into the intermuscular clefts but should be cut long.

7. The length of the resulting stump is of more importance than perfection of its covering.

Amputations of the lower extremity.—Disarticulation of the hip joint is a more serious operation than amputation through the neck of the femur, even when performed by a request incision and with preliminary ligature of vessels.

For satisfactory fitting of an artificial limb an amputation through the thigh should leave the stump extending 12 to 14 cm. below the great trochanter.

Amputations through the upper fourth of the thigh are difficult to accommodate with an apparatus, in consequence of the abduction of the femur which has taken place.

Amputation through the middle and lower thirds of the thigh give good results. The great sciatic nerve should be divided above the level of the flaps.

Amputations of the leg should be performed at the lowest practicable level. A posterior flap appears to be preferable.

The fibula should be cut an inch shorter than the tibia.

Amputations of the upper extremities.—In amputations at the shoulder the head of the humerus should be preserved if possible.

Amputation of the arm should be performed at as low a level as is practicable. Either the circular or the flap method may be employed; 10 cm. of the humerus are necessary for a useful stump.

In the forearm every effort should be made to preserve a lever at least 10 cm. in length below the elbow joint, and to maintain the movement of pronation and supination.

In the hand, whenever possible, trimming operations should be adopted, since every segment which can be preserved may prove of great service.

Abdominal wounds.—Penetrating or perforating wounds of the abdomen, after 18 hours from the receipt of the injury, should not be operated without first consulting with the surgical chief or his representative.

Wounds of the kidney.—In wounds of the kidney, unless there are marked indications of hemorrhage or great destruction of tissue, the most conservative surgical methods are required.

Penetrating wounds of the chest.—Primary hemorrhage is common in both open and closed chest wounds. It is the chief cause of death during the first few hours after the receipt of the wound. When severe, the patient is blanched and restless. Treatment in these serious cases is mainly expectant. Patients with a readily perceptible pulse may die suddenly if rolled over on the wound side within 12 hours after being wounded. Bleeding does not usually continue after 24 hours. It usually comes from the deeper blood vessels in the lung. Nature's method of arresting it is to cause collapse of the lung. The pressure on the lung by the accumulated fluid in the pleural cavity will not by itself assist much in the arrest of the hemorrhage. No single case of hemorrhage from an intercostal artery has been seen. Plugging of the wound is therefore no benefit except after the lung is collapsed, when it may improve respiration by rendering the entrance of air into the chest easier by respira-

tory passages than through the wound. Hemoptysis was present in 65 out of 100 cases of undoubted penetrating wounds of the chest. In no case was it severe enough to cause anxiety.

Any wound which leaks air or blood and pleural fluid freely after 48 hours will become septic. Convalescence and invalidism are only greatly prolonged.

Treatment of these leaking cases is by simple dressing, by plugging the wound, or by sewing up the wound, with or without removal of the foreign body. The simple dressing is sufficient in cases of small wounds. Air will cease to leak in 24 to 48 hours. If it continues, or if the discharge persists, sepsis is almost certain, and resection and drainage is indicated.

Plugging the wound is done to arrest hemorrhage and to prevent the entrance of germ-laden air. It is, however, difficult to render a large wound air-tight with gauze, and therefore danger is present of introducing germs from the edge of the wound.

Sewing up the wound is advisable in all cases, since this means infection can be prevented in more than half of the cases. The removal of foreign bodies from the lung is justifiable only in selected cases. About 12 hours after being wounded is the best time for suture. Shock should have passed off and hemorrhage should have ceased. Muscle and pleura are sutured with catgut, the last stitch being drawn tight during expiration. If the pleural contents are infected, the wound will become moist in 24 hours. The stitches are then removed and a tube inserted. Nothing is gained by sewing holes or tears in the lungs.

Closed hemothorax differs in no way except from greater liability to increased intrathoracic pressure and cardiac displacements. Air in these cases comes from the lung. Rapid pulse, sustained temperature, and localized pain in the chest are signs of infection of hemothorax. Chest cases should be examined each day, special attention being directed to the position of the cardiac impulse. Aspiration should be performed when there is cardiac displacement of 1 inch or more. All the fluid that will run off easily is removed slowly at the rate of about 30 c. c. per minute. Practically all hemopneumothorax cases require aspiration. Do not close skin.

Injury to the nerves.—(1) It is indispensable that all lesions of the peripheral nerves should be investigated with the greatest care in the hospital at the front when the wound is subjected to primary treatment; both with regard to the clinical signs present, and direct examination of the nerve trunk itself.

(2) Whenever a divided nerve trunk is discovered, it should be united by primary suture, if the condition of the wound permits. A special note describing the operation performed should accompany any patient so treated when he is evacuated.

(3) If primary suture is impracticable, a long silk suture left long on each end should be left in the wound.

(4) Either the primary or secondary operation may suffice to obtain restoration of function; but should they fail, the operation has, at least, insured that the trunk is placed under the best conditions for later intervention.

(5) During the whole course of treatment, care must be exercised that the limb is kept in good condition, and that the mobility of the joints and the nutrition of the muscle is maintained. Be sure that nerve and tendon lesions are properly splinted.

(6) Operations on the nerve trunk of whatever character (freeing from adhesions, neurolysis, suture, etc.) demand the maintenance of perfect asepsis, and punctilious care and delicacy in the manipulation of the nerve itself.

THE MEDICAL SERVICE IN EVACUATION HOSPITALS

Chiefs of medical service should constantly bear in mind that the purpose of an evacuation hospital is to render temporary and emergency treatment only, and the real object of these institutions is to insure the safe evacuation of patients to still more favorable surroundings and facilities.

Cases requiring hospitalization for periods of over a few days should not be retained except in instances of military inactivity or when transfer to a more stable service would endanger life or hamper military purpose.

The medical work in evacuation hospitals then resolves itself chiefly into (1) speedy classification of patients; (2) immediate separation of contagious from all other and espe-

cially from the wounded and gassed; (3) administration of first-aid medical treatment; (4) the relief, even though merely palliative, of suffering and discomfort; and, finally, (5) the evacuation under favorable conditions of sick soldiers to hospitals designed for prolonged treatment are the other purposes of these hospitals.

Nontransportable medical cases such as acute pneumonias must, however, be retained for treatment until such time as they may be evacuated to other institutions with benefit and without danger to themselves.

Contagious cases such as scarlet fever, chronic ulcerative tuberculosis, and the like must be evacuated promptly as possible when this can be encompassed without undue danger to life. Cases of these types are particularly dangerous when retained in evacuation hospitals where the tide of cases is normally large and where slight lapses in anticontagious technique may be then followed by widespread infection.

The triage.—The triage medical officer must be selected with great care. He must be a man of high professional training, of decision of character, and one with a full appreciation of the military necessities of the occasion as well as the humanitarian requirements of the work. He must possess speed.

In the triage every nonsurgical case should be considered as contagious, and so handled until the contrary has been shown to be the case. Immediate separation of medical and gassed cases from surgical should be made at the ambulance, and these two grand types should never subsequently come into infection-bearing range of each other. Proper triage at the field hospitals should prevent the transportation of medical with surgical cases except in dire necessity, when masking greatly diminishes the likelihood of infection.

Where both medical and surgical cases must be handled in the same pavilion, all medical cases should be promptly masked and a cubical system established by means of which the unclassified medical cases are prevented from transferring infection to each other or the surgical cases.

Where possible, triage should be well lighted. This is very largely dependent, however, on military circumstances, as in bombing zones, etc. When possible it should be sufficiently ventilated and not overcrowded.

A very high percentage of medical cases entering the triage are suffering in greater or lesser degree from exhaustion, often combined with exposure and malnourishment. Two methods of treatment should be therefore automatically provided for and applied in all suitable cases. Hot nourishing or stimulating drinks, such as soup, cocoa, or coffee must be available at all hours, and external heat must be applied, best by providing a warm room for triage and warm and dry blankets in abundance. Undue exposure of the body for diagnosis should not be permitted in the triage unless sufficient heat is thus attainable. The use of hot-water bags, canteens, or of electric pads may be applied when isolated cases only are in need of treatment. One or more shock beds should be prepared and one should always be functioning during military activity.

As soon as possible (the proper conditions existing) the patient should be stripped and the body, especially the skin and mucosæ, searched for evidences of the exanthemata or of other contagious conditions or of infection. A hasty examination of the heart and lungs should then be made before further investigations or transfers are made.

Contraindicating conditions such as dilated heart or a pneumonia not existing, the soldier should then be bathed, clothed in dry and warmed blankets, and placed in the appropriate ward. Too much time must not be wasted in the preliminary examination; gentleness and celerity of handling are therapeutic agents of great importance in most cases recently from the battle field.

Conscientious salvage and filing of personal effects should be made, and personal articles of clothing preserved when practicable. Wanton destruction of property should not be permitted, but the soldiers' best interests must in all cases be first considered in this respect.

The wards.—All cases of doubtful nature should be sent to an observation ward in which screening and masking, together with other general anticontagious methods, are in vogue.

All contagious, including influenzas, pneumonias, and idiopathic catarrhal conditions, should be placed in screened cubicles, and ambulatory cases must be masked so that crossing of infections is impossible. It must be remembered that nearly all battle field contagions are transmitted through respiratory channels. Screening and masking will prevent them.

Stools, urine, and all other excreta must be disposed of as though definitely infectious until shown to be otherwise, and cleanliness in this respect is always imperative.

All cases except those obviously not seriously ill should be placed in bed and on a liquid diet of which the staples should be soups, milk, eggs when obtainable, cocoa, chocolate, coffee, and tea, to which may be added jam and bread when not contraindicated. An abundant supply of water must be provided.

The wards should be made as comfortable in all respects as circumstances permit. A dry floor is particularly desirable. They should afford sufficient air space for each case, and a certain degree of elasticity in this respect should be preserved for times of great activity or of delayed evacuation. While wards should be properly heated with Sibley stoves or by other methods, heating should not be encompassed at the expense of ventilation. All wards should be so arranged that they may be quickly cubicled by screening whenever necessary circumstances arise. All cases presenting catarrhal symptoms or diarrhea should be cubicled.

Medical officers on duty with medical cases in evacuation hospitals must constantly bear in mind that, while celerity in diagnosis is imperative and while instruments of precision are rarely available, accuracy of diagnosis within reasonable limitations is expected and imperative. The same general observations in regard to therapeutic measures also applies.

Evacuation.—All except nontransportable cases must be evacuated as soon as possible, awaiting only available transportation. Every anticontagious precaution noted in regard to the triage must be applied in the evacuation of patients before, during, and after loading.

Each case marked for evacuation must be plainly so indicated by the ward surgeon and must be seen by a competent medical officer not over one hour before the case is loaded. Chiefs of service will be held responsible for all failures to properly observe this order. No case with temperature of 100° F. or over may be evacuated sitting; and lying only when the case has been marked for evacuation by the medical chief of service.

Cases for evacuation lying must not be removed from their beds until the train for their transmission is ready to receive them. Exposure is particularly dangerous for these cases, and it must not take place unduly.

Medical officers must assure themselves that cases for transportation before loading are suitably clothed, that the supply of blankets is adequate and properly distributed. Ward officers will be held responsible, by the medical chief, for timely report as to special requirements in the way of food, medication, or other special care required by cases to be evacuated. The proper heating of the train should also be investigated by the evacuation officer. During loading the evacuation officer should assure himself that proper observance of anticontagious regulations are considered. Lapses from these rules are to be tolerated only under instances of urgent military necessity.

Four points must be constantly borne in mind by officers working in the medical service of evacuation hospitals.

First. The evacuation hospital is, first, a military institution and, second, a hospital. Its prime purpose is to free the dressing stations and field hospitals of the sick and wounded so that they do not constitute a military incumbrance.

Second. The second function of the medical service of the evacuation hospital is to minimize or prevent the spread of contagious diseases among the sick and wounded.

Third. The individual soldier must receive in the evacuation hospital every consideration and medical attention which circumstances permit. No facility at the command of the hospital is to be denied or limited in this respect which does not definitely encroach on the effectiveness of the principles stated in the first two articles.

Fourth. To prepare patients for evacuation to the rear as rapidly as is possible.

(h) *Mess.*—Extensive menus and elaborate preparations for furnishing special diets are impracticable and unnecessary in these hospitals.

Large quantities of hot nourishing liquids upon short notice are essential. Facilities for the preparation of stews, cocoa, and coffee, with bread and jam, should be at hand. A nourishing stew is perhaps the most important of all, as it will furnish at once either a liquid or solid diet, as may be required. The equipment for cooking should, in the main, be collected in a central kitchen. This equipment can be augmented from time to time by the addition of

wheeled kitchens, which besides augmenting the cooking facilities render the serving of hot food to distant wards possible and practicable, as the kitchen may be wheeled to the door of the ward. There should be a soup, cocoa, and coffee station in the receiving ward and triage section, where these articles of hot liquid food so necessary to the cold, exhausted, and hungry may be served under careful supervision of an officer, nurse, or intelligent aid. This work was done very acceptably by members of the Smith College unit in several hospitals of the First Army area. When it is considered that a vast majority of cases treated are retained in hospital not longer than 36 hours, it will be seen that extensive menus are impracticable and unnecessary.

II. REGULATIONS

Until the functions of evacuation and mobile hospitals are more definitely expressed in order, uniform sets of regulations can not be written for their internal administration. A set of regulations when written would of necessity have to be general or broad in its specifications. Details should not be covered, for the reason that some features of the work are performed differently in the various Army areas. If, however, each evacuation and mobile hospital could be furnished a standard set of so-called "general regulations," and upon its arrival in an army, corps, or division area another set of army corps or division "special regulations," the matter of regulations would be satisfactorily covered. The greatest difficulty has been experienced in obtaining general and special orders with circulars and memoranda. Where they had been sent to the hospitals there was no assurance that they would or had arrived. The question of reports, returns, and proper performance of certain duties in the hospitals was therefore in an uncertain state at all times. It appears necessary, therefore, that some special means be taken to assure the proper collection of data covering the points of special regulation, and it is suggested that this be done in the office of the chief surgeon of the army. An officer of experience should be detailed to perform this work and to see that the various requirements regarding reports, records, returns, and methods of administration are noted and up to date. The need of such a department as is here suggested is very apparent to one who has had an opportunity to discuss with commanding officers and adjutants the subject referred to. Newly organized hospitals, and in some cases hospitals which had been organized for some time, were constantly in doubt as to the proper method of procedure in some of their most important functions. A case in point was frequently referred, namely, burials. The regulations for this very important function are found in various orders scattered throughout the regulations of the American Expeditionary Forces, modified, rescinded, specified, and circularized. In order that the argument may be set forth more clearly, we may suppose that the officer detailed on "administration" in the chief surgeon's office had collected in one circular the current regulations, stated simply and accurately, ready for issue to organizations coming into the area, and that upon arrival he would personally visit the commanding officer and with the adjutant hold a conference in which he would turn over and explain the latest regulations covering proper function of the hospital.

Herewith is shown a sample set of "general regulations" for the administration of one of the evacuation hospitals.

EVACUATION HOSPITAL No 10,
AMERICAN EXPEDITIONARY FORCES,
October 8, 1918.

A. ORGANIZATION OF HOSPITAL

1. The following offices are established, which will report to the commanding officer direct: Adjutant, chief of service, registrar, quartermaster, admitting officer, evacuating officer, mess, sanitation, regulating officer.

2. The adjutant will act as commanding officer of the detachment, Medical Department, and will be charged with rendering all reports of the organization, with correspondence, and with the preparation and transmission of orders from the office of the commanding officer.

3. The chief of service is charged with the care of all professional activities of the hospital. He will exercise control over the sorting of patients, the preparation for operation of the operating rooms, the X-ray rooms, and wards. Officers in charge of medical service, all ward officers, and laboratory are also under his charge.

4. The registrar is charged with the preparation and care of all records of patients. He will turn in to the office of the adjutant all statistical and other reports called for from his office.

5. The quartermaster is charged with the requisitioning, securing, and storing of all supplies of the hospital, with the management of the laundry and the motor transportation assigned, and with salvage.

6. The admitting officer is charged with the admission of patients from hospital. He will be notified from the office of the adjutant when trains will arrive and what patients will be evacuated. He will see that wards are promptly evacuated and trains loaded and rationed, making report of evacuation to the adjutant's office upon completion.

7. The mess officer is charged with the management of all messes. Mess sergeants are under his direct control, and he will prepare menus and see to the proper preparation and serving of food throughout the hospital. He will secure supplies from the quartermaster.

8. The sanitary officer will supervise the sanitation of all buildings and grounds, and is in charge of outside police.

9. The regulating officer will act in the capacity of liaison officer throughout the hospital. He is particularly charged with the proper regulation and movement of sick or wounded from point to point in their progress through the hospital. He will make frequent inspections and insure himself that duties are properly performed, and see that the proper distribution of enlisted men for necessary duties is made. All litter bearers and unassigned are placed under his charge.

B. ADMISSION OF PATIENTS

1. Patients will be admitted to the hospital at the door marked "Bureau des Entres." They will be seen at once by the admitting officer. All cases which have not received A. T. S. will have same administered at once.

2. While waiting for records and sorting, patients will be deposited in the receiving area in the following order:

All prone cases in the first large room; sitting cases in the same room as far as accommodations permit. When the space becomes overcrowded, sitting patients will be admitted to the small room marked "Hospitalization," the overflow being accommodated in the large room behind.

3. Patients will be sorted and assigned to wards by the admitting officer. All cases requiring hospitalization will be assigned to the numbered wards. All officers will be assigned to ward No. 7. Cases in shock will be sent at once to the shock ward. Hospitalized cases will be delivered to the dressing room in front of south operating area, the overflow being placed in the rear end of south reception room. All cases which will be fit for evacuation after operation or other immediate treatment will be assigned to the lettered wards, filling the wards in order from east to west. Gassed cases and medical cases will be assigned to ward G. Walking wounded will be sent at once to wards assigned; others will be delivered to the dressing room in advance of north operating area.

4. The admitting officer is also charged with the care of patients' valuables. He will inquire of each patient as to his desire to deposit valuables and will insist upon taking valuables of all patients who are to undergo operation. He will keep a record of valuables in a duplicating book, delivering a signed original to the patient. Upon notification of evacuation he will deliver to the patient the valuables and secure his signature on the duplicate in the book.

5. In order that record of assignment be properly kept, the admitting officer will keep a sheet showing at all times the vacant beds in each ward. This sheet will be balanced and a new sheet prepared on each change of tour. Debit will be entered for each case assigned and credit entered for each case leaving the ward. In case the operating surgeon desires reassignment, the surgeon will be notified as to which ward patient has been reassigned, and the proper entry will be made on the assignment sheet.

6. When the space allotted for reception is full or in danger of overflowing, the regulating officer will be notified at once in order that admission to hospital may be stopped.

C. EVACUABLE OPERATING AREA

1. This area will extend from door of admission room in the north operating area to exit door toward evacuation wards. An officer will be constantly on duty in the area and will be charged with the examination of all patients admitted therein, the determination of need of operation, movement of patients through the area to X ray, operation and wards, general discipline and police of the dressing room, hallways, and preoperative space.

2. An officer will be detailed to superintend the preparation for operation and dressings, under charge of the officer of the area. Upon admission to this area, patients will be examined at once, dressings removed, and such cases as require operation prepared for operation, taken to X ray, to operation, and to the ward assigned in proper order. Where it is necessary to change the ward assignment the officer in charge of the area will notify the receiving officer and secure the reassignment. Patients requiring dressings only will be dressed and moved at once to their assigned wards.

3. When cases are being admitted too rapidly to permit the proper cleaning out of this area, selected cases awaiting operation will be sent to the tent area, after consultation with the regulating officer. A constant liaison will be necessary in this event to assure that these cases are operated before those of like character admitted at a later hour. It often becomes necessary to send this type of cases by train to operating hospitals at the base, and therefore becomes that every case passed through the dressing room to await operation should be prepared to go without for a period of 12 hours.

D. NONEVACUABLE OPERATING AREA

1. An officer, designated as a nonevacuable triage officer, will be detailed in charge of all the area from the receiving rooms to the exit from his area. This includes dressing room, X-ray room, and preoperative room. His duties are to see to the preparation of patients for operation, care for the orderly flow of patients through the area, secure assignments to wards when necessary, and to maintain discipline and proper police of the entire area.

2. Under his orders are placed the nurses and enlisted men on duty in the dressing room, and the litter bearers of his area.

3. Upon admission to his area, patient will be examined by the triage officer, and prepared for operation under his direction. They will then be sent to X ray, to preoperative room, and to operation in order. Upon completion of operation they will be sent to wards designated.

E. WARDS

1. Officers assigned to duty in wards are held responsible for the care and treatment of all patients under their charge, discipline of personnel attached for duty, and rigid police of their respective areas. They will be present for duty, or within easy call of their wards, at all times during their tour. Upon admission, patients will be assigned to beds by the nurse in charge, and the ward surgeon notified. A record will at once be made on the ward list of the patient's name, and will be checked in the proper column. A clinical history will be started in all numbered wards, showing patient's name and hour and date of admission. This clinical history is designed as a running commentary of the patient's condition while in the hospital, the orders of the surgeon's report of consultation, dressings, and other treatment.

2. As soon as practicable after admission the surgeon will visit patients. He will examine the patient's records, assure himself that field medical card, or its substitute, is in evidence and complete, special attention being given to the notes of surgical operations and X-ray findings. He will also assure himself that the personal possessions of the patient, other than valuables, are with the patient. All cases in the wards will be dressed under supervision of the ward surgeon. He will dictate the treatment and note same on the clinical record.

3. Where nurses are assigned to wards they are placed in charge under the ward surgeon. They will be held responsible for the condition of ward lists and the history of patients, for care of the patients under direction of the ward surgeon, and for the discipline of enlisted men. It must be understood that although the ward personnel is not responsible for the police of surrounding areas, they are forbidden to soil these areas or to deposit refuse or slop except in authorized containers. Wards will be kept in an orderly manner at all times, and surplus equipment will not be kept in wards but will be turned in to the quartermaster.

F. EVACUATING

1. Evacuators are placed in charge of the evacuation officer. He will be informed of the arrival of trains, the number of cases in each class to be loaded, the number of rations to be placed on the train, the hour of departure, and destination.

2. From the evacuation reports he will determine which wards are to be evacuated, aiming to evacuate wards in toto where practical. Evacuatable cases from the hospital area will always be evacuated when possible. He will inform ward surgeons of the hour when patients will be loaded for evacuation. These latter are charged with the preparation of the patients for evacuation at the time set. The evacuating officer will secure loading detail sufficient to load the train within the time limit from the regulating officer, who will see that detail reports at the appointed place at the designated time under a noncommissioned officer. He will also notify the mess sergeant if rations are to be placed on train, giving the number of rations and the time when they will be called for. He will attend in person to the orderly loading of the train, and assure himself that the work is progressing satisfactorily and in an orderly manner.

3. Ward surgeons will select cases for evacuation from the ward lists, always aiming to send out patients which have been longest in the wards. He will also notify the receiving office of the fact that patients are to be evacuated, in order that valuables may be returned before evacuation.

4. Evacuation by ambulance will be conducted in a similar manner.

5. The evacuating officer will have prepared a list of patients evacuated, showing whether sitting or prone; making separate lists for Americans, other allied patients, and for German prisoners. These lists will be turned into the registrar at once upon completion of evacuation, giving also the number of train, date and hour of departure, and destination. He will keep a record of evacuations, showing destination and number of patients evacuated.

6. It will also be the duty of the evacuating officer to load trains with patients from other hospitals when so directed. He will secure sufficient details for this work in the usual way, keeping report of train, number of patients, etc., as above.

7. Upon completion of any evacuation, the evacuating officer will at once report to the officer in charge of evacuations at Fleury.

G. REGULATING OFFICER

1. The regulating officer will act as a coordinating officer for all activities at the hospital. His duties will carry him to each department and he will see that patients proceed through the hospital in proper order, that supplies are properly requisitioned and issued, that an orderly appearance of the hospital be maintained, that all departments cooperate with the policing details in keeping buildings and grounds clean, and that there is a proper distribution of the enlisted force for the work necessary.

2. In his charge are placed the unassigned enlisted men and all litter bearers, who will be assigned to duty at such places and in such numbers as may be required. He is authorized to commandeer such men as are not actively engaged to fill any emergency. These latter, will, however, be relieved at once upon need for their services in their proper department, where emergency arises, in which sufficient personnel to meet the need is not present for duty. He is authorized to call on men who are off duty for detail. In this latter event, men will be called in accordance with a roster to be kept by the first sergeant.

3. In addition to the above duties, the regulating officer will act as fire marshal, and will see that proper provisions for control of fire are made and that the personnel are instructed in the use of the apparatus provided. He will detail sufficient men to man the fire apparatus from the litter bearers, and instruct them in their duties in case of fire.

4. He will perform in addition the usual duties of the officer of the day.

H. WARD RECORD FOR THE EVACUATION OF PATIENTS

Name	Regiment	Nonevacuable			Evacuable					
		Surgical	Gassed	Medical	Surgical		Gas		Medical	
					Sitting	Prone	Sitting	Prone	Sitting	Prone
Jones, John.....	22d Cavalry.....									

1. Above form to be kept current in each ward. An admission nurse puts name and organization in proper place. Check mark is placed in appropriate place as "Nonevacuable, surgical." If class changes, put ring around check, and check in new column as "Evacuable, surgical, prone." If status changes, proceed as before, checking new space as "Evacuable, surgical, sitting."

2. When case is evacuated, the evacuating officer will cross off name after taking it down on his list.

3. This enables evacuating officer to tell at a glance how many cases of each class are present in the ward, and also permits him to check out cases for evacuation.

I. REPORT OF EVACUATIONS

1. The following report will be rendered at 6 a. m. and 6 p. m., using the form as written below.

2. This report will be made for each of the following classes of cases: American, French, Italian, English, German officers, and other German prisoners. If any of these classes are not in evidence, report may be omitted in that class.

3. Report should reach this office not later than 7 o'clock. This report may be called for at any other time.

EVACUATION HOSPITAL No. 10,
September 30, 1918—6 a. m.

	Nonevacuable	Evacuable	
		Sitting	Prone
Preoperative wounded.....	25	110	62
Other surgical.....	15	5	7
Gassed.....	2	0	0
Medical.....	20	251	101
Total.....	62	366	170

By order of Colonel BAKER:

(Signed) F. J. GOSIN,
First Lieutenant, M. C. Adjutant.

Another very handy arrangement is a so-called adjutant's check list of reports and returns. It is this list that the officer in the chief surgeon's office should keep up to date in each hospital. As kept up to date by the adjutant of evacuation Hospital No. 6, it was a constant source of information for commanding officers and adjutants ordered into the area of the First Army.

III. FUNCTION OF MOBILE AND EVACUATION HOSPITALS

The evacuation hospital was known to us almost entirely in theory before our entrance into the present war. The mobile hospital, in as far as our Army is concerned, is a development of the present war.

(a) The evacuation hospital with which we entered the war has developed into an entirely different institution than that described in the Manual for the Medical Department; or, it may be said more properly, the requirements of the evacuation hospital now demanded by our Army

have gone far beyond the provisions made in the manual for such hospitals. What it is at present, however, we find expressed in some 20 hospitals, termed evacuation hospitals, no two of which are alike in appearance or function. This development and present state are a result of their having had to meet urgent necessity wherever and whenever found, under circumstances new and peculiar to us as well as to the French and British, namely, the conditions of a rapid advance, which had not occurred prior to our entry into the war. The situation met by the Medical Department of the United States Army was just as new to the French and English and found them relatively as poorly prepared to meet the condition as it found our Medical Department. The loss of thousands of beds, valuable equipment, and personnel by the English and by the French from March 21 to July is a decidedly pointed argument and must be met for the mobile and evacuation hospital if they are to be made effective and satisfactory. It is possible that the situations which did develop were impossible to foresee. It seems, however, reasonable to suppose that army hospitals should be prepared for sufficiently rapid movement to prevent capture and to follow and advance, no matter how rapid. With the provision of proper transportation and the service of sufficient engineer and labor troops mobility can be had. It may be thought by some that mobility is impossible. It certainly is not impossible and is not impracticable. It is furthermore essential. For the realization of this essential feature we depend solely upon a definite presentation of the problem, with a demand that regulations and organization furnish the necessary facilities. If these are not furnished, the question ceases to be a medical problem and becomes a military condition imposed upon the Medical Department by competent military authority for sufficient reason and with full realization and responsibility for inconvenience, suffering, death, and loss of equipment and personnel.

The problems met by our evacuation and mobile hospitals varied with certain well-known conditions found to exist in the army areas.

(1) With fixed trench warfare in easily defended areas the hospital usually became fixed. Buildings were adapted or constructed for hospitalization. Facilities were usually at hand for good work and the hospital tended to become anything but mobile. Many of the evacuation hospitals had no rail facilities for the reason that desirable buildings had been occupied at a distance from a railroad, and spurs had either not been demanded or had been refused. This hospital was not an evacuation hospital, neither was it a mobile hospital, and it approached more nearly the function of the base hospital. The essential features of rapid admission of large numbers of patients, with facility in triage and transmission to large evacuation areas located on a sanitary siding, were usually not available as the function of the hospital had necessarily been adapted to the facilities found to exist. As none of the civil or barrack buildings found in an army area were built with the idea that they would at some time be occupied by evacuation hospitals, it was not surprising that they were not found adaptable to the essential functions of these hospitals.

(2) Another type of hospital has developed under somewhat similar circumstances to that mentioned under the first heading. The hospital in many instances so developed has been admirably built and equipped to meet the problem which existed at the time of construction. The problem was the receiving, operation, and leisurely care of perhaps 5 or 6 cases a day, or, with a great and sudden rush, 35 or 40 cases. There being no particular demand upon bed space, cases were usually given complete treatment. It was, therefore, not an evacuation hospital. These hospitals were frequently specialized, some taking only gas, others head cases, some contagious diseases, and in some instances various and sundry medical and surgical specialities. With the problem these hospitals were expected to meet, in a relatively leisurely and businesslike warfare, where mutual agreements existed that shots would, or would not be fired during lunch hour, or on various special and national holidays, or at certain areas, crossroads, etc., there was no need for the evacuation hospital as we see it now, or as it was demanded when mobile warfare commenced in fact. It was hospitals similar to these that were captured with large amounts of valuable and almost unobtainable equipment.

(3) The third type of hospital, termed an evacuation hospital and which as a matter of fact was very nearly in principle an evacuation hospital, had its origin some time in June, and through successive actions, stations, difficult and well conducted "shows," passed through various stages of evolution, accumulation of property, and duties, to a stage of relative

perfection which bid fair to develop into the typical evacuation hospital suited to our purpose in this or any other war or campaign in France or elsewhere. This hospital has been known on repeated occasions to perform excellent service in two widely separated positions with a lapse of only a few hours in function. In one instance Evacuation Hospital No. 5 evacuated its patients, dismantled its establishment, packed, was transported, set up its essential department, and received cases in slightly over 36 hours. The task was accomplished in spite of various handicaps which can and should be eliminated. This hospital had in its equipment a few Bessonneau tents, a few camions, a mobile laundry, and trucks, all or most of which were poorly adapted to mobility and the source of unending labor, exasperation, and inefficiency. In a move of some 35 or 40 kilometers this so-called mobile equipment was almost wrecked, requiring the greater part of three days in its transportation. Wheels which were never intended for anything but support and were never meant to be used in transportation, developed hot boxes, came off, and caved in. The commanding officer, who should have been free to travel up and down the line of march regulating, arranging, and informing himself as to the progress of the march, rode in a truck and depended for his information upon reports which reached him on or about two days after he had arrived at his new station, which reports usually consisted of details concerning a truck which had broken down, or information regarding the location of a wrecked camion or laundry. His truck transportation was inadequate and of the cast-off, crippled type. In need of supplies and rations, he was dependent upon requisitions which had to pass through division channels and usually resulted in nothing but confusion. The balance of the equipment of this hospital consisted of what the commanding officer, his supply officer, his surgical chief, and others had made it by dint of persistency. There were three other hospitals which in a way resembled the hospital just described. Their equipment, methods, regulations, and personnel were anything but standard except in the particular that they were invariably incomplete.

(b) Mobile hospitals were more fortunate in the matter of standard equipment. Most of them were in fact "mobile," and performed indispensable service in relieving the evacuation hospitals of the heavy surgery and in taking the serious cases relatively near the firing line. They were greatly handicapped by lack of transportation when needed for rapid moves. In fact, these hospitals have been known to move on transportation procured by the commanding officers from various sources, through devious channels, and entirely as a result of forceful and tactful management on the part of the commanding officer. They functioned in this respect in spite of adverse circumstances and not as a result of facilities at hand. Their mobile equipment was often in trouble on account of imperfect adaption to the requirements placed upon it.

IV. STANDARD TYPES OF MOBILE AND EVACUATION HOSPITALS

1. Mobile hospitals are essential in the army area. They should be so standardized in equipment and function as to allow of their efficient function at the rate of one hospital per division in time of attack or activity. In quiet times one mobile hospital can care for the wounded of two divisions with certain organization to be mentioned later. It is believed that this rate, or proportion, of establishment troops in the line will be efficiently served. As stated, the parent or main portion of the organization should be established close up to normal artillery fire. Each hospital should have what might be termed an "advance section," consisting of 1 or 2 Bessonneau tents with facilities for handling from 2 to 6 operating tables, this to include teams, an administrative officer, and soldiers as anesthetist and operating assistant, with a small clerical force. Nurses would have no assignment in this advance section. Upon call in case of necessity, this advance should be thrown forward to a dugout, a protected building, or favorable area for the pitching of tents, where they would be able to care for that hazy classification of the wounded, called "nontransportables." Their supply of instruments, sterile dressings, laundry, rations, and other essentials would be sent them from the parent organization by a system of automatic supply or replacement. This arrangement of an advance section could be made to cover the work now performed by the much discussed and in most cases unwelcome mobile operating unit, supplied divisions, and left by them in many instances along the road to be salvaged on account of lack of transportation, surgical teams, and other small essentials. In case of an advance of the line, the "advance

section" might well prepare the location for the gradual establishment of the parent organization about it. Function would thus be almost uninterrupted when another "advance section" or two could be sent forward to a more advanced station. Certain well-known changes are necessary in the mobile equipment, satisfactory arrangement of which can be accomplished by the commanding officers of experience, who only await an opportunity to recommend and carry out changes which will make this hospital a truly mobile and effective organization. It has been the object of this paper so far to cover points of administration, function, and organization, which apply equally to mobile and evacuation hospitals. The specifications mentioned, as necessary for mobile hospitals in particular, are few, as the organization now existing is believed to be very nearly satisfactory.

2. *Evacuation hospitals.*—The function of a typical evacuation hospital should be decided upon and expressed concisely in orders. The points considered essential are: (a) Its location on a standard-gauge railway with adequate ambulance roads from the front, draining the required sector. (b) A sanitary siding of between 1,400 and 1,600 feet, with a loading platform, and ambulance roads within the area to be occupied by the hospital as shown in plan attached. (c) A water system piped as shown in plan. (d) Standard equipment, consisting of equipment A, of 500 beds; equipment B, which added to equipment A will give accommodation to 1,500 patients; equipment C, which added to equipment A and equipment B will give accommodation for 3,000 patients. For each army there should be an army hospital group for the supply of equipments A, B, and C, which equipments would consist of the specified number and types of tents, teams, officers, nurses, soldiers, labor troops, transportation and hospital equipment. With this understanding and with these facilities the hospitalization of an army area would become simple, and could be done quickly and accurately with assurance that the area of the army, in so far as the care of the wounded and sick is concerned, would be handled very efficiently.

Some of the reasons for the specifications necessary in evacuation hospitals may be stated in detail as follows: Standard-gauge railways in areas operated by American officers were rapidly constructed and kept well up in the army area. From information regarding future plans for railways, it is reasonably certain that in any future war they will be in a position for use as far as location and availability are concerned, as an army can not well go ahead of its supply. By consultation with the railway engineers, prospective construction into new areas can be determined; and by timely request, sidings can be had in favorable locations with the minimum effort, while the labor, materials, and special personnel are on the ground. It is certain that with definite plans, blue prints, and specified statements regarding our needs, the Medical Department can get what is required in the matter of railway accommodations and sidings. An indefinite request for a siding made after the railway engineers have been moved to another area will result in little more than the detail of an officer to make estimates and plans, which may be reported upon after some delay. If the chief surgeon presented this plan to G-4, with blue prints which can be made to fit any situation, with a request that this work be done while materials and personnel are at hand, the work would be accomplished. A hospital acting as an evacuation hospital located beyond practicable litter carriage to a loading platform should not be considered an evacuation hospital, and should be avoided, as this hospital requires additional handling of patients and an amount of ambulance transportation which exactly equals the amount and number of ambulance loads required to bring the patients to the hospital. Location on the railway reduced by this much the number of ambulances required for an army, and it is presumed that ambulances will always be difficult to obtain; that is an important consideration. Where the hospital is not located on a railway with a sanitary siding, the evacuation time of the area is increased by the time required to load and unload the ambulances, transport the patients over roads which may result in injury to the patient, all of which may require from one to three hours of time, during which time the patient may be subjected to cold, rain, injury, inconvenience, lack of toilet facilities, and even danger to life as a result of being out of touch with nursing and surgical assistance. This method of evacuation also requires the introduction of complicating features which is entirely unnecessary; i. e., the feeding and housing of the loading platform which means practically the duplication of the evacuation force and equipment already in existence at the hospital from which they are being evacuated. In the absence of these entraining facilities at the hospital, patients have been known to lie

out on platforms in inclement weather for hours. In one instance some 300 patients were returned to the hospital which was attempting to evacuate them, with the result that the patients were in ambulances on dark roads most of the night. This unfortunate state of affairs being the result of the nonappearance of the hospital train. It is reasonable to suppose that hospital trains will frequently arrive after the hour at which they were intended to arrive, so that unless the evacuation wards are along the loading platforms where loading may be commenced when the train actually appears, inconvenience, to say nothing of suffering, will result. Under the heading (b) of essential features in the evacuation hospital, ambulance roads in the area of the hospital were mentioned. These roads were shown in the ground plan.

Arranged in the manner shown, admission, distribution, supply, and evacuation may be accomplished with efficiency. The difference between an evacuation rate of 2 patients per minute and 1 patient in 5 minutes is largely one of roads, walks, and favorable location of evacuation wards. Here also the construction and procurement of this vital feature depends largely upon knowing what we require and upon our ability to turn over to G-4 and the Engineer Corps a well-made blue print which can be at hand and made to apply to any location we may find ourselves in.

(c) Water will, in the majority of instances, be found near the railhead and can be piped to a supply tank from which distributing pipes can be placed, as shown in ground plan. If water is not available at railheads, it can be supplied to the hospital by railway tank cars. Here again a definite statement of the number of gallons required in 24 hours, whether to be chlorinated or not, and the blueprint showing the distribution, will facilitate the obtaining of a water system. Two water carts should be supplied for equipment A, 3 for equipments A and B, and 4 for equipments, A, B, and C. Equipment proposed under (d) will not be defined, as it is believed that the details or tables should be the result of recommendation by a board composed of commanding officers, professional chiefs, and supply officers who have had experience in these hospitals. The general plan, however, of a standard unit equipment for 500 beds which could be raised without confusion, as the conditions required, to 1,500 and then to 3,000 beds, is proposed. With the ground plans shown herewith, an A or unit equipment could be sent by rail to a siding, unloaded, and put up. The administrative personnel for this hospital, or for anything it might consequently become, would therefore be at hand. As the situation developed, and upon demand, equipments B and C could likewise be sent by rail, unloaded, and placed around the unit equipment as shown in layout plan. With facilities similar in a way to those herein recommended, an organization fresh from the United States developed and expanded from what they had expected to be called upon to perform into a hospital which hospitalized on one occasion 2,190 cases and evacuated by train faster than trains could be supplied. Should retreat be necessary, this hospital with its equipment and patients could be moved by rail very rapidly. With an advance of the line a new type "A" equipment from the army hospital center could be "leap-frogged" to the new position and the "B" and "C" equipment of the old location could be packed and transported by rail when required.

Equipment for the standard evacuation hospital will have to be greatly modified, as our present conception of what this equipment should be is lacking in many respects. Kitchen equipment in particular needs attention. Heavy ranges are impracticable and unnecessary. There should be adequate boiler equipment similar to that used in some of the French hospitals, which can be set on tripods or upon extemporized bases of stone or brick. It is believed that a board should be appointed for the purpose of standardizing kitchen equipment and that they should be particularly instructed to make this equipment light and compact for transportation and that the main use to which this equipment will be put will be in the preparation of stews, soups, and liquid diets.

Laundry equipment has been unsatisfactory. Several excellent suggestions have been made by commanding officers and others regarding essential and necessary changes. It is believed that the laundry equipment should contain a large and effective dryer, as much time has been lost in drying linen and it has frequently been sent to the storeroom in a damp condition. Several excellent suggestions have been made regarding dryers. It is believed that the dryer of an evacuation hospital should be mounted on railway cars for the purpose of

quick transportation, by which method these laundries could be transported without damage, which has invariably occurred when they have been sent over roads. It is believed that an evacuation hospital with an adequate laundry plant manned by trained personnel could do the work required of the mobile hospitals of the area. A certain number of mobile laundries should be available, however, and a practicable mobile plant can be very easily designed which will travel readily, under its own power, over ordinary roads. This can not be said of the present French mobile laundry.

Truck transportation, though essential for evacuation hospitals, would be much less necessary if these hospital were located on a railway near railhead, as supplies could be furnished on the hospital siding and unloaded from the cars into the storehouses or trucks for a short haul.

Wheeled litters for transportation of cases from ward toward or even to the unloading platform will save much labor and 50 per cent of the number of litter bearers required for the ordinary litter. Large supplies of duckboards for walks should be at hand and a standard equipment of duckboard should be furnished with each type of hospital.

Ambulance tracks made of 2 by 12 inch timbers, with side guards constructed in sections, or Decauville or 60 cm. track may be used in some of the less traveled roads. These tracks can be used especially about mobile hospitals. An ambulance road can be constructed with these tracks in a few hours.

Illuminated signs marking the hospital, the receiving ward, office, and various departments are easily constructed of boxes, with signs of translucent material.

V. GROUND PLANS

Standard ground plans for the typical evacuation hospitals will depend particularly upon the type of tent used. It is believed that the most satisfactory tent for all service is the Bessonneau tent. The small tent measures about $19\frac{1}{2}$ by $58\frac{1}{2}$ feet. One of the hangar tents measures 65 by 84 feet. It is believed that the standard A type hospital should have at least 10 Bessonneau tents of the small type, arranged as shown in the drawing of ground plans. This number would suffice for receiving triage, shoe, and operating departments, with at least two which could be used for the more urgent type of hospitalized cases. The additional tentage might then, especially in favorable weather, be made up to 500 beds by the use of the present ward tent where it was desired that the hospital should be reduced to the minimum weight. It is believed, however, if we establish this hospital along a railway with a siding, the question of weight could be well ignored and that the entire equipment could be Bessonneau tents. With the addition of B and C equipment, a hangar tent should be erected over the receiving tent while it is in operation, as more room for receiving will be required than that which is available in the small Bessonneau tent. With the complete establishment of the Bessonneau hangar, including a ceiling about 12 feet high, the small Bessonneau tent should be dismantled and removed without interruption to receiving. Another large Bessonneau tent might well replace the two operating tents at the other end of the area, with central sterilizing facilities for instruments, dressings, and supplies. This tent should also have a ceiling, especially in winter for conservation of heat. The ceiling should be made of an opaque material to hide the light from aviators at night.

The ground plan furnished shows only distribution. Dimensions can be readily set in upon determination of the type of tent to that used, allowing 25 feet between tents laterally and 15 feet between ends. A canvas-covered frame should be constructed over the ambulance drive in front of the receiving ward for the protection of patients being unloaded. The arrangement of tents in the receiving, triage, and operating area provide for a continuous flow of patients to the wards and evacuation area, which reduces the litter carriage and confusion so often found in evacuation hospitals where a patient is littered back and forth throughout the area where tents have not been arranged with a view to continuous flow. A Bessonneau corridor, or an improvised corridor, might well be placed between two sets of tents in the rear of this area for the protection of patients from rain and cold and for use in case large numbers of patients accumulated in the preoperative area. At the end of this corridor is shown an X-ray equipment for slight and walking wounded cases. This would be in addition to the plant for severely wounded shown in the third row of tents. Communi-

cation could be had between the light and heavy operating tents and the sterilizing tent by means of short corridors, as a section of the side wall of each can be easily removed or turned outward for the side wall of the corridor.

Distribution of water plugs as shown in the drawing makes the establishment of one pipe line sufficient for distribution. There being no angles, this line could be quickly laid. A water tank erected near the siding could be filled from a general water supply or from tank cars brought in by rail.

The loading quay should be at least 14 feet wide and 1,000 feet long. It may be constructed of earth covered with gravel or cinders, by putting the siding in below grade and throwing the excavated earth to the hospital side, where it can be arranged in a gradual slope from the evacuation wards up to the usual car-door level. As evacuations would be made from the evacuation wards situated along the quay, litters could be placed directly upon the quay from the tent door and there loaded into the car. With classification of evacuation wards into medical, gas, surgical, walking, and sitting, arrangements could be made to load these special classes directly into cars placed opposite the wards. This will reduce the danger of contagion, especially where large numbers of grippe and contagious cases are being evacuated.

The laundry is shown mounted on a railroad car and is placed at the end of the sanitary siding where laundry could be delivered and sent out on the loading platform.

A lighting plant and a generating plant for X-ray use might likewise be mounted on a car.

A delousing and bathing equipment could be constructed with the use of railway cars and additional tents or knockdown buildings which could be set up near or around it.

Dimensions other than those given in ground plans are not possible without a decision as to what type of tent will be used. The type of ambulance road will depend largely on the soil and season. They should, however, be adequate to prevent miring as much as possible, as much valuable time has been lost by trucks and ambulances as a result of poor roads. Ambulance roads should be at least 14 feet wide.

A standard red cross made of material which will furnish a contrast for aerial picture should be constructed with the first sign of activity on the ground to be occupied by the hospital. This cross should be at least 100 feet in diameter. The width of the crossarm would therefore be $33\frac{1}{3}$ feet.

The table "Tents" is provided for tentage of the A, B, and C types and provides for (1) Bessonneau and hospital tents; (2) Bessonneau, ward, marquee, and hospital tents; and (3) aviation hangars and Bessonneau tents (small size). This table should be filled in when the tentage equipment has been decided upon by a board appointed for the purpose.

VI. ARMY HOSPITAL CENTERS

Hospitalization of any army area is a question which must necessarily come under the control of the chief surgeon.

In order that the chief surgeon may have at his disposal the essential elements for hospitalization, he should have in the army area a center of supply for equipment, personnel, and supplies.

Early in the Argonne-Meuse engagement, with some 30 hospitals established in the area of the First Army, it became evident that there was need for a replacement or supply center from which replacements and reinforcements of personnel and equipment could be furnished quickly and accurately. A center similar to the one proposed has been established for the assembling, equipment, and training of mobile hospitals.

In the area mentioned, teams, soldiers, nurses, and labor troops were overworked, tired out, and insufficient in number to meet the demands of the station. With rush work, preoperative evacuations were often found necessary where quick reinforcement or replacement of personnel would have made it unnecessary. Surgical teams and their personnel worked continuously for longer periods than the average human is intended to work rapidly and efficiently. The troops this personnel cared for were relieved and sent to rest and replacement areas when necessary.

With the formation of armies it is presumed that general training camps for the training and equipment of medical personnel will be formed in the Services of Supply. Here evacuation and mobile hospitals could be organized and trained with standard equipment. Administrative officers, especially, should be developed, as men of insufficient training and adaptability to hold responsible positions have been at fault in most instances where hospitals were found to be inefficient. From these Services of Supply training camps personnel as units or as replacements could be supplied to the army hospital centers located near the center of the army area, close up to the corps area. With the call for hospitalization of an army area, the chief surgeon would make requisition for a certain number of mobile and evacuation hospital organizations, which would be sent to the prospective hospital center area. With these hospital organizations it should be understood that a definite percentage of replacement personnel and equipment would be sent. A reserve of B and C type units of equipment would also be sent according to a table decided upon by the equipment board mentioned. A commanding officer of experience should be placed in command of this center and made responsible for the efficiency of organizations sent out when called for.

After a study of the area, prospective railway construction, future railheads, possibilities of the various elements of the action contemplated, roads, water supply, protected areas, etc., evacuation points and, therefore, evacuation hospital sites could be determined. The establishment of sidings, construction of roads, and installation of water supply could be commenced as soon as material and personnel become available, and certainly before these necessary elements had been removed from the area. After preparation of the area the necessary equipment could be sent by rail with the orderly and timely establishment of evacuation hospitals. Mobile hospitals should be established later to meet the specific needs with developments of the situation, there being less haste in the establishment of these hospitals, as less transportation and work is required to get them into operation.

Communication between the hospitals and the chief surgeon's office, "G-4 evacuation," the regulating officer, and the corps surgeon by telephone and a courier system which will function are absolutely essential to the proper conduct of hospitalization and evacuation from any army area. The chief surgeon's office should be constantly in touch with all the offices mentioned. If communication by telephone is not possible at all times, serious delay in evacuation will result, hospitals will become overcrowded, with resulting preoperative evacuation which might have been avoided.

A graphic chart, for use in the chief surgeon's office, is shown herewith (blue print). This chart shows at a glance the status of the various hospitals in the area, in so far as the number of officers, soldiers, nurses, patients, and the teams is concerned. It also shows the bed capacity in each hospital.

It is desired again to acknowledge the source of a large part of the material of this article and to state that the object of this paper has been to collect in one article the good features developed in the various hospitals and to attempt to explain and point out the reason for unsatisfactory function where it has been found to exist. It is desired particularly to acknowledge the valuable suggestions and notes of Colonel Garcia, of general headquarters; Colonel Brooks, of the chief surgeon's office, Second Army; Colonel Baker, Major Jamison, and Captain Blackburne, of Evacuation Hospital No. 6; Major Rice, of Evacuation Hospital No. 10; Colonel Flint, of Mobile Hospital No. 39; and the excellent examples set by the hospitals which did such splendid work under trying circumstances around Chateau-Thierry, Villers-Cotterets, and in the Argonne-Meuse activities.

Army Sanitary School No. 158.

DIVISIONAL MEDICAL CAMPS FOR THE TREATMENT OF VENEREAL DISEASE IN THE
AMERICAN EXPEDITIONARY FORCES

Maj. H. L. Sanford, Urologist, Second Army

REASONS FOR THEIR ESTABLISHMENT

The original policy proposed by the division of urology for the treatment of venereal disease in the American Expeditionary Forces contemplated the handling of cases as near the front as possible and, with their units, sending to base hospitals or other special urological hospitals which might be formed only such cases as could not properly be treated farther forward. It was hoped by this method to avoid certain results which followed the English and French system of sending all such cases to the rear, a system which involved additional transportation, prolonged the patient's period of ineffectiveness, and deprived organizations of the services of these men, often valuable, since they were sent to replacement camps after completion of their treatment.

DIVISIONAL CAMP, 1ST DIVISION

Although the system proposed for the American Expeditionary Forces proved both logical and practical for troops in rest or training areas, it was found to be unsatisfactory when the 1st Division went into the line. Organizations were split up into small units, the men got separated from their medical officers and from their medical records, so that those in charge of this work found they had no control of the situation and that patients suffered for lack of necessary care. The urologist of the 1st Division accordingly proposed and was authorized in March, 1918, to form a camp in which should be concentrated all cases of venereal disease in the division where they should receive uniform and intensive treatment and where the services of those physically able might be employed in the formation of working parties.

This camp, after being in successful operation for a few weeks, was broken up when the division left the area, and this organization subsequently changed its station so frequently and was constantly under such active fighting conditions that it was never subsequently possible to reassemble the camp for any length of time sufficient to get results in venereal treatment.

DIVISIONAL CAMP, 42D DIVISION

It was determined to try out this same plan in the 42d Division, at that time holding the quiet Baccarat sector, and in April, 1918, a camp of this sort was established in the divisional area. The following details are taken from our reports to the division surgeon on the camp at that time.

Location.—Outside of the ordinary considerations which govern the selection of a camp site, it was desirable that this camp be: (1) Centrally placed in the divisional area; (2) near projected work for which labor parties would be needed; (3) near enough the front line so as not to put a premium on acquiring venereal disease; and (4) provided with natural camouflage.

These points were covered by the selection of a wooded site near projected road improvement and halfway between headquarters and the trenches.

Officers, personnel, and equipment.—Officers: Three lieutenants from the Medical Corps were found necessary to run the camp properly—officers from the Medical Corps instead of line officers were intentionally chosen, as the latter might regard such an assignment with little enthusiasm. One lieutenant had general administrative control of the camp, and was selected with especial regard to his known ability to maintain a high standard of discipline; a second officer, who had had special training and experience in the treatment of venereal disease, had purely medical duties; a third officer was needed to act as relief for the other two.

Personnel: A detachment of 23 men from Field Hospital No. 167 was assigned to this work, consisting of the following ranks: 1 sergeant, first class; 1 sergeant, acting as mess and quartermaster sergeant; 1 sergeant in charge of infirmary; 1 sergeant, drill sergeant; 1 cook; 2 corporals; 8 privates, first class; 8 privates.

Equipment: The equipment was taken from Field Hospital No. 167 with the exception of the Bessonneau tent used for the infirmary. No wooded barracks were used, though they would be needed for a winter camp.

Plan of camp.—The tents for patients and personnel are regulation ward tents in field hospital equipment. Two large tarpaulin flies cover the kitchen and mess tables. The company office is located in a pyramidal tent, with two smaller tents for officers. All tent floors are made of a 3-inch layer of small stones.

Infirmary.—A Bessonneau tent 60 by 20, donated by the American Red Cross, contains the infirmary. The tent is divided into three sections by blanket partitions; the first is the infirmary proper, which has a board flooring. The rest of the tent has a gravel base.

In the infirmary all the furnishings, operating table, other tables, chairs, stools, supply shelves, and irrigating stand were made at the camp out of duck boarding or boxes from the sales commissary, and no little ingenuity was shown in their contrivance.

Two old coffee boilers with faucets were reclaimed from the salvage dump, and now make excellent containers for hot and cold sterile water, and the irrigating trough was lined with tin also obtained from the salvage dump.

The second section of the tent is used for sleeping quarters for the sergeant in charge of the infirmary and the third section for storage of patients' equipment, with a rack for rifles.

Patients.—During the six weeks this camp was in operation, before the division left the area, a total of 241 cases were treated.

The greatest number of patients at the camp on any one day was 182; the daily average was 167. These cases were classified as follows:

Venereal:

Chaneroid.....	3
Gonorrhea.....	145
Syphilis.....	60
	<hr/>
	208
	<hr/>

Nonvenereal:

Cystitis, cause undetermined.....	1
Hydrocele.....	2
Phimosis (for circumcision).....	13
Suspected syphilis.....	4
Urethritis (nonspecific).....	2
Varicocele.....	3
Venereal warts.....	8
	<hr/>
	33
	<hr/>
Total.....	241

Chancroid.—But three true cases were seen; most of the men admitted with that diagnosis proved to have syphilitic or mixed infections, as controlled by smears and Wassermann tests.

Gonorrhea.—The majority of cases were old relapsing cases in the chronic stage. Many developed symptoms following duty in the trenches, without opportunity for exposure. Many others were infected before enlistment, and it was often hard to differentiate between a relapse and new infection, as symptoms appeared atypically.

Syphilis.—Of the 60 cases, 35 were infected before enlistment, at dates running back as far as 1904. Some of these patients presented relapses after having been assured they had had adequate treatment for a cure. In other cases the diagnosis was made for the first time, as previous manifestations had not been recognized.

Of the 25 men infected in the Army, 16 had taken no prophylaxis whatever, while in 9 prophylaxis was for some reason inadequate.

Four cases at first suspected to be syphilis were removed from the list, after careful inquiry into the history, and repeated negative Wassermann tests, including provocative injections of Neoarsenobenzol.

Administrative.—Discipline: It was felt that a very high order of discipline should be maintained to handle successfully this type of case, and the camp was accordingly run as a military camp and not as a hospital. Men sent to the camp were detached from their organizations "for duty" at the camp and were not carried as "sick" unless actually sick in quarters. As a matter of fact, patients proved extremely amenable to the regulations prescribed and showed an excellent spirit.

An effort was made to raise the morale of these men by impressing on them two things—first, that they were being given the benefit of uniform and intensive treatment by men trained in that work and with the best type of equipment and medicines; second, that with a sufficient treatment they could be cured.

Employment: As one of the main objects of the camp was to form working parties from those patients physically able to work, the problem of classifying patients as to their fitness for labor required solution.

It was found that roughly one-quarter of the men could do no work at all, either from the intensive nature of the treatment they were taking or from disabling complications of their disease. A second quarter were able to do light work about camp, while something over half could go out for a day's work, taking treatment either before leaving camp, or on their return. This corresponded practically to acute, subacute, and chronic types of disease.

Working parties: Those able to do a day's work left camp at 7.30 a. m. and returned at 4.30 p. m. If the location of their work was a kilometer from camp, they walked to work and returned to camp for their midday meal. If the work was farther away, they were transported in the hospital trucks and took their mess with them, the trucks calling for them in the afternoon.

Details were chiefly employed in quarries in breaking stone and in road improvement, much of which was needed. One thousand six hundred and twenty three days work of eight hours each were sent out from camp.

Lectures and drills: The subacute type of case was the most difficult to handle. Though not able to work hard, these men were still much too active to be kept out of mischief by the small amount of work involved in guarding and policing the camp. Accordingly a schedule of lectures on personal hygiene, camp sanitation, and gas defense was made out and given. To this was added various drills, setting-up exercises, close-order drill, gas drill, litter drills, application of splints and bandages, and general simple first-aid work, given by a drill sergeant assigned for the purpose.

Odd jobs department: It was also suggested that a hospital tent be equipped with a carpenter's bench and a few metal-working tools in which patients able to do light work could do various odd jobs. It was proposed that the many signs needed in a divisional area could be made and lettered there, and we were assured that, if such a place was known to be available, many things would be turned over to us. We were promised the tools and equipment but a change of station prevented its being tried. It was also proposed that the rides and equipment of patients in the divisional hospitals could be sent to the camp to be cleaned to avoid deterioration. Some basket making was done by a patient who knew how, and who taught several others. It would be a question of determining some product for which there is a steady demand in a division, and which could be turned out satisfactorily by untrained labor, involving light work. This should only require the installation of inexpensive and easily transportable shop equipment.

Amusements: This type of patient needs a certain amount of amusement to avoid the mental depression often associated with venereal disease, and a day which furnishes only hard labor and sometimes painful treatment is not inspiring.

A Red Cross tent, with phonograph and writing material, is useful. A canteen is not necessary, and would only be an aggravation, as patients are generally under sentence depriving them of pay. Tobacco and other comforts were frequently distributed by the Red Cross, and a regimental band came each Sunday and gave the patients a much appreciated concert.

Medical treatment.—Infirmiry: The equipment of the infirmiry, which occupied a 60 by 20 Bessonneau tent, furnished by the Red Cross, was described in the first report.

Personnel: The entire time of one medical officer with previous special urological training was given to this work. The care of 170 patients and the responsibility of seeing them all and treating many of them each day is too much for one man, and he needs the help of at least half the time of another officer, who could take over the work in case of illness or change of the regular man.

In this work the medical officer had the aid of 1 sergeant, in charge of infirmiry; 1 private, as clerk; 2 privates, general assistants; 4 patients, cleaning infirmiry and calling patients for treatment. This help proved insufficient and should be increased.

Records: A brief history of each patient was dictated by the medical officer, within 24 hours after his admission. This was followed by his examination and first treatment. The histories are recorded on the regular clinical history forms supplied and attached to the back of the record so that it can be referred to quickly without turning over any of the various slips which form the record.

A special history sheet for syphilitic cases has now been supplied. The daily treatment is also noted in abbreviations. Syphilitic registers are posted daily in triplicate; the original goes with the patient at his discharge, one is sent to the division surgeon, and a third is retained at the camp. This insures a permanent record being at hand at all times of all known cases of syphilis in the division, and from these registers a check list may be kept, noting when the patient is to be sent for further treatment after a rest period, during which he is doing full duty with his organization.

A weekly report is also made of all new cases of infection, giving name, rank, company, organization, diagnosis, place and date of infection, whether and when prophylaxis was taken, and any remarks appropriate.

Bulletin lists: On the bulletin board in the infirmiry is posted a typewritten list of all patients in the camp classified according to disease. In squares ruled opposite each name, one for each day of the month, is indicated on each afternoon the treatment that patient is to receive the following day. From this are made up the lists of working parties for the next day.

It was also found convenient to have separate lists of syphilitics on special treatment and patients with chronic gonorrhea who received massage and sounds twice a week.

General routine: The medical officer makes rounds of the tents each morning. All cases sick in quarters are recorded as such, and the diagnosis in each case is the original diagnosis of venereal disease on which the case was admitted, and not the intercurrent ailment or complication which may be the cause of the disability.

Some syphilitics are treated in the morning and are able to go out to work in the afternoon; others are treated at the end of a day's work.

All other men are seen in the morning, and the afternoon is kept free for special work.

The morning parties are inspected in the infirmiry by the medical officer in the afternoon on their return from work. They are then treated. Any man who has not stood up well under full duty is relieved and put on light duty. No case of overwork which interfered with the satisfactory progress of the patient was observed.

Equipment: The regimental infirmiry urological set is ample and complete, and comprises articles of the best workmanship adequate for all occasions. The medical supplies, especially for the treatment of syphilis, are put up in convenient form for simple rapid administration. The other furnishings of the infirmiry were made at the camp and described in a previous report.

Treatment.—Syphilis: Syphilis has been treated according to a system in use at Hospital Broca, Paris, involving periods of intensive treatment, with intervening periods of rest, the length and sequence of the periods being controlled by Wassermann tests.

Neoarsenobenzol: Neoarsenobenzol has given no striking reactions. The medical officer who gave the injections reports that in his opinion there was less reaction where the drug was diluted up to 6 to 10 c. c., of distilled water than when given in 2 c. c. dilution, and usually no reaction at all. There was rarely any local reaction in the vein and in no case was it more than a transient soreness.

Cyanide of mercury: This drug in 1 per cent solution gave more trouble. Quoting from the medical officer's report: "Mercurialism appeared early and often after three injections. We found it necessary to reduce the dose of 1 c. c. of a 1 per cent solution one-third or even one-half. In some cases we abandoned the drug entirely and used intramuscular injections of gray oil. Mild phlebitis was common, and this in cases where it seemed certain that the needle had not gone outside the vein."

Gray oil: No reactions, local or general, followed.

Dentist: A dentist is needed in a camp of this kind to spend all or at least a part of his time. The intensive mercurial treatment requires constant dental supervision.

Gonorrhea: The acute type was treated by three to four daily hand injections of protargol in from one-half to 1 per cent solution. The patients came to the infirmary for these injections, which they took themselves under supervision of the sergeant.

The chronic type received prostatic massage and sounds twice a week, with daily irrigations of 1 to 10,000 silver nitrate or 1 to 5,000 permanganate. Many of these cases which were admitted with only a slight morning drop developed a profuse discharge after the first prostate massage; this quickly disappeared, however.

Chaneroid: Our experience with simple chaneroid was very limited. The chief trouble came from inflammatory phimosis or paraphimosis requiring dorsal slits of the prepuce. A secondary circumcision was always done in these cases after the infection had disappeared.

Results.—During six weeks, 36 cases of gonorrhea were discharged as cured—8 were acute cases and 28 of the chronic type. The supposition of cure was based simply on persistent disappearance of symptoms after passage of sounds.

Sixty cases of syphilis were under treatment, of which all but five showed marked improvement. In the latter persistent anemias or advanced cardio-vascular changes were present. The others showed marked gain in weight and general well-being.

When the camp was broken up, on June 18, 1918, all but 15 patients were returned to their organizations for duty; 8 of these were sent to a base hospital and the remaining 7 expected to join their units a few days later.

It is a pleasure to acknowledge the splendid and enthusiastic cooperation given us by the officers and personnel of the camp in carrying on this work.

Summary.—The plan outlined above seems to have proved of value in certain definite ways:

(1) It relieved the regimental medical officers of a class of work in which they usually have little interest and no special training.

(2) The morale of patients is increased by their realization that they are getting intensive treatment at the hands of specially trained men.

(3) The division gains rather than loses in effectives when venereal cases are sent to such a camp, because the amount of labor performed by the working parties greatly exceeds the amount of work these same men would accomplish in their organizations, where they are apt to be dissatisfied with their treatment and to exaggerate their physical disability.

(4) These working parties release sound men for front-line duty who otherwise would be detailed for this labor.

(5) In such camps venereal disease is actually better treated in the Army than is possible in civil practice, as here the patients are under complete control.

GENERAL CONSIDERATIONS

(1) A venereal camp of the type described is adapted for troops in areas of training, of rest, and in quiet sectors of the front.

(2) For troops in zones of active fighting or frequent movement the more scientifically ideal arrangements which can be carried out in quiet sectors must be sacrificed to the demands of military efficiency, which involve keeping with their organizations as many men as possible who can fight.

(3) During such active periods the following disposal of venereal cases is suggested:

(a) In organization infirmaries should be treated all venereal cases able to do full duty. In times of military activity they should expect to receive only such treatment as circumstances permit—this will often mean no treatment at all.

(b) To corps or army concentration camps, for the treatment of venereal disease, should be evacuated (1) trench cases of syphilis in the infectious stage; (2) other venereal cases with complications preventing men from doing full duty.

Subsequent experiences.—Following this six weeks experience, the 42d Division, like the 1st Division, was moved frequently, and was in active fighting sectors almost continuously up to the signing of the armistice, and though repeated attempts were made to reestablish these camps, they would no sooner be set up than another move would break them up again. During these months, men with venereal disease who could do full duty were kept in the front line, and their treatment was necessarily irregular or wholly lacking. It was for this reason that, realizing there must be many cases, especially of syphilis, which needed further treatment, that plans were made by the division of urology to establish one or more venereal concentration camps in each army area in which these men might receive proper care.

These plans were in turn interrupted by the armistice, and it now seems probable that for troops which remain on this side for any length of time the venereal cases will be sought out and intensively treated in divisions, and that for returning troops, venereal centers will be established at ports of embarkation where patients will be thoroughly treated before being allowed to sail.

Divisional camps in other divisions.—Besides the camps mentioned of the 1st and 42d Divisions, similar camps were established in other divisions, their success generally depending on the length of time they could be kept together, and the activity of the special division in the fighting zone. The writer is not sufficiently familiar with the details of these camps to describe them—except to mention that in the 26th Division a scheme was worked out very successfully of using patients able to do duty for laundry work for the division.

Working parties formed by patients with skin disease.—It is also worthy of mention that in divisional or other hospitals devoted to the treatment of skin diseases, patients, especially scabies cases who remain in hospital four or five days, may be used to form working parties. These are physically fit for work and, if they are treated in the morning, can work in the afternoon, or vice versa. Employment improves their morale, besides furnishing labor often urgently needed for various projects in the vicinity of the hospital. This plan was carried out in the 42d Division, and from the field hospital at that time caring for skin cases (Scratchville-by-the-Sea) 100 men were sent out in trucks in the morning for a half day's work, and another set in the afternoon.

Army Sanitary School No. 159.

HISTOPATHOLOGY OF WAR WOUNDS

By Col. Bailey K. Ashford, M. C., United States Army, September 2, 1918

Gentlemen, the truth of the matter is, this lecture, "Histopathology of war wounds," is a very important one, because it is the basis upon which modern surgery is being done, and I am going to ask you to draw as clear an idea of this histopathology as possible. Into this little talk will have to come some consideration of the missiles that are received.

Wounds in the Civil War were quite different from the wounds that we receive now because, generally, of the velocity of the bullet. They were generally bullet wounds—at least 90 per cent of them—and they were bullets that traveled at a low velocity. They were of rather large caliber, blunt, and somewhat soft; they became deformed and their tendency was to produce, in addition to the punctiform wound of entrance, a laceration and contusion to the immediate surrounding tissue through which the bullet passed. * In fact, so low was the velocity—and so large the projectile—that it very frequently was turned aside on encountering masses denser than the tissue through which it was at the time passing. For instance, if a bullet of low velocity traveling through muscular tissue encountered a bundle consisting of the nerve, vein, and artery encased in connective tissue, it was swerved aside and the nerve, vein, and artery were not injured. It happened with enough frequency to demonstrate the fact that denser tissues did swerve these bullets. That was the more striking when you consider the condition of the bone struck. Now the fractures in the Civil War were generally fractures by contact. They were not the finely comminuted bursting fractures of the high-power bullet. The consequence is that as a matter of fact infection of the bone should not

have occurred with anywhere near the ease that infection of the bones occurs in wounds of to-day, because it is the perforation of the bone and the attainment of the marrow that causes the osteomyelitis, and the fractures by contact are considered to be the less severe of the fractures because the projectile does not penetrate the bone, and, therefore, does not carry with it clothing. So in those days fractures were by contact and they tended to assume the familiar butterfly shapes that we all know about. Everybody knows that the typical fracture—contact fracture—is the butterfly fracture. The diagonal lines cross each other up and down forming the open wing of a butterfly. There are innumerable modifications of that, but in general you can trace out the butterfly. That is, of course, when the bone is not perforated, because it is comminuted and the butterfly semblance is lost. These fractures extended up and down, very frequently invading the joints, as you know. The low-powered bullet very frequently lodged in the cancellous portion of the bone, whereas a high-power bullet would cause great comminution. You should always keep before you the fact that these bullet wounds tend to produce laceration and contusion in the immediate vicinity of the tract of the bullet without any molecular death farther out than a few millimeters; that is to say, no explosive effect except in an exceedingly short range. They are said to be more painful too—I don't know how true that is—on the principle that a very sharp blow, a high-velocity bullet, doesn't hurt so much. The effects on the bone and the nerves and muscles are more important. Division in both cases would be the same whether from a high-power or low-velocity bullet; but the modern bullet will nip a nerve causing molecular death up and down in the nerve, or nip out a piece of a vessel, which may be closed up by a clot temporarily, and afterwards form traumatic aneurysm. That's the modern bullet wound to a nerve or vessel, and the old wound was a bruising which would partially or totally devitalize the nerves at that point and then would come on the infection, which did not necessarily come from the bullet wound itself but superadded. Now, undoubtedly, clothing was carried in in the Civil War just as it is to-day—not to the extent that it is to-day by any manner or means, however; no doubt about that because the velocity was low and beyond shivering the bits of cotton at the point of contact it managed to slip in without carrying much clothing, whereas the modern weapon delivers a missile that will punch it, just like a conductor's punch, and carry it in en masse, scattering fibers as it goes. The percentage of shrapnel wounds in the Civil War was from 5 to 10 per cent; it depended on the action, whether it was a tremendous bombardment previous to an advance or a tremendous bombardment to make men retire from a position. In these cases the wounds by artillery were more frequent, but in general 5 or 10 per cent were shrapnel. They rarely had other wounds because the solid shot was used for demolishing.

Now we still have shrapnel, but shrapnel has diminished to a considerably less amount than what it used to be. It used to be the *bête noire* for advancing troops, but to-day it is high explosive, and we don't have to think about shrapnel wounds as we used to. There is another thing that was brought out by an officer when I was with the French. He says the Hun uses iron. These bullets are now made of iron and they pierce the helmet very easily; the lead ones won't. The overhead shrapnel, if it were made right, wouldn't go through helmets ordinarily, but being made wrong it does go through them. As we say in Spanish "It seems as if the devil did it."

It is rather important to consider these wounds of the Civil War because in those days they didn't know anything about bacteriology—didn't use it; and the good old ladies back home used to put up packages of lint and send them to the soldiers and that used to infect wounds with intestinal bacteria homemade. Lots of old ladies with the best intentions in world sent down choice varieties of streptococci to infect the soldier lads. It was, of course, to be expected that our men would be infected; they had to have laudable pus. You will see, later, what that means. It is an extremely applicable term to-day in some ways but the whole thing was that everybody expected infection and was rather surprised when they didn't get it. But if these wounds could have been treated in the light of to-day they could have easily been treated aseptically. Those wounds of the Civil War were far more benign wounds than those we get to-day because they were localized quite strictly to the tract which they followed. If a man was unfortunate enough to have a bone fractured it didn't make

much difference whether it was a high-power or low-power bullet, but it did mean a great deal of difference if the wound was through his thigh, because then there would be actual molecular shock.

Now we come to the wounds of the South African War, the Russian-Japanese War, the Spanish-American War, and the Balkan War. I hesitated before I mentioned the Russian-Japanese War, but even then the wounds by rifle were exceeding the wounds by artillery. In certain battles the wounds by artillery were enormously frequent, far more so than in this, far more so still than in the Spanish-American or the South African War. In these we were using a high-powered bullet—in general, in these wars, the percentage of bullet wounds still hung around 90, 95—I speak from memory; I haven't any books with me to read on this subject—you remember it as well as I do—it was about 85 to 90 per cent of rifle bullets and the rest of shell. They were commencing to use shell, especially in the Russian-Japanese War, some in the Balkan War, of course; but in the South African War it was what we used to know as the old field artillery shrapnel. There the change was in the bullet they were using—a high-velocity, small-caliber bullet, weighing some 450 gm.

The effect of the bullet was that of a stiletto in the soft parts, if fired at ordinary ranges. If fired at ordinary ranges, sharp pointed, it would slip in quite easily; it would enter by a hole infinitely smaller than itself, because it would throw the skin upon the stretch, it would pierce the skin which would retract just like a rubber band when you stick it with a pin. Once inside it took up a straight course through the fleshy parts. Here its piercing quality was its chief quality; it pierced—that's what it did above everything else. The bullet that preceded it tore, rent, and contused. Being fired at a very high velocity it did not turn aside when it encountered denser tissues, but went through them, including bone. There have been a number of very beautiful examples of nice perforation of bone without much fracture surrounding it. Now the chances of hitting a vessel or a nerve square (a direct hit) are not very great, and I believe ——— in his experience in the South African War is responsible for the statement that there were more wounds of vessels and nerves because these bullets were not swerved aside. They did not lacerate them, the same energy went into piercing, but when they struck a very solid shaft of bone instead of penetrating they perforated it and burst it. Usually, however, in the soft parts, the wound of entrance and the wound of exit were not very different in size, but the wound of exit was always a little larger; but if a bone had been encountered on the way and comminution had occurred the wound of exit was even much larger than the wound of entrance, generally, but it was not always so. There were many cases where they struck a bone and comminuted everything and went out the other side. Now, we are seeing these wounds to-day; the more and more frequently we get into open warfare the more we see them. In open battle that is the wound we see; the wound of the bullet—of the sharp-nosed, high-power bullet. But its character is always that of the stiletto, and on encountering a structure like bone its tendency is to shatter. Now at short ranges of from 300 to 500 yards, this bullet has an explosive effect; that is to say, its centered energy, hitting suddenly on a substance filled with fluid or solid, like bone, and encased in unyielding casing like aponeurosis, it tends to explode, on the principle of physics that in a closed vessel, if you run up a tube the pressure on the vessel will be multiplied by the area of the cubic contents of that tube, tending to rend, tear open, and kill everything within it if it is alive. This is what happens when the brain is struck; when the liver is struck. At ranges shorter than 500 yards there is explosive effect. That must be counted with. We are going to see why in the modern weapon it is very much to be counted with. There is another kind of effect produced by a bullet over 1,500 yards where it commences to wobble or turn over; it hits butt on or sideways; there the wound is one like a shell wound, a piece of shell; it tears; laceration and contusion is here the rule—fracture of bones by contact rather than by comminution. Make a distinction between that and explosive effect. The two are very frequently confounded. Now I wish to ask you to remember that there is a little example which I like quite well in speaking of the effect of these high-power bullets, likening the bullet to a top. Throw a top on the floor and give it a spin. There is a brief time when the top trembles before it settles down to a steady spin, and just before it ceases spinning it wobbles, topples over, falls; and that is the way to look upon the matter of range of these missiles. For a short while after it leaves the mouth of the gun it wobbles. Now that wobbling movement will kill tissue for a great distance on either side of the tract. It

is molecular energy which is easily communicated to tissue cells for quite a distance and kills them; and later on the last wobble is simply to take away from the missile the property of entering as a dagger or stiletto. So in general the wounds produced by the high-power, high-velocity bullet are those which are preeminently puncturous at usual ranges and explosive when these ranges are reduced below 500 yards.

In order to increase the damage done by this bullet—which was a humane bullet, the Boers are said to have deformed these bullets and I personally have seen bullets deformed by the Germans. They have been created into dum dum bullets simply by removing the nickel jacket, exposing the lead or iron, or by taking out the bullet from the cartridge and inserting them again point first. In that case as soon as the bullet strikes it herniates and a very bad bruising is produced. But the point of all these bullets—shrapnel bullets and the low power—is that they were smooth, blunt, or sharp projectiles, but they were always smooth, in general.

Now there was even less tendency of the high-velocity bullet to carry in clothing than the bullet of the Civil War; with this sharp point it slipped in between fibers and didn't carry clothing in, ordinarily; it always carried in germs; neither the heat developed at the time of leaving the gun nor the speed through the air sterilizes it as was formerly and fondly believed; but what happened was that it did not cause very much damage to the tissue except at the point where it went in and there were not enough microorganisms carried in with them that they could not have overcome by nature's own forces; the local shock was not great enough to take away the very resistance, the local resistance of the tissues. The result is that these wounds were very promptly observed to be very much better wounds than the old wounds of the Civil War. There was not so much rending, bruising, they could be held down better by proper treatment, and very soon it became a dictum in our Army that all you had to do was to apply a first-aid bandage, a first-aid dressing, to one of these wounds and you need not worry about them at all. In other words, if a man wasn't killed he would surely get well; if he wasn't hit in some vital place he would get well; and people began to talk about it as a humane bullet and the profession began to insist on teaching all the soldiers how to put their first-aid dressing, and bye and bye, in a very short while the very Army became infiltrated with the idea that military surgery was a thing of the past; didn't have to worry much about it, all you needed was to put on a first-aid dressing—and you knew as much about that as a doctor—and give nature a chance. That was all very nice, but that had a great effect, as these things always do, on the Army.

Now, we are coming to something that I think is quite important. You know military surgery has always been the Greek slave of military necessity. Just mark what I say. At that time they always closed up all argument by saying, "It is military necessity." Now those fellows didn't realize there are military necessities of various kinds and nowadays surgery is no longer the Greek slave of military necessity, but sitting in high council with us she has got to be subjected to military necessity. We will explain how that is better later on. But, be that as it may, in those days the men who didn't care to use the Medical Corps of the Army were allowed too much to say "We don't need so many doctors; we don't need so many Hospital Corps men; we know as much about it as you do. These things are common knowledge; they have become part of our body politic. We know how to care for our own wounds; each man carry a packet and every man his own doctor." This is a fact. I remember it very well because I went into a war myself 20 years ago with that attitude; that idea in the back of every line officer's head. But the whole story had not yet been told. We were just fooling with the humane bullet those days. It was true as far as it went. The first-aid packet did do the trick for the majority of them very nicely; but then there were little foolish things like splints to be put on, compound fractures of the thigh, and bullet wounds of the skull to be treated—just little troubles like that that still existed; and at Santiago they had it brought back to them that a demand for a medical corps was still left, still needed, and that wars couldn't be won without it.

Now we come to the wounds produced in this last invasion of Europe by the Hun; and he is the same old Hun. Now just think for a moment what this war really is and what this fellow is trying to do. We went through this area that he has just besmeared; saw every one of those pretty little villages torn limb from limb, and not a house that was not wrecked. Every house that hadn't been hit enough from our own shells was blown up from the inside by

dynamite, soaked with mustard gas; fruit trees cut down; everything torn up. His aim was to destroy everything. He destroyed homes, hopes, morale, and morals—everything was to be destroyed. Now let us get down and look scientifically at the wounds this fellow makes. He has used gas; he prepared to use gas in 1914 and there is plenty of evidence that gas shells were being manufactured in 1911; some of those shells used to come over against us. When you get down to his high-explosive wound there it is that you really see that he is trying to do to the human body just exactly what he has done to villages, to homes, to that wife or that child—destruction absolute. The aim of the Hun to-day is to cut in and then blast out everything—destroy, not only where he has been but as far from him as possible. It is not only what the missile does in passing in, but it is the influence of that missile on the surrounding tissue; and nowadays you see the shell of a body, the shell of a leg, the shell of an arm, when you used to see simply a hole in the arm, a hole in the leg, because he aims to make all of his wounds explosive wounds. Now, how does he do it? He does it by the high-explosive shell. The high explosive is a devilish thing and produces a great many wounds. Leeceno told me he had seen 200 wounds produced by the grenade on one man. He does it by means of the high-velocity shell—tremendous charge of high explosive, that at 50 yards has the same explosive effect that the bullet will have, and that is the distance at which men are generally hit—50 yards. Of course, they are hit at greater distances, but it is the general thing that if a man gets 150 yards away he generally escapes, but at 50 yards the thing he gets is a piece of shell that cuts just exactly like an explosive bullet. And most of the shell wounds that we see are those. They come in at tremendous velocity and here is where they differ from all the other wounds and weapons that we have considered before; they are irregular, and at some portion they are cutting, at some portion there is an edge as sharp as a razor. Now that thing goes hurtling through into your flesh. Its irregularity will soon bring it to a stop; they are very frequently lodged. But it is hell the way it tears things to pieces. It will go through skin somewhat smaller than itself; it gets to the subcutaneous tissue and it makes a hole somewhat larger than itself, plus the tearing of vessels and the production of hematoma; it sheds off a few particles of cloth and plunges through the aponeurosis, making a hole its own size, and that aponeurosis is shredded. It then has gained the muscle which the aponeurosis covers. Of high velocity, the effect is to explode it, and here it is the high-power shell fragment does its greatest damage. The little fibers are burst and if they are not killed they are devitalized to the extent that they will die by the lack of blood supplied by the same injury, the stunning. You have the tearing of vessels here, the outpouring of blood at a great distance from the tract, so that the fibers are separated by blood clots, the circulation ceases, the roads of communication are blocked, and the situation on a battle field is created right there up to a certain point. There is no passage of blood, nutrition fails; the shattered, stunned, half-dead muscle dies from lack of food in the next few hours, and you have an organ which furnishes an ideal culture media for bacteria which are not, ordinarily, pathogenic, but which are saprophytes and feed on dead material. Now bear that in mind from to-day to to-morrow To-morrow we take up that very thing. But it is the shocking that produces material that ordinarily would do nothing if injected into healthy flesh. Reaching the bone, if it has got enough kick in it, and it probably will have, it will perforate two-thirds of the bone, passing through the marrow, and blow out the last third, breaking the bone into little bits which act as secondary missiles, making an ever-increasing dispersion. Now, here you see we have all the bad qualities of the missiles that have been used in war, plus another one which we never counted on before, namely, the sudden explosive effect—which is present only exceptionally at short ranges and only in the high-velocity bullets, and the cutting or nipping of large nerves and vessels. That is a very important thing indeed. If there is one thing more than another which is coming out of this war it is that this cutting effect has increased very much the wounds of vessels and the wounds of nerves. They are much more frequent than they used to be.

I heard no less an authority than General Ruotto, who was chief surgeon at Salonika so long, and in addition an authority on vascular surgery in the army, make the astounding statement that every wound, practically, of a vessel became a traumatic aneurism; I couldn't believe it. Leeceno, on the other hand, made the very remarkable statement that it was the majority of nerve injuries that caused paralysis, etc., where a combination of two things

always, however, happened. One was the molecular stunning or death of the axis cylinders above and below the point where it was struck or shocked by the missile, simply by the extension of these molecular vibrations. That is to say, the majority were due to the fact that the missile passed near them but didn't hit them, and up-down axis cylinders were killed—some surviving but most not; and there we get the partial paralysis following war wounds. Leceno states further in his lectures on the brain and wounds of the skull that in this war we are getting little tiny pieces of missile, very sharp, that enter the brain that don't carry in infection with them at all. They go hurtling through the brain tissue and will nip important nerve paths and produce what the experimental physiologists would like to produce in order to prove some point in physiology. In other words, there are some remarkable actions on certain paths in the brain that will explain some of the effects of a war wound of the brain. General Wallace calls attention to the fact that one of the most peculiar effects—and our own Pool, at Evacuation Hospital No. 1, corroborates it—that the most peculiar effects of war wounds were seen in wounds of the abdomen, where men have not apparently been wounded at all and yet will give the clinical signs of perforation of the intestines. Brewer mentioned that in one of his lectures. The man looked perfectly all right; he stripped him, couldn't find any wound at all; he was forced to conclude he had a rupture of the appendix. He operated and went all over his intestines until, just by accident, he thought he heard a little sound of gas escaping and found a tiny wound of the intestines, through which a tiny sliver of shell had passed, which made a pin-point opening in the intestine, and out of this came gas. So you see these shell wounds are doing some things that we really hadn't anticipated.

Now, what has happened? They cuss us in the line, saying: "You fellows are all the time changing"; and the reason why we are doing this is to keep up with them. They are changing the drinks on us; they are using new and different kinds of high-explosive shells, and it is only natural that surgery in war is changing because of the effect on the tissues when we get a new deal.

Grenades usually wound at 40 yards. These wounds are most frequently of the lower extremity, where shrapnel would be of the head and shoulders. Look out for wounds of the buttocks, because wounds of the buttocks in this war are often also wounds of the intestine. They go up through the buttocks, through the pelvis, and cause many of the severe intraabdominal wounds. Avion bombs, of course, produce things more like a railway accident than anything else. Those who are near enough generally are not in position to need any surgery.

I mentioned the wound of the bullet and shrapnel. Be careful always to consider that wounds around the shoulders are apt to be found to go through the intestine down into the abdominal cavity; that is to say, thoracic peritoneal wounds are very common, far more than what they used to be. Now, of all things remember something that a man had the courage to say to our class at the French front. "It is true that the element of infection comes from clothing and only from clothing, practically. It is the cloth that is blown in that causes infection usually." To-morrow we are going to talk about how the laws of biology will govern the development of germs in these wounds, just exactly like the crops. You have certain crops in the spring and others in the fall. Now, no matter what antiseptics you use, in some measure crops are going to come on if the wounds are at all infected. Clothing is, of course, heavily infected with the spores of anaerobic bacteria and are constantly being invaded from the soil by anaerobes, intestinal bacteria. We are fighting over a country that has received the contents of the intestinal canal of men and animals for many centuries. In fact, we have had scientists that wish to prove just exactly how many centimeters of the outer crust of Europe is feces, and the per cent of feces it contains. Well it contains enough, and the clothing, of course, is the chief source of infection. We have been told that is practically the only one. Of course, it can not be the only one, but it certainly must be the chief one, because the high-velocity bullet that used to wound us didn't produce infection ordinarily, and the shell piece that carries in the clothing does produce infection, and wherever clothing is carried in there is infection unless it is taken out; if it is large enough, unless you take away the food for the germs that it carries in with it. But if you take away the dead and devitalized tissue within 24 hours infection can be prevented. Now,

that one sentence is the exposition of modern surgery as distinguished from the surgery that we used to know years ago. It is recognition of a bacteriologic principle that we have always known, constantly used in research, namely, that if you will provide food for bacteria, these bacteria can be brought to the point where they will live in their new environment. Lecceno considers that 80 per cent of the wounds of trench warfare are due to shell, grenade, and shrapnel—80 per cent. Wallace considers it 85 per cent. Be that as it may, it is pretty universally admitted that it lies between 80 and 85 per cent, the rest being bullet wounds. Now in a war of movement—I am giving you what I have asked in my trips up that way, and I can tell you a rather remarkable story. For instance, I asked down in the Twenty-sixth, "What percentage of bullet wounds are you getting?" They had some 6,000 casualties, and they said, "About 75 per cent machine-gun or rifle and 25 per cent shell." Up at the Thirty-second I asked what kind of wounds they were getting. "About two-thirds shell and one-third bullet." Well, I immediately raised a kick. I said, "You are guessing." They said it depended entirely on the stage of the battle. If the enemy had had time to take up a position he uses shell every time. Every time he can he will use high explosive. He don't like the rifle like we do and he will use the shell. That is what was the matter. The Twenty-sixth got him on the run and he had to shoot back with what he had. He was on the run, he used machine guns—that's what he used generally. When the Thirty-second got him they had reserves and big guns and there it was that our Thirty-second, in trying to get past him, to drive him out, came up against the shells. So it depends entirely on the phase of the battle what kind of a wound you get. It shows you can not answer the questions in a dogmatic way. People ask, "What's the best arrangement for a field hospital?" It depends entirely on what kind of a sector you have.

Now the histopathology of war wounds we will just run over a little bit more because there are a few things to be said which are absolutely vital. The explosive effect in the missile that we spoke about leaves what the French call a "chamber of attrition," and in that chamber of attrition you find clothing, you find bits of skin that have been blown in, and you find pieces of tissue through which the missile has passed, and very often pieces of foreign body, and everything dead and mixed up, and the whole business has liquified by the blood that is pouring in there. Now after the twelfth hour you commence to get the multiplication of microbes and the collection of leucocytes and the transformation of these leucocytes into globules of pus.

I am going to leave the consideration of the bacteriologic portion of this matter until to-morrow. It is such a tremendously important thing that it ought not be mixed up with this. I am speaking about what actually happens to the tissues. Now in that mass of dead stuff and dying stuff, these torn vessels that constitute the numerous lines of communication of our bodies are out, our roads are blocked; their food no longer comes up and the exhausted and dying tissues have every chance of dying outright for lack of food, with the additional shock that is brought them from having their food cut off. You have got to consider that the albumins before they can be gotten rid of when they die have to coagulate, and the way they are gotten rid of naturally, by nature, is by ferments that will render them into their primary molecules. They are made up of groups of aminic acids. These acids of themselves are not toxic. All albumin has to be coagulated before it is normally digested. Examples of that are seen in milk, in the coagulation of blood, and so on. Theseamins, chemically, are crystallizable and dialyzable and are not toxic. They group themselves into polypeptones, and from there on they are built up into albumin through what we call the peptones and proteoses. Now the peptones and proteoses are poisonous, toxic,—not all, but a great many of them; the majority are toxic. Now proteolysis is a term which is used to describe the dissolution of albumins by ferments. It is in the digestion of these coagulated substances that fermentation results in breaking up of the albumin, some of it into aminic acid, but generally it only goes as far as the proteoses and peptones. Then other ferments come on that get rid of the proteoses and peptones. In the meantime they are limited, as toxic substances are escaping by lymph channels and bring about proteose intoxication. That is only necessary to recognize as a cause of fever, a cause of intoxication, which we all thought came from germs. Of course, the blood and the lymph and the muscular tissue are far more easily digested by these ferments than the fibrous tissue and the elastic tissue, which are

quite resistant. These ferments are in the nature of a diastase. These proteolytic substances are more active the sooner you get to 40° C., but you can destroy them at 65° or 70°, and you can very often cause them to suspend their action by simply chilling the tissue. It is supposed that a great deal of the good effect of heliotherapy and hot air is due to the fact that it has effect on the ferments. Now water is always noted for fermentative action and a dry wound is not apt to present much ferments as one in which liquefaction is going on. It is especially active in oxygen free action. Antiseptics have no effect on the proteose at all, as a rule, as some work in acid medium, some in neutral, and some in alkaline.

Now the sources of this diastase. They are generally natural sources. There are four sources; and we are not speaking of a theory, we are speaking of a fact. There are two of these sources that are always cited. They are the so-called autolyses. If you take muscle in perfectly aseptic condition and preserve it, there comes a time when it automatically digests itself because it contains within itself the proteolytic ferments, the autolyses. The autolysis is not very good to produce proteolysis. Then the plasma of the blood in the lymph contains a certain amount. I think a good deal of that comes from the polymorphonuclear leucocytes. They are the real sources of the majority of proteolytic ferments and they are reinforced by microbic action, the anaerobes not the aerobes. The aerobes do not produce much proteolytic ferments, but anaerobes do. Talking now about that enormous influence on digestion of the dead albumins which is exercised by the polymorphonuclear leucocytes, of course you all know the famous contention of ——— and the relative value of phagocytosis. That is recognized to-day by all men and there is no greater exponent of it than Sir Almroth Wright, whom I have the pleasure of knowing personally and with whom I have spent considerable time. I have seen him work in his laboratory and I have seen him work out to my own entire satisfaction the getting of white cells. Wright does not believe in antiseptics. Sir Cuthbert Wallace, the greatest civil surgeon that England has, says that antiseptics have failed, absolutely failed. I am prejudiced in the matter, I acknowledge it frankly, but I feel very strongly on the subject itself. Antiseptics have always seemed to me to cause a considerable amount of harm. But it is a religion with some people. Some people will defend it just as they defend the whole scripture. Sir Wright is a perfect revolutionary; he says what he thinks is right; that's all there is to it. He makes this statement: "White cells being the chief source of proteolytic ferment, the death of white cells being the chief way of liberating these ferments, it is all right at the beginning because it is nature's way of getting rid of dead material. The quickest, natural way of getting rid of dead material is to attract a large number of leucocytes, to kill them and thus liberate an enormous amount of ferments which will dissolve the dead albumin, which will clear the way for healing." That's nature's way. You know the difference between animal and man is that an animal strictly follows all of nature's ways, and man is constantly struggling to overcome nature and to better nature. A great many of us, I believe, have never stopped to think about it, the best way is nature's way. The best way is not nature's way; the difference between man and animal is just that. Now that goes along very well provided in the first place we get enough proteolytic ferments to reduce the albumins. Now the harmless amines, which are soluble and can be easily gotten out of the way, but if we only get them down to the peptones and proteolysis, then we get the intoxication which is not due to infection, and which accounts for the fever which you see coming on 24 hours after the man is hit. You have all seen that.

Now, in the healing of a wound the greatest obstacle is the large amount of pus, a large amount of white cells. It is all right at the beginning to have a large amount if you can get rid of that dead material, but to have it at the tail end of the process you continue the thing for a long time, and you get the long suppurating wounds with the constant septic intoxication, the absorption of which means a proteose. Wright thinks that all antiseptics are bad. He used hypertonic solution to get a large number of white cells, he exerted their degree of resistance and cut down the microorganisms as much as possible and prevented these long suppurations.

The vitality of granulations is in inverse proportion to the number of leucocytes they contain, and they are the cause of the process of granulation. So Policard says to preserve the life of the leucocytes, and they are the cause of the process of granulation; also get full phagocytic effect and prevent their death, which causes the outpouring of destructive pro-

teoses. For that reason he disbelieves in antiseptics. Now the French school has gone the full limit on this, and having the courage of their convictions at Boulouse they used no antiseptics at all—Carrel or anything else—wherein they err, I think. I think they have gone to the other extreme. It is very remarkable that their results are fine, but what they do is this: They have beaten nature by removing that dead tissue and the tissue that is bound to die surgically, and in that way they got rid of a large amount of dead albumin, which is a possible source of proteoses and peptones which will bring about a state of proteose intoxication and which has heretofore been confounded with septic intoxication due to germs, and that is why it is at Boulouse they don't have these septic fevers. They treat all cases surgically; they leave nothing for nature to dissolve away in her clumsy way, producing a large amount of toxic by-products, and what is left is the germ with nothing to feed on. But I believe there is a better way. I believe that when we get wounds not susceptible of primary suture we should use the Carrel-Dakin solution for the reason, with which Policard agrees, that the Carrel-Dakin solution carries leucocytes quite readily. It will dissolve away dead material quicker than any other solution so far known; a chlorine compound, it will dissolve the dead material and you can get rid of necrotic material by the Carrel-Dakin quicker than by any other means. It is constantly washing away bacteria. It oxidizes very readily and falling upon the albumin destroys it. Now the process of nature to control that albuminative process is by means of antiferments, and it has generally been conceded that the fatty acids are the controlling element as far as antiferments are concerned; that the blood contains a certain amount of the fatty acid substances and that they act as antiferments and prevent the proteolysis of albumin normally. It has been observed that gangrenous tissue, for instance, has a considerable amount of fat in it; that it will lie, as it were, without being influenced, not being dissolved. You see a bit in trench foot, for instance, as a great many of us have seen; there is a piece of perfectly dead flesh that is full of grease and fat. The instant it begins to secrete laudable pus it begins to do away with the necrotic material. That means an enormous increase in the white blood cells through death and the liberation of this ferment. The proposition is not settled, but that is the theory. The important message that I want to bring to you is this: That there are a considerable number of men that believe that a large number of so-called septic intoxications that we get are due to the fact that we are harboring dead material, which is turned into poisonous substances which are absorbed and produce part of the intoxication which we have been heretofore interpreting as having been due entirely to germs.

Army Sanitary School No. 160.

THE PREVENTION AND TREATMENT OF VENEREAL DISEASES

By Col. Edward L. Keyes, M. C.

Several members of the section of urology will come and speak to you on various topics relating to our province, which is miscalled urology. For if urology means anything it means surgery of the urinary tract, and that is one of the things which we especially have not done during our stay in France; we have been occupied with venereal diseases and skin diseases. I shall not attempt to exhibit to you my knowledge on the subject of skin diseases because we have in the department several specialists, real dermatologists, who will handle that topic. Also, Major Sanford will be here next week to tell you definitely what is being done in the fighting forces toward the control of venereal and skin diseases. What I want to talk to you about this morning is the management of venereal diseases in the Army. Just now, of course, our whole interest is no longer the winning of the war, and the enthusiasm with which we have talked to some of the previous classes has taken a different slant. Our interest in the Army work just now should be, in some measure at least, a historical one.

The senior consultant in urology, Colonel Young, landed in France early in July, 1917. He went along the British front and observed what they had done in the treatment of venereal and skin diseases; and he went a bit along the French front and saw what they had done. He visited the very large base hospitals that the British devoted to the treatment of venereal diseases, and he was immediately impressed with the number of beds wasted for the treatment of these diseases by both the French and the British Armies.

Many of you perhaps realize how great the shortage of beds has been at various times during the past summer, and you perhaps realize that it was apparent if this war kept on we should need two, three, or four times as many hospital beds as we have at the present time. Now, on the English standard, it was proposed that there should be about 10,000 venereal beds per 1,000,000 men; so that we should have had about 20,000 venereal beds if we had 2,000,000 men over here, which was the number we expected this winter. Obviously that was a great wastage of hospital beds for patients who did not particularly need them; they do not, generally speaking, need to lie in bed at all; they don't in civil life. So it seemed a great wastage to put them in hospitals as the British, French, and Germans have done.

In the second place, Colonel Young was impressed with the fact that by putting a man in hospital when he got venereal disease you gave him a very good reason for getting infected. If he was in the line and exposed to fire he had only to get a dose of gonorrhea and get back to a comfortable hospital in the rear and spend many weeks in peace and quiet. It put a premium on self-inflicted venereal disease. There are two ways of doing this: The men may pass the pus from one urethra to another in the trenches, or they may cohabit with women who can guarantee to pass them gonorrhea. That is alleged of one of the towns at home and of several here. In a certain French city it is said that the women get twice the usual price if they can guarantee venereal disease. They do not always make good. Colonel Young was impressed with the shirking possible from self-inflicted venereal disease. The British told me it did not assume any importance in any of their armies. Whether they know how important it is remains of course, a question. However, taking these two basic principles, hospital beds wasted and men shirking duty by means of venereal disease, Colonel Young devised a theory which was expounded in a book which was published by the department last spring, that all venereal cases should be treated in their organizations. This book, the *Manual of Military Urology*, can be gotten from the Medical Supply Depot No. 3 by applying through the regular channels. The theory was that the man should be treated, each in his own organization, by his own organization surgeon. That theory has worked well in the Services of Supply. In the fighting lines it was soon discovered to be impracticable. Those of you who have been in the line realize why. The units are sobroken up, the men are so frequently separated from the main body of their unit, their surgeon, etc., that even were it possible to have the physical facilities to treat the disease in the trenches you couldn't get at the man to treat him. It proved impossible. As a compromise the divisional venereals were therefore collected in a venereal labor camp, usually situated at a field hospital. Major Sanford will describe to you in a subsequent lecture the nature of these camps.

But we had difficulty not only with the men in the fighting divisions, but also with the replacements. A division, as you know, is made up not only of the men in it but is constantly being resupplied with large numbers of men in order to replace those fallen in battle or who come down sick. These men are supplied by the depot divisions; and if venereals in line divisions are detached to labor camps, as they are called, it is sheer waste to send up new venereals from the depots. So venereal camps were established in the depot divisions. Moreover, had the fighting continued we should have been obliged to establish army camps for the evacuation of venereals from divisions actually in the fighting. An order for the establishment of these had just been issued when the war came to an end. The details of all this Major Sanford will give you. The depot labor has been working since the end of July in the 1st Depot Division, which handled most of our replacements; and it has worked so well that we can feel that it is perfectly practical. The army labor camp has never yet really functioned. We started with divisional camps, and on account of the slowness of getting orders changed we have only just got the plans of our army labor camps approved, and now the war is stopped. The stoppage of the war was a good thing for us individually, but a bad thing for the organization. So far as we have gotten, therefore, the underlying plan of capturing venereals and preventing their cluttering up the fighting forces is to have divisional labor camps, army labor camps, and replacement division labor camps.

Now let me tell you what I mean by labor camp. The idea of the labor camp is that all venereals who have not got complications of some sort, such as suppurating buboes or swollen testicles, should be kept at work as far as possible. The venereals in civil life keep on working; in army life they can do certain types of work. If you keep them in the trenches or at hard physical work, they will come down with complications that will knock them out for a month or two and you will lose more than you gain. By putting them in labor camps you treat their disease adequately, waste no hospital beds, which ought to be used for sick people, you keep them under military discipline and they are of some use to the army by the work they are able to do.

Take the 1st Depot Division medical labor camp as an example: They are divided into three companies, A, B, and C., in duty status, and a fourth company, D., hospitalized. Company D constitutes about 20 per cent of the men, chiefly acute gonorrheics during the first week or 10 days of their treatment. All patients with complications also go into class D. A, B, and C classes are managed by A class doing full duty, viz, road digging, piling lumber, any work however heavy it may be. B does moderately heavy work except straining work, and C does only light work, such as light kitchen details and policing around the camp; duties that require very little physical effort and very little moving around. If a patient comes in with acute gonorrhea he is put in class D for a few days and treated according to his needs medically. If he shows he is not going to have any complications he is immediately put into class C. He is kept there until his discharge is diminished, and then he is moved up to class B, and when his discharge becomes relatively unimportant he is moved up to class A.

Now in order for the camp to succeed it must be located where there is work to be done. That must be the headquarters of something; at a railhead, at a dump, at a quartermaster headquarters, at an engineer headquarters. The type of work to be done is governed by circumstances. At this first depot the men paint signs, mend roads, pile lumber, and haul things around for the quartermaster. Building coffins was one of the earliest of productive occupations of this camp because they had just got going well when the grippe struck them and they had to supply 20 to 30 coffins a day for the division. The camp treatment of venereals has been extraordinarily satisfactory in that we have not wasted ten or twenty thousand beds and we have been able to exercise a certain disciplinary action over these venereals and keep them at work and not allow them to run down as they would do if they were in hospitals. On the other hand, it may be argued that we are treating a large number of venereals with their organizations, which means we are not treating them well. I am inclined to believe that there is something in that argument. The average regimental surgeon is not interested in venereal diseases. You can hand him books and literature on the subject as much as you please, but he won't bother with them. That is extremely bad for the syphilitics, and a certain number of them have suffered. But even the best hospital care does not guarantee them the cure of gonorrheics. I have studied with some interest the results obtained by the British, who keep their patients there for 6, 8, or 10 weeks, and in one hospital as long as 12 weeks, on the average. But despite this care there is quite a group who spend their time going to hospital and back to the line and back to the hospital again. On the other hand, the results of treatment by regimental surgeons on the whole averages extremely good. Complications are few because the treatment is simple.

As I said in the beginning, much the most important thing is the plan of prevention, and first of all let me give you a few words about what you have heard so much about, and seen so much of—the prophylactic station. The United States Army and Navy were the first in the field with venereal prophylaxis, which was officially recognized in the Army in 1912. During the past year both the British and French Armies have introduced it; but without any penalties attached; therefore, one may well doubt whether it will prove effective among our Allies.

The results of prophylaxis in the American Expeditionary Forces are excellent. At Bordeaux they have kept larger records than anywhere else—they have run up to 150,000 at the present time. That covers a little over a year and they have less than 2 per cent of failures among those 150,000 taken, regardless of the time at which the prophylaxis was taken, that is to say, 1.7 per cent of these 150,000 men have had venereal disease following prophylaxis.

laxis. It is presumed—the presumption is a little indefinite—but it is presumed that the average prospect of getting venereal disease for a soldier who exposed himself is about 1 in 10. If that is so, and I think that is a fairly liberal figure, considering the kind of people he picks up, prophylaxis reduces the danger of infection to about one-fifth of what it would be without prophylaxis. Now, of course, if prophylaxis is well given and given early, the results are even better, and some sets of figures covering a few hundred or thousand cases have shown that if prophylaxis is given within one hour, it is certain, as far as one can humanly say, to prevent the disease. Within three hours the percentage of failure is still smaller, and it is only when you get up to seven hours that it runs up to the average failure, meaning that you are not doing the patient any good at all.

But it is extremely difficult to get prophylaxis well given. It is of the greatest importance that you should study the methods of giving prophylaxis that are employed by the men in your outfit. One must go around and look over the prophylaxis station and see whether it is clean and decent and whether the attendant is on the job. Unless you do that the treatment will be badly given. There are two ways to give it badly: One is to give it so it won't do medically what it is meant to do, the other is to give it in such a fashion as to persuade the man never to come back for another prophylaxis. Let me take the second one first. Your prophylaxis station should be a somewhat decent spot; it shouldn't be the dirtiest hole in the camp; it should be policed as well as may be, and some effort should be made to have the materials and system of arrangement in running such that the man in charge of the giving of the prophylaxis shall take some pride in it. There are two ways of achieving this: One is to inspect frequently, and the other is to make the attendant a professor in the giving of prophylaxis; and see to it that all the Medical Corps men are taught how to give prophylaxis. In that way he will develop a very natural pride in the method of doing it, and then when his turn comes to let up and some one else takes charge of the prophylaxis station the job can be handed down and the men will take some pride in both getting the medical effect and not hurting the patients. A man can be considerably hurt by the protargol injection. Sometimes it will hurt them. Some men faint. A little discretion on the part of your men will bring you back a good crop of men for further prophylaxis who might not otherwise come back.

Now as to the medical side of the prophylaxis, there are several points that are worthy of consideration. The most notable one is that the way you get your hands clean is by washing them with soap and water. As soon as anybody's mind turns to medical things, they run to antiseptics and away from soap and water. Now the way to clean off a man's penis after cohabitation with an uncertain female is to wash it with soap and water. I am rather a partisan to ablutions in whisky to prevent venereal disease. It has been employed by many people who are experienced in that matter, for a number of years, to my certain knowledge. Fifty per cent alcohol is a fair antiseptic and that's about what whisky is, and I should say that if a man were to use soap and water immediately after cohabitation and follow it with a douche of whisky—brandy in this country—that he probably would keep himself free from venereal disease. However, you can't trust prophylaxis to the man himself. Prophylaxis, I believe, is going to fail in the British Army because they entrust it to the man himself. They hand out the materials and tell him to use it himself. That won't work. It is hard enough to have it done right when it is done at the prophylaxis station where the men are specially trained. You should always include the washing in soap and water as the first step, because, if for no other reason, the patient is very likely to develop chancreoid and syphilis. We have record of a number of epidemics of chancreoid, so-called, chancreoid complicated by syphilis; several epidemics have broken out in men who have taken prophylaxis well and early, and in each instance it was given without a preliminary washing with soap and water. Now all these things you can find much better put out in the appendices of the Manual of Military Urology, where methods of good prophylaxis are described, but I feel it worth while to go over with you because we have found that venereal diseases are much neglected and so are the prophylaxis stations neglected. There is one thing more about prophylaxis stations. The best thing I can tell you is this: That while we are not ambitious to have the greatest number of prophylaxis given, yet if the station doesn't do enough work to keep the men in practice they will give rotten prophylaxis. If the sergeant is reading the *la Vie Parisienne* six days a week and gives prophylaxis only one day a week he won't do

good work; on the other hand, if you are running 250 a day as in Bordeaux and Paris, the prophylaxis is extremely well given. Endeavor should be made to have it run in such a way that it will do the greatest possible business.

I think I have time to speak of one more thing, and that is the lectures to the men, which after all is the only other strictly military thing I am going to speak of. I don't speak of courts-martial, and so forth; as to lecturing to the men, I quite agree with a good many that there are two sides to the question of lecturing men on the subject of venereal disease, and I quite agree that certain lectures probably do more harm than good. At the same time, I think it is wise; it is necessary—it is ordered in general orders, it is also wise—that some effort should be made to get the men properly informed as to the dangers that they run in having intercourse with casual females. I don't think there is any harm in presenting them with information; I do think that the harm comes in when the man who lectures permits his own individuality to get away with him and then proceeds to talk on morals which the doughboy is entirely unable to comprehend, or else who tries to throw the fear of venereal diseases too strongly into the men. It is not at all clear to me that the average medical man gives a good lecture on venereal diseases to the average nonmedical audience. We are inclined to go formally through the various symptoms of the three principal venereal diseases and leave an impression upon the minds of the men that we think that if they get venereal disease they will have all those symptoms. On the other hand, these fellows know a thing or two and they know a good many men who have had the clap and who presented a singularly healthy appearance and are able to enjoy life pretty much as the rest of the world does, and they are very likely to get the impression that you are trying to "throw the bull" at them when they contrast the known facts with what a man says when he tries to scare them too much with venereal disease. You can not keep the men afraid of the boche; and you can not keep them afraid of venereal disease. The men that they know who have venereal disease will not correspond with the impression they get from the lectures from the officers who try to scare them. You will scare a certain portion of the men and they are the men who know they have syphilis, and others (which is far worse) the men who think they have syphilis; and if you depict the horrors of gonorrhea they will pester you as you deserve; so don't lay it on too thick. But plainly state to the men that they should use prophylaxis and not run the risk; I think you should plainly set that before them.

The final point I think comes up in the minds of many men: Why not issue condoms to the men and let it go at that? Well, because like everything else human, it doesn't work. The New Zealanders and, I believe, the Australians issue condoms in their army. When I was with them I was very interested and talked to the sergeants. They are the people in the army who know what is going on. I talked to the men in charge of the prophylaxis stations and inquired what they learned as a result of their various methods. They handed out a packet very much like the officers' packet—a little collapsible tube of calomel with camphor and carbolic acid in it. As you know, these used to be handed out in the Navy, and the result was that the boys played craps for them and the winner went on shore and sold them to a druggist. The passing out of condoms to the New Zealanders and Australians, if you can judge from what a sergeant in charge of these stations told me—when I got them separated from the officer—was that about half the men used the condoms and half didn't, because they didn't think that that was the way to play the game. A large proportion won't use them. But in the meantime it doesn't cover the question, and I confess myself frankly opposed to the proposition of giving condoms to the men, because I don't think you should hand them out a license to cohabit, and the condom pretends to represent an absolute guarantee. If you give him a condom you will separate him from the idea of coming in for prophylaxis. On the other hand, I think from my civil practice before the war, from what I have seen in the Army, that the giving of prophylaxis treatment is far safer than the condoms. Our system is not yet perfect; it will be improved in some of its details. But what it most needs everywhere in the American Expeditionary Forces is for the medical man to take the trouble to see that he has a prophylaxis station that he doesn't have to be ashamed of, and see that he has a man running the station who is not a congenital moron and who is somewhat interested in making the thing work right.

Army Sanitary School No. 161.

THE FIELD HOSPITAL IN CAMPAIGN

By Major Spear, M. C., December 4, 1918

I did not know until yesterday that I was expected to come down here and say anything. This isn't going to be a lecture; I am just going to tell you, in as good form as I can, what we had to contend with and what we did.

When we came over we were filled up with M. M. D. ideas. I came over here myself in an advance school detachment presumably to come to this school. I landed in Brest, stayed there three weeks and got orders to rejoin the division; so I did not have a chance to come here. The night that I rejoined the division the sanitary train had also gotten in and we went right to work. We thought, of course, that we were going into field hospital work and have nothing but field hospital work to do. We went into the Toul sector. Two hospitals took over base hospitals. They were field hospitals by name, but they were acting as base hospitals; and two other field hospitals really went into the field hospital work. I don't know whether any of this class has gone up to the Toul sector and has seen any of these hospitals up there?

The CLASS. No, sir.

Major SPEAR. When we were up there they brought two or three detachments from this school up there.

Well, one hospital took over, as I say, a base hospital in Toul and handled all the sick of the division. The other hospital in Toul handled all contagious cases. One hospital was on one half of our sector acting as triage or sifting station; the other hospital was on the left half of the sector acting as triage. Triage work consists in sifting of all cases. There the gassed cases are given preliminary treatment—held if necessary, or evacuated if they are so severe as to make evacuation dangerous. Wounded are redressed if necessary and immediately evacuated. That worked very well when we were in a quiet sector, getting not over 15 or 20 wounded in a day and perhaps 3 or 4 gassed cases. Many a day we didn't get any gas cases and there have been a few days when we didn't get any wounded. The organization at those times worked very well. Everyone could do just exactly what he was supposed to do, and the evacuations went along without any trouble. There were always three or four ambulances there ready to evacuate one patient if necessary.

The organization of the triage in this sector had been perfected by the field hospitals of the 26th Division. We had quite a bit of our work mapped out and perfected for us when we took over. The situation was ideal. The ambulances could come right in, unload at the receiving and forwarding station, and drive around in a circle and go out. The evacuation ambulances were splendid, and all they had to do was to drive right up to the receiving and forwarding station, get their load, and go out another way. There were no crossed roads; the evacuation to the rear and the incoming patients from the front never bumped into one another, you might say. Everything was mapped out ideally for a triage, and that is what you must have to facilitate your work; you must have an incoming road and an outgoing way for your patients coming from the front; you must have a place to evacuate that does not in any way interfere with the other route, because if you do and you get into a push you are going to get so congested in a short while that you can't handle it. The only push that that triage got into the whole time we were in the Toul sector was on the 8th of August when the Eighty-ninth took over the Eighty-second. The Eighty-ninth ran into a bunch of gas, and they were severely gassed men, who were coughing up practically casts of their bronchii; their eyes were severely burned; they had splash burns all over the body. The least severely gassed of the whole bunch was as badly gassed as any that I saw in the St. Mihiel and the Argonne drives. In 20 hours we put through there, in that triage, seven hundred and thirty and some cases of severely gassed. They were all washed—undressed first—treated, and evacuated; every one of those cases but 16 who were so severely gassed that they had to remain at the hospital. This was only possible because of the way the triage was situated. There was no congestion; if there had been it would have been impossible to handle it. The organization of the triage in the gas department consisted of, first, the commanding officer having, of course, charge of everything; one noncommissioned officer

in charge of the washroom; one noncommissioned officer in charge of three wards; and another noncommissioned officer in charge of three more wards. Luckily we had in our two hospitals acting as base hospitals some female nurses, and when we got into this push we took these female nurses up and had them assist in the treatment, especially the eye treatment of these patients. Otherwise, the personnel of a field hospital would have been so far below the number required that it could not have been handled, and we were helped out on that by one of the 89th Division hospitals that was there ready to take over our hospital. The only thing that helped, or the only thing that let us get rid of that number of patients in that short time, was the organization and the system of outlet and inlet—no bumping into one another.

In Toul the sick hospital and the contagious hospital, acting as base hospitals, took care of, at times, 600 and oftentimes more patients at one time. Here we were pretty well stumped lots of times with only the personnel—6 officers, and sometimes we had only 4 or 5 and oftentimes less, and the number of personnel sometimes down as low as 60 men. It was a proposition, but they were things that a field hospital is liable to have to handle. What was the average, Captain Flagler, of that field hospital?

Captain FLAGLER. We took it over with 400 and got it down to 200 by evacuation; and it was 630 when we turned it over, on account of the gas.

Major SPEAR. That was the way we had it in those two field hospitals; from 200 to 630. It was absolutely beyond field hospital work, but we were put in there and we had to do the work, because the base hospitals were not completed in this region at the time; there was nowhere to send them and it was a thing that had to be taken care of and there was nothing else to do but do the best we could, and all this was done when we were in a quiet sector—very quiet as I say. Oftentimes no wounded would come in during the day, or may be we would get only one with an accidental wound, a hand grenade went off in his hand and may be injured him or some one near him—nothing serious. The average there was around 15 to 20 a day—not over that.

Then as to our equipment: We came over with our field hospital equipment minus our tentage. When we took over these hospitals everything was there; the beds were there in the triage; we had Bessonneau tents and a large airplane hangar. There were beds, sheets, pillows, mattresses, bedpans, urinals—everything that was necessary for the treatment of patients. In the base hospitals that we ran there were, of course, beds, mattresses, and in the officer's ward we had 40 beds for officers with bedspreads, and so forth, and everything was there to do it with.

Then from the Toul sector we went into the Pont-a-Mousson sector; our division held the Pont-a-Mousson end in the St. Mihiel drive. There one field hospital acted as a triage again; one acted as a nontransportable hospital; one as a gas hospital; and one as a sick hospital. At the triage the same thing obtained as in the quiet sector. Instead of putting up tentage, we had an old tannery that was nicely divided off into sections, and we selected one for the treatment of surgical cases, one for the treatment of gassed cases, and one for the treatment of shock. At the triage at this time we had the division orthopedist, the division medical gas officer, and the division psychiatrist. We tried to sift out in every way possible all the cases that came there right at this sifting station. The psychiatrist would take the neurotic cases and send them over straight to the rear into Toul, or he would send them to the sick hospital. The division orthopedist was responsible for the condition of every splint that went out of that triage. The division medical gas officer was responsible for the treatment and the sifting of all the gassed cases. The hospital personnel and the officers of the hospital did all the treatment that was necessary—the changing of dressings, feeding the patients, taking off their clothing, under the supervision of these specialists. At the nontransportable wounded hospital we had an X-ray outfit; for a while we had a surgical team with two female nurses. We were operating in an old French hospital of Adrian huts which were well planned out. We dropped right into an X-ray room; all warm. All we had to do was to take out X-ray apparatus in there and set it up. From the triage all nontransportable wounded were sent there to be operated on—the nontransportable wounded cases, consisting of perforating abdominal wounds, the sucking chest wounds, and all badly shocked cases.

The sick hospital, of course, treated the ordinary sick. The gas hospital treated all the gassed. And right here the gas question comes up. One of the worst things we had to contend with was the differentiation between gassed and malingerers. Right at this time there was not much literature put out by the chief surgeon, A. E. F., as to what to do and what not to do with gassed people. Orders were that if a man came up and said he was gassed he was to be treated as a gassed patient and be treated as a litter patient. That all worked very well in a quiet sector like the Toul sector, but when you have 500 to 600 men to evacuate in 24 hours you can not comply with these things; you have got to use your medical knowledge and differentiate between a man who is slightly gassed and a man who is really gassed and a malingerer. That is all supposed to be handled by the division medical gas officer, but one man can not do it. As a consequence, into your gas hospital get men of all three classes. And when you have a hospital with a capacity of 250 people and you have 500 to 600 sent back in a day you have got to evacuate to the rear, and you have got to evacuate them sitting, because you can't get transportation to evacuate them as litter patients, and it is impossible to comply with the instructions saying that you will hold them for three or four days and differentiate between the gassed and nongassed and then send them back to duty or to the rear, as the case may be. In the Pont-a-Mousson sector we had that very forcibly brought to our attention. We had between 500 and 600 men in there inside of 24 hours. We had to evacuate what came back from the field hospitals, and we evacuated a bunch of men who showed no symptoms whatever. We had to do it to make room in the hospitals for men coming from the front. The next day the division surgeon asked me to come to Toul with him to investigate the matter, and we went there and men from our division were then being evacuated from the gas hospital in Toul on an evacuation train. It had been 36 hours since some of them had been gassed, and some of them had been gassed for 48 hours. When they left our hospital they showed no signs whatever of having been gassed. We had to evacuate them, as I say, to make room for others. When they were walking to the train at the end of that time they were just developing gas symptoms; some were just developing conjunctivitis; some were just developing burns; and that was the class of cases that we had been criticized for sending back. Orders are that you shall keep these men in your division hospital until you can determine whether they are gassed or not; but if you get in a push you can't do it, because you have capacity for only so many and you can only keep that many. You have got to evacuate as fast as you can.

From the Pont-a-Mousson sector we were shifted over into the Argonne. All we had to move was our men, leaving the equipment behind. We moved out and we had a rest of about two days and then the division was ordered into action. We went into action in the Argonne. We had one field hospital complete and tentage for three others, and all that these other three had were a medical and surgical chest, a sterilizing chest, about 25 litters, and 75 blankets. That's all we started into the Argonne with. I got orders to establish a triage one night. At 8 o'clock when I got the orders we had about 15 miles to go and be ready to function the next morning at daylight. We got three or four trucks that were assigned to us loaded and got onto the road. You could move about 100 yards every 15 minutes. But we got up there, got the triage established, and were ready to work about 8.30. and they immediately threw a bunch of cases in on us. All we had to work with was a medical and surgical chest, a sterilizing chest, and some bandages, and the wounded came in by the truck load and ambulance load. The medical supply man immediately got on the job, and it wasn't long before he had enough equipment up there to tide us through. That same day we established a gas hospital alongside the triage, leaving the sick hospital back in the rear. We had, as I say, no equipment with us. If a man came in and had to move his bowels, we gave him a helmet. An official report went in criticizing us for allowing a man to use a helmet to move his bowels, but I think it was a pretty good idea; but one of the corps specialists came in and saw it and put in an official complaint about it. But we had no equipment and that was the best we could do. While we were up there a shell came in and killed 11 men and wounded about a dozen or 15 more. These men were in the kitchen or around it. It came right in the door. The shell was just about spent apparently; that is, the gun was quite a distance off, a long-range gun, and it hit right alongside the field range. We were right at the crossroads; we had orders to be there; and although we complained about it, we had to establish there, and the boche

began shelling the crossroads and hit us. We were near Varennes then; it was just at the beginning of the Argonne drive. While we were up there our equipment was, of course, increased quite a bit. After being there a few days we moved up to Avocourt. As to transportation, we had practically no transportation. In our division we had four G. M. C.'s, four Fords, and two S. S. U. units. We had during the greatest period of activity one evacuation ambulance company having anywhere from 8 to 12 ambulance to help us. Now the personnel. The number of personnel required to run a field hospital is at least 120 if you are going to run it and run it right; you can not run a field hospital with 83 men and get away with the work unless you tire your men to such an extent you can not get any service out of them.

Another thing that must be established to keep your hospitals from filling up is liaison with the rear at all times. If you don't have that it is going to be bad for the patients, bad for every one concerned.

Army Sanitary School No. 163.

GENERAL CONSIDERATIONS OF THE WOUNDS OF WAR

By Col. Joseph A. Blake, M. C.

Wounds of war differ from those usually observed in civil life in that they are produced by missiles traveling at comparatively high velocities. Without entering too far into a theoretical discussion, we may say that the effects produced on the tissues of the body depend chiefly upon the nature and the velocity of the missile.

The principles missiles are rifle balls, shrapnel balls, shell and grenade fragments, to which we must add secondary missiles consisting of various substances to which velocity has been imparted by the impact or explosion of the first named. This latter group comprises fragments of stone, wood, accouterment, or of bone.

The effects produced by rifle balls are exceedingly diverse and depend not only upon their velocity but upon whether they strike on end or are tumbling, whether they are deformed or not, and also upon the nature of the tissues on which their energy is expended. For instance, we know that a rifle ball at certain velocities may pass entirely through a limb or the body with a minimum destruction of tissue. In such cases the wound of entrance and exit are both small and punctate, no more injury being done than if a sharp-pointed skewer had trans-fixed the parts. When traveling at a still lower velocity they may become lodged. At higher velocities they often produce the so-called explosive effects, which is largely due to the spattering of the ball, the shattering of bone, and the imparting of its energy to the fragments of the latter, thus producing secondary missiles. True explosive effects are observed in wounds of the cranium. An undeformed rifle ball seldom entrains clothing or other foreign substances, and the seriousness of the wounds caused by it depends almost entirely upon the amount of tissue destruction. As a rule, rifle balls remain in the tissues without causing irritation.

Shrapnel balls possess some of the characteristics of rifle balls traveling at low velocity. They are often lodged—the wounds of entrance are small and as a rule they do not entrain infected materials, and therefore, if an operation for their removal is likely to be serious they may be allowed to remain in the tissues.

Almost every variety of wound may be caused by shell, the character depending largely upon the size of the fragments, for their velocity is generally low. The great seriousness of these wounds is due to the fact that the fragments of shell usually punch out portions of the clothing corresponding exactly in shape and size to the striking side of the fragment. If the fragment lodges, then clothing usually remains attached to it; if the fragment passes through, portions of the clothing are as a rule detached and remain in the tissue. As the clothing contains all sorts of bacteria and particularly those indigenous to the soil, a more efficient method of infection could hardly be imagined. In this connection it may be mentioned that it has been noticed, at least in the British Army, that in recent fighting over devastated country the incidence of gas gangrene was much less than was the case when the soil was under cultivation and full of anaerobic germs.

A grenade bursts into very small fragments and the seriousness of the wounds produced by them lies in their multiplicity rather than their size. Each fragment may carry in its

little piece of clothing and consequently the body may be peppered with little foci of infection. It is practically impossible to operate on all the minute wounds, possible a hundred or more, and not infrequently death results after some days from general infection.

Let us now consider in somewhat greater detail the effects produced by missiles on the tissues. The skin may be perforated; portions of it may be punched out and carried in, or torn away, or large flaps may be raised. The point to bear in mind is that only the edges and fringes are devitalized, and therefore it is unnecessary to sacrifice more than these when operating.

The injuries to the muscles possess the greatest pathological significance. As has already been noted, the effects of the missiles are various. Usually the muscles are torn, shredded, or pulped, and portions are detached from their vessels. This dead or devitalized muscle tissue is the breeding ground par excellence for bacteria, particularly the anaerobes, and the successful treatment of war wounds is based upon its surgical removal.

Nerves, and to a less degree blood vessels, present more resistance to explosive effects, and frequently a nerve is found practically intact passing across a cavity or through a mass of pulped muscles.

The effects produced by missiles on bones are extremely diverse, depending upon the nature of the missile, its velocity, and upon the character of the bone itself. Wounds of the diaphyses differ from those of the epiphyses on account of the difference in the architecture of the bone. The effects on the diaphyses depend also upon strains set up by the muscles at the moment of impact, as well as by the nodes of vibration. I have under observation at the present time a transverse fracture of the femur above its middle caused by a bullet which made a clean hole through the lower third of the shaft.

Passing by an interminable discussion of the various lesions that may be produced, I wish to call your attention to some points which are of the greatest clinical importance. Firstly, in regard to diaphyseal fractures, is the distinction first made, I believe, by Leriche, between fractures by contact and by penetration or perforation. In the fracture by contact the missile stops at the surface of the bone and consequently no infectious material is carried into the medullary cavity. On the other hand, in the fracture by penetration or perforation, the missile lodges in the medulla, or in passing across it may leave portions of its burden of infectious material which has been torn away by the sharp irregular fragments of bone. It is evident that in the treatment of the fracture by contact no exploration of the fracture is necessary, while in that by penetration or perforation it is imperative. The second point is in regard to the lesions produced by missiles to cancellous bone which forms the epiphyses of the long bones and the carpal and tarsal bones. While extensive fragmentation of cancellous tissue may be caused, I wish to draw your attention more particularly to the small punctured wounds frequently produced by small shell fragments. These at first sight appear almost negligible, yet they are often the most dangerous and refractory bone lesions we meet with for the following reasons: The path of the missile is commonly closed by the elasticity of the shell of the bone, which folds in and springs back; the tract is as a rule infected; in addition hemorrhagic areas are produced throughout tissue which form areas of diminished resistance and later foci of suppuration. Consequently, those wounds are apt to lead to interminable suppuration and to infection of contiguous joints. To prevent such disastrous results, it is necessary to find and remove the entire tract with the missile, which is generally a difficult operation and one entailing much greater sacrifice of bone than would seem justifiable; especially as the defects thus produced are repaired by connective tissue and only slightly by ingrowth of bone. It is better, sometimes, to resect articulations rather than be satisfied with partial removal of devitalized and infected cancellous bone. The decision as to what should be done requires experience and judgment. It is as wrong to denounce all resections and excisions as it is to practice them too generally.

Let us now consider the principles upon which the treatment of war wounds is based. They are as follows:

First. The elimination of contamination before infection becomes established. Contamination becomes infection as soon as the bacteria commence to pullulate and extend throughout the wound, which requires about 8 hours for the anaerobes and about 12 hours for the pyogenic cocci. Operations should therefore be done before the expiration of 8 hours in

order to be consistently successful. But it has been found, especially recently, that very many operations are successful as far as wound healing is concerned at much later periods, even when 36 to 48 hours have elapsed. These late successes lead one to believe that the next principle to be enunciated possesses a greater importance than hitherto believed. This second principle is the elimination of the pabulum for the bacteria. This should be accomplished by the operation and consists, as we shall see later, when we come to consider the technique, in the complete removal of all dead and devitalized tissues, leaving the wound as if it had been made by the stroke of a clean sharp scalpel.

If through lack of skill, or for anatomical reasons, this procedure has been imperfect, we call to our aid chemical or physiological substances which dissolve or hasten the elimination of this bacterial food and sometimes destroy the bacteria themselves; such as the various antiseptic fluids and more particularly the hypochlorites.

Third, and very important, is the principle that we have all been taught, but are apt to forget, and that is, the elimination of pockets and dead spaces in which bacterial food may reaccumulate; and, if we can not eliminate them, the installation of efficient drainage.

In addition to the principles already enumerated the following must be mentioned, which are in the line of conservation rather than that of direct wound treatment. These are:

First. Prevention of augmentation of injury, which is accomplished by proper transport splinting and in which the essential underlying principle is traction, as exemplified in the Thomas splint.

Second. Restitution of structure and form, as, for instance, the reduction of fractures and the suture of muscles, tendons, ligaments, synovia, nerves, and in general all plastic operations.

Third. Retention of form, as accomplished by splints, traction, etc.

Fourth. Maintenance of function, such as is accomplished by the methods of suspension combined with traction that have been perfected during the war.

Fifth. Restoration of function, as is obtained by nerve and tendon operations and by proper exercises and massage.

A résumé in chronological sequence of the steps in the treatment of a wounded man would be:

First. Splinting for evacuation from the battle field.

Second. The primary operation, which includes elimination of contamination; that is, removal of foreign material, elimination of pabulum for bacteria that is dead and devitalized tissue, and, lastly, restitution of structure when possible.

Third. The aftertreatment, which includes retention of form, the use of chemical solvents and bactericides when necessary, secondary suture when needed, and, finally restoration of function.

Before entering upon a detailed description of the application of all the principles I have enunciated, for one's time is limited, I shall touch upon some of the later developments in the preventive treatment of infection. The preventive treatment of tetanus is familiar to all of you, but some of you may not be aware of its limitations. The protection afforded by a dose of antitoxin lasts apparently only from 10 to 14 days, hence the necessity of repeating the dose within that time, and also before any later operative intervention which may open fresh channels for absorption, the tetanus bacillus commonly remaining in wounds for many weeks. In fact, the slight traumatism caused by roughly handling a fracture may be sufficient to provoke the disease. Many cases of late tetanus are not recognized. Within the past week one came under my observation which had been evacuated a day's journey by automobile, although the symptoms had been present for at least a week. As ordinarily observed in such cases, the disease first manifests itself by local contractions in the fractured limb (for usually there is a fracture), which often are present for some time before the more characteristic ones appear. The treatment of those cases is after a sensitizing dose of antitoxin to give large doses, in the neighborhood of 100,000 units in the 24 hours, most of it intramuscularly. Happily most of these cases recover.

Exceedingly encouraging reports are coming in in regard to the preventive treatment of gas gangrene by the use of antisera. In the early part of this year the antitoxic serum developed by Bull at the Rockefeller Institute was given a trial in the British Army but the data collected were insufficient to prove its efficacy. Later an extended comparative trial was

instituted in the same army. A double antitoxic serum was prepared against the *Bacillus aerogenes capsulatus* and the tetanus bacillus, but the results were not encouraging either from the standpoint of treatment or prevention.

During the past year the French have prepared antimicrobial sera against the bacteria causing gas gangrene, namely, the *B. aerogenes capsulatus*, the *Vibrio septique*, the *B. oedematis*, the *B. bellonensis*, and *B. sporogenes*, and have reported good results by the use of these sera, given by simultaneous injection, both for prevention and for treatment. They claim that the incidence of gas gangrene has thus been reduced by five-sixths of what it was formerly, and that in established gangrene the process has become localized.

Let us now consider in more detail the principal points in the treatment of a war wound when it first comes to the surgeon. We have to confess that the progress in the treatment of these wounds consists chiefly in the emphasis and generalization of principles which were already practiced before the war, although perhaps, in the case of some surgeons, subconsciously. We have also learned that these principles can be applied successfully much later than we used to suppose was possible, namely, wounds in which infection has become established.

In the early months of the war, during the period of movement and before the transport of the wounded became organized, it was the exception for a wounded man to reach the operating table before several days had elapsed, and consequently infection was in full swing. The operation then was essentially a débridement, which consists in laying open the wound sufficiently to drain all pockets and to remove foreign bodies and loose ends and shreds of tissues, including detached fragments of bone. Drainage was effected in various ways. Such an incomplete treatment naturally created a demand for some method or substance to combat the terrible infection persisting in the wounds. Thus, in spite of conviction as to the undesirability of antiseptics on the part of at least some surgeons, all had recourse to every known antiseptic, one after another, and actually the old antiseptic era of surgery was revived.

During the winter of 1914-15 one of the younger French surgeons, Lemaitre, commenced to systematically surgically cleanse the wounds which came to him within a few hours of reception and close them immediately. The results were extremely satisfactory, and this treatment became generalized throughout all the armies in the year 1917. The operation consisted in paring off the entire surface of the wound, sparing all living tissue, but removing all devitalized tissue and, of course, all foreign material. The operation is termed *épluchage* (literally paring or peeling as applied to the preparation of vegetables). The paring is followed by a most careful, punctilious hemostasis, which Lemaitre followed by an application of iodine. The wound, if the patient is to remain under the observation of the operator, is then carefully closed layer by layer, all dead spaces being obliterated. Many surgeons insert strands of silkworm gut to serve the double purpose of drains and telltales, they being removed at intervals and cultured. Valuable information is thus obtained in determining whether the wound should be reopened in case of infection. Obviously, such an operation requires long incisions, but does not necessitate removal of more than the mere edges of the original wound. The common error of enthusiastic and inexperienced surgeons is to excise wide ellipses of skin. As I have said, the wound is closed when the patient is to remain under observation. When the patient is to be evacuated before 10 days have elapsed after the operation the wound should not be sutured, because continuous observation is interrupted and accidents may occur.

Judging from the patients who have come from our evacuation hospitals, there is still ignorance, or at least doubt, as to how an *épluché* wound which is not closed should be treated and dressed. Many are packed with dry gauze, necessitating an anesthetic for removal, and not infrequently damming up infection at the bottom of the improperly and insufficiently treated wound. In many of such cases one or two days en route full-blown gas gangrene has been observed. Other operators use paraffined or vaselined gauze; others antiseptic substances such as dichloramine-T. The rational method is, if the operation has been complete, to insert some strands of silkworm gut and let the surfaces of the wound fall together, laying a dressing of dry gauze flat on the surface. If clean, the wound will in all probability close and may not need a delayed operation. If it becomes infected there will be no obstacle to drainage.

Wounds that are closed immediately at the first operation are said to have undergone primary suture, the term "delayed primary suture" is applied to the closure of a wound at a second operation within a variable period, but not one requiring repairing or revivifying of the wound. The term "secondary suture" is applied to the operation, usually upon a granulating wound, in which the surfaces of the wound are removed. Generally in secondary suture a plastic operation on the skin is necessary.

Successful primary closure of wounds complicated by fractures is much harder to obtain than of those of the soft parts alone, on account of the difficulty of removing contamination on and between the fragments of bone. This difficulty has led to extensive resection of the fragments, a procedure which should be condemned, for although extensive reproduction of bone usually takes place if the fragments are resected subperiosteally, yet the period required for union is prolonged, and, not infrequently, pseudarthrosis results. Furthermore, it frequently happens, if the operation is not successful in preventing infection, that necrosis of the ends of the fragments occurs, thus defeating the object of the resection. The opinion, at the present time, of the most experienced surgeons in all the armies is that, while all absolutely detached fragments should be removed, the greatest conservatism should be exercised in regard to those remaining attached to the periosteum. Soiled portions of these should be cut away and just enough of the fragments removed to permit inspection and cleansing of the marrow. In regard to the latter it has been determined that it is very rarely contaminated for more than 8 to 10 mm. beyond the line of fracture. It is very important to remove this terminal pulpified portion, for it is frequently found to contain minute shreds of clothing torn from the patch on the missile.

If fragments of bone have to be resected the long ones should be left, in order to preserve the continuity of the shafts. As has been said, in fractures caused by simple contact of the missile, resection is not necessary and the wounds complicating them may be closed as if of the soft parts alone. When fractures are caused by missiles which perforate the bone, whether they lodge in the soft parts beyond or pass entirely through the limb, it is usually advisable to operate from both sides of the limb, because the damage to the soft parts is generally greater on the far side of the bone and because less traumatism is done to the site of fracture. In regions where loss of bone is structurally unimportant, and where infection is disastrous, as in the case of the cranium and the ribs, it is wiser to resect liberally. Internal fixation in fractures of war is bad practice. It provokes necrosis and is unnecessary.

In speaking of the indications for and the contraindications to primary suture of wounds, I wish to say a word in regard to wounds caused by rifle balls. It would seem almost superfluous to state that a perforating rifle-ball wound with a punctate orifice of exit does not require an operation, yet in one of our hospitals the staff was carefully débriding these wounds and allowing other wounds caused by shell to wait. As I have already indicated, the size of the wound of exit is a pretty accurate measure of the damage done to the deeper parts; consequently, when the wound of exit is small, an exploration is more than likely to cause greater damage than already exists.

Rifle balls when they produce a bursting effect cause terrible damage to the muscles, and the worst examples of gas gangrene occur in these cases; consequently these wounds must be thoroughly epluched. Yet a bullet rarely entrains infectious material, the probability being that these wounds are not contaminated from within, and therefore must be infected from without. It would seem reasonable to use iodine freely about such wounds when putting on the first-aid dressing and to protect them carefully. As you know, iodine has been removed from the first-aid packet on account of its inefficacy. I imagine that its supposed inefficiency came about from its use on shell wounds which contained infectious foreign bodies. During the period of trench warfare most of the wounds were caused by shell. Lately a large number must have been caused by machine gun and rifle, and some method of preventing their becoming infected would be of value.

As I have already stated, the application of the principles of épluchage and primary suture has been considerably extended, and now many wounds 36 to 48 hours old are being thus treated, even in the presence of redness, a seropurulent discharge, and a febrile reaction—thus proving that the earlier opinion that wounds could not be sutured primarily when more than six to eight hours old is erroneous. In regard to this point, it is impossible to formu-

late rules to cover every case. The question whether to do a primary suture or to wait for a delayed primary or secondary suture must rest for the surgeon to decide. It is better for the inexperienced operator to err on the safe side. But there are other conditions and circumstances in the presence of which we know primary suture is unwise, if not actually dangerous. These are, first, when the patient can not be kept under the observation of the operator for 10 days; second, in periods of congestion of the operating room with wounded; third, when there is doubt as to the thoroughness of the operation; fourth, in fractures of the upper part of the humerus, the shoulder, the pelvis, the hip, and upper part of the femur; and, fifth, in large wounds when the principal artery of the limb is ligated. The danger of suturing the last two classes of wounds is chiefly from gas gangrene. Delayed primary suture is always a possibility except, perhaps, in some wounds, such as deep wounds of important regions, where it may be anatomically impossible to lay open the wound sufficiently to remove its surface. In these cases one has to be satisfied with as free drainage as possible.

Simple incision, removal of foreign bodies, and drainage is insufficient for cases of gas gangrene. These cases must be radically treated—the muscles affected must be removed until healthy contacting muscle tissue is reached. Sometimes an entire muscle has to be removed. The wounds should be left widely open. If an entire group of muscles is involved, amputation is safer than excision. If the main artery of the limb has been destroyed, amputation should always be done.

Let us now turn to the treatment of wounds of the articulations. The experience drawn from the war has changed our ideas greatly, both in regard to the susceptibility of the synovia to infection and as to methods of treatment. The most striking developments have been the Wilhelm's treatment, which is, essentially, the continuance of the function of the joint during treatment. In the case of a wound of the knee or ankle, the patient is made to walk each day, even though pus escapes from the wound at each step. The active motions must be commenced immediately after the operation and repeated several times a day. If the treatment is delayed, motion of the joints is so painful as to be impossible. By this treatment functional results are obtained which by any other treatment would be unattainable, since the maintenance of function seems to conserve the cartilage.

Primary closure of wounds of joints is extremely successful, even when foreign bodies have rested in the synovia for comparatively long periods. However, if a wound of the cancellous tissue of the epiphyses becomes infected and it can not be isolated from the joint, the latter is doomed to suppuration and usually destruction. The rule, therefore, in penetrating wounds of the joints, is to close the synovia and drain the bone wound exteriorly. Attention has already been called to the difficulty of combatting infection of cancellous tissue, and likewise to its persistence. Consequently, in the case of the weight-bearing articulations, such as the knee, a typical resection involving removal of the contused and presumably infected bone is indicated when the architecture of the joint is destroyed by loss of bone. In the upper extremity, typical resection is rarely indicated. Dead cartilage prolongs suppuration, as repair can not take place until it is eliminated consequently its early removal is often indicated when a typical resection is not done.

In regard to the drainage of a suppurating joint, no through-and-through tubes should ever be employed. Tubes have to be employed in the case of the deep joints, namely, the hip and shoulder. In the other joints free gaping incisions usually suffice, together with removal of the loose fragments of bone interfering with drainage or liable to necrosis. Where there is no injury to the bone, free incisions and early active motion are indicated. Metastatic joints often are cured by repeated aspiration and washing through the aspirating needle. Resection sometimes saves a limb which otherwise would have to be amputated.

I shall not attempt to burden you with the indications for resection of the different joints. It would take too long, and besides it is not within the province of my subject. I do wish to mention some points in regard to amputations.

In the first place, the whole question of the sites for amputation in the lower extremities depends upon the fitness of the stump for an artificial limb, with the exception of some of the anterior amputations of the foot in which no apparatus is required. In regard to the tarsal and tibiotarsal amputations, I do not think that it has as yet been determined whether the stumps are more practical than those of the amputations through the leg, given the excellence of the modern artificial limb applied to the latter.

In the case of amputations of the thigh there is no question as to the desirability of as long a stump as possible. In fact, an artificial limb for an amputation above the middle is impractical for the average man.

When a guillotine amputation is done, the final result is a stump which is almost without exception too short for an artificial limb. I believe also that drainage after the guillotine is no better than that after a flap amputation made with a long anterior flap. In the latter the anterior flap falls over the end of the bone and protects it to a certain extent, the drainage being dependent. The flap should never be turned back. Neither is there any reason for traumatizing the stump by filling it with gauze. Secondary amputation is the rule after the guillotine and the exception after the flap amputation.

A recent and, I believe, valuable point in the technique of amputations for suppurating knee joints is to make a long anterior flap including the patella and divide the soft parts behind the knee without touching the bone. In a short time the wound is clean and fit for secondary suture, when the condyles are removed and in some cases a Gritti may be done. This operation has the great advantage of not opening new channels of infection in the bone at the primary amputation as well as causing little or no shock.

It is a good rule never to amputate the upper extremity for lesions of the bones. Amputation is only indicated by extensive destruction of the soft parts—muscles, vessels, and nerves.

In the case of injuries to the metacarpus and fingers, it is wiser to do plastic amputations with a view to eliminating infection and thus preventing irremediable stiffness of the uninjured fingers. For example, if a metacarpal bone is fractured and the tendons of the corresponding finger are destroyed, the metacarpal and finger should be resected, always leaving the proximal extremity of the metacarpal to avoid opening the carpal articulations. In other words, fingers which will undoubtedly be stiff should be removed at the primary operation in order to eliminate infection and to obtain rapid healing and, therefore, an early return of function in the remaining digits. The only exception is the thumb, every portion of which should be conserved.

Army Sanitary School No. 164.

WOUND BACTERIOLOGY

By Capt. B. Jablons, M. C., United States Army, November 26, 1918

Wound bacteriology has developed into a special science as a result of the extended investigations of the past four years. As its name indicates, it deals with the study of the bacteria that infect wounds and by their evolution interfere with the healing of wounds or menace the life of the patient. The aseptic or operative wound of peace times differs from those caused by gunshot injury in that it is the seat of comparatively little traumatic destruction and contains no infective bacteria. The war wound, on the other hand, is characterized by extensive destruction of tissue, with widespread implantation of numerous bacteria by the projectile inflicting the injury. The determination of the type of the bacteria as well as their location helps the surgeon to decide upon measures to be adopted for the conversion of the infected war wound into an uninfected aseptic operative wound, and thus facilitate the physiologic healing. The convalescent period may be thus markedly shortened, and men enabled to return to their respective units in 15 days to 3 weeks instead of being bedridden as formerly for many months.

The evolution of the subject is of interest. The attitude toward gunshot wounds during the Balkan wars of 1912-13, the only recent wars preceding the great World War where modern projectiles were used, was a very conservative one. Gunshot wounds were considered relatively sterile. Infection was usually thought to be secondary and not due to the projectile. Bullet wounds were considered to be uniformly sterile and all operative measures were considered unwarranted where active infection was not present, so much so that a great deal of discussion followed the attempt of several surgeons to probe and remove bullets or other foreign bodies. Shrapnel shell wounds were treated by local application of iodine or other antiseptics, and covered by Matisel dressings. The attitude of most surgeons was that nature's barrier must not be interfered with, and the necrotic tissues

must be allowed to slough off of themselves. If no fracture was present, occlusive dressings were applied. Occasionally the wound was irrigated with hydrogen peroxide preceding the application of the dressing. If a rapidly progressive infection developed, radical amputation of the limb was resorted to. There was a difference of opinion as to the proper treatment of wounds of the abdomen or lung. As a general rule little intervention was practiced in abdominal wounds. It was thought that nature would accomplish all that could be accomplished, if a fatal peritonitis did not occur immediately. As for wounds of the lung, these were treated by means of occlusive dressings, and when empyema developed extensive resection of the ribs for further drainage was the usual operative measure.

The early days of the European war saw no change in this attitude. The same views obtained then as were current during the Balkan wars. The results obtained were so disappointing that many surgeons began to use the more powerful antiseptics, and insisted that war conditions made it necessary to return to the treatment advocated by Lister. Cauterization with carbolic acid, irrigation with formalin solutions, and the use of other strong antiseptic agents became then the accepted methods of treatment, with removal of some of the foreign bodies present in wounds. It became very apparent, however, that this was not sufficient, and not a few investigators began extended researches into the nature of wound infections and the best methods that could be devised to overcome the extensive infection of wounds. Carrel was one of the foremost of these investigators, and was prompted to undertake these studies as a result of his unsuccessful attempts to transplant limbs from human to human owing to the extensive infection present in the tissues around the wound. While looking into what was being done at the American ambulance of Neuilly to control wound infection, the use of eau de Javel as a wound antiseptic attracted his attention. This antiseptic had been employed some 50 years previously by a French surgeon, but had fallen into disuse, until Doctor DuBouchet reintroduced it at the American ambulance hospital with some remarkable results. The patients, however, complained of the marked irritation which accompanied its use, the pain following its application being almost unbearable. Carrel set about to look for a modification which would conserve its antiseptic properties, but which would be nonirritating. He had Dakin come from the Rockefeller Institute to work on this problem and to investigate the bactericidal effect of these different solutions. The result of these researches are now well known. In order to control the progress of wound sterilization, Carrel adopted the plan of counting the bacteria present in the exudate of wounds, and by charting the results obtained the so-called Carrel bacterial curve. It was thought that when the count reached a certain low level that wounds could then be safely closed. At about the same time researches into the histological nature of wounds demonstrated that wound margins were almost always necrobiotic, and in many instances were heavily infiltrated with foreign particles; and that wound healing was markedly retarded because of the necessity for preliminary sloughing of these tissues. Some surgeons, among whom Lemaitre was active, suggested excision of the wound margin, combined with antiseptic treatment of the wound. It was only a step from both of these procedures to secondary closure of the wound. It was soon found, however, that many of these wounds refused to heal, or would develop rapidly fatal or progressive infections despite the excision of the wound margins or a very low bacterial count. It became, therefore, necessary to carry out more extensive and more thorough bacteriologic investigations to explain these failures. As a result of these investigations it was found that certain bacteria did not interfere with wound healing, but that others, either because of their proteolytic ferments or toxins, destroyed tissue cells or produced a toxemia which markedly affected the outcome of the wound.

This is what has led to the development of wound bacteriology as a special study and indicates its importance in the scientific control of wound surgery. Wound infection depends closely on several factors which are responsible for wound production. The factors of greatest importance are naturally the substance inflicting the trauma, the bacteria which it introduces into the wound, and the energy which it transmits to the tissues that it injures. Other factors of secondary importance are the types of tissues that are affected, the local resistance of these tissues, and the physical changes resulting from the injury which may favor bacterial development.

In general, the wound itself varies, depending whether it is produced by regular or irregular missiles, or whether the energy transmitted to the tissues is that accompanying primary or secondary projectiles. A detailed discussion of these factors will be taken up under the chapter on ballistics. The bacteria that are introduced into wounds varies, depending upon the sources from which they are derived. The projectile may have been primarily contaminated as a result of handling or by being in contact with the earth. It may become secondarily contaminated as a result of its passage through trench earthworks or by contact with the outer clothing of the soldier, which is almost always contaminated by soil. A habit of some soldiers, that of spitting on bullets or other projectiles, is responsible for the introduction of mouth bacteria into the wound. Its passage through the skin enables it often to carry shreds of the skin into wounds, with their contained bacteria. This means that the wound is often infested with the innumerable varieties of microorganisms found in the soil, usually derived from the excrement of man or animals, as well as the common mouth or skin bacteria. Not all of the bacteria introduced into wounds are capable of development, as other factors are necessary for their further development and multiplication. Examination of the wound contents would show a very varied flora during this stage, but would in no way indicate which organisms are going to interfere with wound healing or menace the life of the soldier.

Following a latent period, which seems to be the same in all wounds, certain bacteria develop, depending upon the type of tissues injured. Muscle tissue furnishes the protein and sugar which favor the development of certain bacteria of the saccharolytic anaerobic group over other bacteria which may have been carried into the wound. Wounds associated with extensive injury to blood vessels favor the development of the streptococcus group of bacteria. Wounds of bony tissue favor the development of the *Staphylococcus aureus* group of microorganisms. This early type of wound infection is usually spoken of as the selective type of infection. The organisms which appear later usually represent bacteria that have adapted themselves to the conditions present in wounds and which have been able to find a sufficient amount of nourishment to maintain themselves during the period of adaptation. Other organisms may extend from neighboring parts or localize in the wound after having penetrated into the general blood stream. This constitutes secondary infection and is subdivided into adaptation and metastatic infection.

A type of wound infection that deserves special consideration is the mixed infection of wounds. The importance of bacterial association in the production of infection has been known for some time. Its importance has been more generally appreciated as a result of the numerous investigations of the past four years. We now know that certain bacteria are capable of increasing enormously the virulence of associated bacteria, and are also capable of hindering the development of other bacteria. The former is a malignant symbiosis, whereas the latter is a benign type of symbiosis. Thus the *B. sporogenes* is capable of increasing the virulence of quantities of *B. Welchii*, which alone are incapable of producing any lesions whatsoever, while virulent quantities of the *Vibrio septique* are rendered comparatively avirulent when associated with the same organisms.

The importance of another type of infection occurring in tissues has been appreciated due to the prolonged observation made possible during the present war. Due to a secondary trauma, or other factor capable of lowering the resistance of the individual, bacteria implanted at the time of the initial injury may develop some time after the infliction of the wound. This has been known to occur several months and in many instances even years after the original wound. The importance of latest infection is not to be underestimated, as it contributes very much to the production of dangerous sequelae.

The bacteria that have been reported as occurring in war wounds may be roughly subdivided into saprophytic and pathogenic. This classification, although a classical one, is not a very good one, as the experience of the last few years show that saprophytic or non-pathogenic, is only a relative term since many of the so-called saprophytes are capable of becoming pathogenic under favorable conditions alone or when in combination with other nonvirulent organisms. We prefer to classify these organisms into aerobic and anaerobic, although some of the aerobes are likewise facultative anaerobes.

The most common aerobes found in wounds are:

Gram-positive cocci:

Staphylococcus group.

Streptococcus group.

Diplococcus group—

Pneumococcus.

Enterococcus.

Diplococcus griseus nonliquefaciens.

Gram-positive bacilli:

Endosporing bacilli—

Bacillus subtilis.

Bacillus anthracoides.

Bacillus mesentericus.

Bacillus mycoides.

Corynebacterium.

Bacillus cutis communis.

Bacillus diphtheriæ.

Gram-negative bacilli:

Saccharolytic—

Bacillus coli communis.

Bacillus Friedlander.

Proteolytic—

Bacillus proteus.

Bacillus pyocyaneus.

The most common anaerobes are:

Toxic group:

B. Welchii.

Vibrio septique.

B. tetani.

B. adematians.

B. fallax.

B. histolyticus.

Proteolytic group:

B. sporogenes.

B. putrificus.

B. bifermentans.

B. ærogoetidus.

Nonpathogenic: *B. tertius*.

These bacteria have been reported in wounds sometimes alone and sometimes in association. The most common associations are aerobic associations, although in the gangrenous types of wound infections anaerobic associations are most common. The most common aerobic associations can be seen from the following diagram:

The most common anaerobic associations similarly can be seen from the appended diagram:

We have gotten up a chart for the purpose of teaching the subject at the central laboratory, which subdivides the organisms, first, whether they are aerobes or fall into the coccus group; whether they are aerobic bacilli and those which are Gram negative and those which are Gram positive. An attempt has been made to study bacteria, not only with regard to certain characteristics, but to look at them from a biologic basis to determine the type of reactions which a given bacterium is possible of manifesting when put into different environments. So we study the bacteria on the basis of morphology, their ability to split sugars and their ability to ferment or split protein substances, their ability to break up peptone, and their characteristics. In other words, their ability to produce bodies when injected into the human organism. The Friedlander and colon bacilli are more dangerous because they split carbohydrate substances, and wounds that show an absence of gas bubbles may be any of the group which are sugar-split bacteria. The proteoses digest protein substances, and this interferes with wound healing.

Army Sanitary School, No. 167.

INTERNAL MEDICINE IN THE ARMY

By Brig. Gen. William S. Thayer, M. C., United States Army

We are all here to say something in regard to internal medicine in the American Expeditionary Forces. I am going to start by saying a few general words about the function of the division of medicine. I don't think anyone in this course has explained to you exactly what the three divisions of the professional services are.

In the first place, in times of war, officers of both the Army and Navy have been called "surgeons," and the explanation is suggested by considering "battle field," "dressing stations," "transportation of the wounded," and so forth—just a military proposition. This is the picture that comes immediately to the mind of one who thinks of war, and quite naturally, as shells bursting, opening of wounds, amputation of limbs, and so on, as the main function of the Army medical officer. But in all modern wars before this—and it will probably be so in this war, although perhaps not so up to the present time—the greatest loss of men has been from disease rather than from wounds; and if our duties are to preserve the man power of the Army certainly the medical side of our functions, more properly speaking, are not less important than the surgical. In the moment of battle certain purely surgical and administrative propositions come, it is true, overwhelmingly to the fore. Some one said the first important duty of the medical officer is the prompt evacuation of the wounded, and at certain times that is unquestionably true. But how much of the time of soldiers is spent in actual combat? The great bulk of the time is spent in preparation of men and material, and on this preparation and the conservation of these men and this material the outcome of the battle and the war itself depends. The functions of the physicians in private practice are often summed up as consisting in the prevention, the early detection, and care of disease. But there is one other function which outweighs all these. The greatest influence for good that the physician exercises in his practice is the mental and moral influence on the patient, his personal influence. He can do much toward preventing disease, and in treating disease, but far more can he do in fortifying, cheering up the patient and the men in his command.

The medical officer in the Army can do much toward preventing disease by attention to the sanitary regulations, the cleanliness of the troops in his command, but in the region to which he is attached he can save much trouble by the early detection of disease. Upon the medical officer as much if not more than the character of the battalion and regimental surgeon much depends. The position of a battalion or regimental surgeon is a position of danger and one of honor, a very real position of honor. I don't know that I can better illustrate this than by speaking of two experiences I have had over here. Two of our men who graduated in the last 10 years from our school of medicine came over before we came into the war to work with the British. One of them—I don't think it is any harm to say—was a nephew of General Gorgas, a very exceptional man, who occupied an important position in the school of medicine in which he was teaching; he had very unusual qualities as a laboratory worker, and when he spoke of coming over everybody told him he was doing the wrong thing, that there were very

few men who could stay and do the kind of work he was needed to do in the school. But he wouldn't be stopped, and finally he went to see General Gorgas and he seriously told him it was no place for him; that his duties were at home, that he couldn't go, and so on. The young man listened most patiently, and said: "Uncle William, if you were in my position what would you do?" and the general laid down immediately. He went over; did exceedingly good work for the British; got a decoration. As we came over he was needed very much in the laboratory department; we couldn't get men of his type for work there. It took Colonel Siler three months to get him out of Italy. He was still with the British Army; he was a regimental surgeon with the British Army in Italy in active work. We finally got him to the laboratory department and he stayed there about two weeks. The man felt so strongly that his proper position was one of battalion surgeon, that was the place where he could do the most good and was most needed, that he couldn't stay in the laboratory, and finally Colonel Siler let him go, and he went back.

The other man was another man of a similar type. He came over to work with the British, and when the American Expeditionary Forces came over he was taken out of the British and put in a hospital where he belonged. He was a man of special medical training more than laboratory training. I wanted to put him in charge of a medical service, and he came and talked to me the same way. He said that he did not want to do that kind of work; that he felt that his position, the place where he could do the most good, was as battalion surgeon. That one could do more for the good of the service around there by setting the example there than he could in any other way. Finally, very reluctantly, we let him go.

Within the month I have been down the line to the base hospitals. At Nantes, I think it was, I came across a man and asked him what division he was in, and he told me, and said: "I was sent into the hospital by Captain So-and-So"; and he smiled and said: "Do you know him?" I said "Yes." He said: "There is nothing that the men in our regiment wouldn't do for that man; he is perfectly wonderful." He said: "Do you know where he made his dressing station on such-and-such a day? He made it in the second-line German trenches. One day he came into our company kitchen and he said 'That's a nice looking kitchen. There's \$10 for the best kitchen in the regiment this month; and you ought to see those kitchens shine.'" Well within two weeks, at Limoges, an officer said to me "I wonder if you don't know So-and-So?" I said I did. It was the other man. He said "He is the most extraordinary man. Do you know, he knows the regiment. He is the regimental surgeon, and on the march he is going steadily from one end of the regiment to the other looking for men who are falling out, looking out for everything. He knows everybody and more than that he knows everything, and if the regiment loses its way he finds the way. He is a most extraordinary person."

That shows what a regimental surgeon can do, and it brings to mind something that a major general said to me not long ago. He was speaking of the necessity for divisional rest camps so as to prevent the men slightly ill, when they are merely tired, from getting way down the line of communications and getting away from the division. He said: "What I want is not only a good medical officer to take care of the men but I want a medical officer who can tell me to look out for the men and find them out before they get away. I want him to say, 'Such and such an officer is about ready to break.' Then we can save him." That is where the regimental or battalion medical officer comes in. It isn't only a question of the personal influence on the men, but there are many other things of great importance there because of his close relations with the men. It is on the regimental and battalion surgeons that the prevention of little epidemics that are extremely annoying sometimes depends more than anyone else. Keeping up the sanitation of his detachment, he may do much toward preventing dysentery, typhoid fever, which despite our vaccinations crops out here and there, and may crop out more seriously before we know it. If he keeps in touch with his men properly, he will pick up diphtheria in time to stop it and stop the spread of young epidemics, not to speak of other infections of all sorts which our new replacements coming over from America are bound to bring over and which will crop out from time to time; he will detect men when they are worn out, when they need to go to a rest camp, when they need to be taken out of the line for a little while; the detection of such things as early tuberculosis, etc. The detection of early tuberculosis may seem a rather foolish

thing to talk about in active warfare, but Major Webb, who is looking into tuberculosis work here, brought out something. As you know, a year ago last summer all of our Army was gone over rather carefully by competent committees of specialists on tuberculosis and we weeded out something over 1 per cent, and the men we have over here have been a very fine set and there was very little tuberculosis. It was well weeded out, but, as Webb says, the weeding out of tuberculosis is a good deal like weeding out a garden—after a little while the weeds come up again. And the time when tuberculosis is going to come up is in the course of the next six months, after these divisions have been worn out through great exhaustion; it will come out unless I am much mistaken, and it will have to be looked after. Already the tuberculosis that is coming from the divisions is much too far advanced to be creditable to our "Medical Corps." I say the "Medical Corps" in the broad sense, of course. There are very few cases, but a good many of them have gotten far advanced, and I think a good deal of it is because the regimental and the battalion surgeons haven't known their men, haven't followed the men, haven't looked after them. Now, to pay attention to a few men, you may say, is a small thing when so many more are sacrificed in other ways. There is another side that may be a material side that I never thought of until Major Webb spoke of it, and that is—he said if we don't look out for that few in the course of the next six months, if we don't go through these divisions again and look after things, there will be trouble after the war. There is one thing that the public is more interested in than anything else, and that is tuberculosis. When the men are brought back from this side, I find that in New York the one thing that the people are interested in was the poor T. B. patients. They are more complaining than anything else; they have nothing to do but complain of the way they were neglected. And, as he says, we shall have a congressional investigation on the way tuberculosis was managed in the Army. These cases can be picked up early if the surgeon makes careful inspection of things and his men. He shouldn't leave it to his sergeant; he should do it himself.

Another thing that Colonel Ashford spoke of some time ago is the relation of those officers to the question of gas, a question very few of us knew much about when we came over here, and it isn't in the stress of active work that we ought to learn about it; about its destruction, and who is and who isn't gassed, and who shall be evacuated on a stretcher and who not. These are extremely important points, and much depends on the regimental surgeons and the men in the field hospitals to determine who is and who isn't gassed. These questions need careful attention, careful study, and careful training. The proper distinction between the gassed and the merely tired is a thing that hasn't been mastered very well. There are lots of tired men that have not been gassed, yet have been sent down as far as Nantes. I don't know why they were evacuated, as they were just tired.

In aviation units the duties of the medical officer are of vital importance. It is true the officers for the aviation units ought to be specially trained, and they will be, I think, in the future; but the main thing is to detect the early evidences of strain in the aviator. It is probably safe to say that the majority of fatal accidents that happen in the Aviation Corps have been caused by men flying when they ought not to fly and when a proper relation between the medical officer and the line officer and a proper attention to duty on the part of the medical officer might save the men. Aviators show certain symptoms of strain and exhaustion which the medical man should learn to detect, and one of his most important duties in an aviation group is to detect; but above all, as I said a moment ago, the medical officer in the battalion and regiment is important because of the personal influence he has on his men. Nothing strengthens the men's morale more than to know that the surgeon is with them, going over the top with them, is by their side to help them. This is really almost the most important part of their work.

In the field and evacuation hospitals again the medical personnel is—I say "personnel" because the officers must often act as both physician and surgeon—but they have especially two important functions, with the care of the gassed and the care of those suffering from surgical shock. Now, every officer in a field or evacuation hospital should make it his duty to familiarize himself so far as possible with the proper methods of the care of gassed. Hereafter in our divisions we will have a medical gas officer whose duty it will be to see to it that the medical personnel is well instructed, well up in these matters; that instruction is given,

and that proper attention is paid to the instructions. Arrangements are now being made for a sufficient amount of literature to give the officers an opportunity to learn. Every officer should make it his duty to see that he is familiar with the methods of treatment of surgical shock, for surgical shock is going to be treated largely by men who do not operate but who are medical men, in order that every man capable of operating may take over that side of the work. In the field hospital every officer may not be able to take the contemplated course in surgical shock given at Dijon, but others in his unit will have had the course, and is his business to learn from them. We are in this war to win it, and there is no excuse for a medical officer sitting down in ignorance and not trying to find out about his job. There is nothing so encouraging, as a rule, to a superior officer as to find an inferior who says he doesn't know but wants to find out. In camp and base hospitals also the medical officer should seek to prepare himself in regard to the treatment of surgical shock and gassed cases. Evacuation sometimes in the advance base hospitals is fairly rapid. Evacuation to hospitals as far as Limoges is such that oftentimes within 48 hours he may be in hospital still showing symptoms. Literature—and more and more as time goes on—will be available in base hospitals in regard to gas. Ask for it. If it isn't on hand, the commanding officer will be able to get it for you. Some of it is here; more is coming.

In base hospitals there may be and there has been—there was last winter for those who were here—considerable periods of time in which not much is going on. These are times in which a man may prepare himself for the special problems which he may have to meet; for the officer who desires really to make himself efficient there isn't very much time to spare, even when the hospital is relatively empty.

There is one other class of work of extreme importance, the importance of which is far from being realized, and that is the board work, the S. C. D. boards. These boards to properly do their work must consist of exceedingly good men, must consist of the best men that can be gotten hold of, and the work can not be done hurriedly and at the same time be done well. It is very interesting to see, in crowded hospitals with an insufficient personnel, cases that are boarded and boarded two or three times. It is interesting to see how easy it is to make mistakes and how many things slip through. In board work one gets used to dealing with soldiers who one suspects of malingering or attempting to malingere. In this Army it is very different from what it used to be in the old Army; different types of boys here. It is a serious matter sometimes to send away a common soldier; often a very grave and serious matter to send away an officer, upon a mistaken diagnosis. Major Cohn will speak of that. The most serious mistakes are made in diagnosing cardiac diseases. Now, it is really surprising the proportion of cases in which heart disease is wrongly suspected by S. C. D. boards. If an officer of the S. C. D. board doesn't know that systolic murmurs don't necessarily mean mitral insufficiency he ought to get busy, get a hold of some man in his unit who has had that training and learn some points on the examination of the heart and the significance of functional murmurs. The majority of people under 30 have a systolic murmur at the apex of the heart in a recumbent position—perfectly healthy people. There are an awful number of persons who are recommended for retirement with nothing under the sun the matter with their heart, simply because of the presence of certain murmurs.

Again in base hospitals, as in advance formations, the attitude of officers to the men is highly important, especially in dealing with the neurologic and the exhausted. Few reserve officers, or officers who have come up from the Reserve Corps recently, who haven't seen it over here, can realize the importance of discipline in dealing with men in base hospitals. The discipline of a group of pretty good soldiers will go absolutely to pieces in a few weeks as they pass through base hospitals if it isn't attended to. They become loose, shiftless, good for nothing, and go all to pieces. It is absolutely important to keep up good discipline and to make the men remember that they are soldiers. It is equally important to remember that the keeping up of good discipline is an entirely different matter from lack of discipline. Discipline is something that one can not afford to forget. Neither can one forget to show the proper consideration, proper sympathy for an ill man, but we can not afford to be quite so free and easy in a ward in a base hospital as in a ward in a civil hospital. You have got to remember that you are an officer and the patient is a soldier. Don't let the men go to pieces as they go down the line.

The functions of the officers in convalescent camps which are growing and will grow to more importance will be spoken of by Major Cohn. There, the problems are fascinating, complicated, and I will only say here what some of us heard an English officer say—that they began in the British Army assigning to convalescent camps the older men less able to stand active work and who were, perhaps, not of a first order. They ended by realizing that the convalescent camp demanded the ablest, most active, and vigorous young men in the service; that it was one of the most complicated, difficult, and serious problems in the Army.

Now, I want to say a word or two about what these so-called divisions of professional services mean and what those of us who figure as consultants are trying to do here. When this war began, or a little before the war began, some of you may remember the very small Army that we had, the small medical service, the two or three rather stuffy rooms in the Surgeon General's Office, wanting in assistance of all sorts. It was necessary that this small group of medical officers should direct and manage and control this gigantic system which is growing up. It has been a tremendous strain, and it is quite extraordinary that it has been managed so well as it has. It has become necessary for that small group of medical officers to take administrative positions to manage this huge machine. It was necessary to hand over all matters of treatment to the large body of civilians who came in through the Reserve Corps and that even the notably skilled surgeons of the Army would be unable to practice their profession in any way because they were obliged to take directing parts. So the whole problem of surgical operations and medical treatment has been handed over to you. It is a tremendous responsibility on both sides. A plan was adopted by which the divisions of the professional services were created, and at the outset a director of general surgery, a director of urology, a director of orthopedic surgery, a director of neurology and psychiatry, and a director of general medicine were appointed, and later they were all organized into the division of professional services, of which Colonel Keller is director, with various subbranches in surgery, medicine, etc., for the various departments. What are these groups doing? They oversee and preside over the practical surgery and practical medicine of this great Army.

The surgical service went to work in a very interesting manner long before, I am sorry to say, the medical division was started. There were established two particularly excellent evacuation hospitals; but in the first place, to go before that, the orthopedic surgeons took up the question of splinting and first aid. That was taken up by the orthopedic branch through the aid of the Scientific Society of the Red Cross, which holds monthly meetings in Paris and brings together the physicians and surgeons of the British, French, and our Army. Certain agreements were reached in the matter of standardization, and the surgeons, for instance, have standardized splinting, and the whole proposition has been taken charge of by the orthopedic side of the surgical staff, and they have endeavored to instruct in each division the divisional personnel in the standard methods of splinting adopted over here. Then there were two excellent evacuation hospitals, No. 1 and No. 2, situated on parts of the front which are still fixed, where a certain, steady amount of war surgery was passing through. There were established several surgical teams who operated steadily, and notable surgeons and consultants were put in there. As new base hospitals came in these surgeons were sent up to these evacuation hospitals and given experience in actual war surgery, which is rather different, very different, from surgery in private life. Then in every base hospital teams were formed—surgeons, nurses, and orderlies, to come up on emergency and take up work, and, now that the fighting is on, these teams are doing extraordinarily valuable work. Additional teams are sent to every evacuation hospital, and to certain field hospitals, to other strategical points to which they may be summoned in sudden emergency, and all that has been done under Doctor Finney. The genitourinary service has done a very remarkable work in controlling venereal disease in the Army, looking up the question of delousing, treatment of seabies, and other questions of that sort. The orthopedic service established a large camp for the treatment of flat foot and other things. There are a good many weak sisters who come over with the Army with weak backs. They have been taken down to this camp and in a good many instances turned out fairly well.

In the same way other departments have been added which are especially looking after treatment in base hospitals and arranging so that eventually there may be special centers for the treatment of special things. That is the general sort of work the surgical service has done.

In medicine we are trying to do the same. For instance, at the outset it became evident that one of the things that we must do was to provide so far as possible for the instruction of personnel in connection with the treatment of the gassed. So far as possible we have endeavored to help in the instruction of personnel; we have obtained literature for them. We are sending men to different divisions whenever they desire it to give such instruction as we can, and together with Colonel Gilechrist we have succeeded finally in bring about the establishment of the divisional medical gas officer, which is going to be an admirable thing. The evolution of the divisional medical gas officer is a rather good example of what a civilian may do in the Army if he is on to his job. Colonel Grissinger had appointed to his division, the Forty-second, a medical gas officer. Before this the division went through their difficulties in regard to gas and they lost a great many men. Accordingly, Colonel Grissinger took out of his division a medical officer who was probably not much younger than I am. He was a captain; I think he was connected with the field hospitals. He took him out because he thought he was a pretty good man and sent him to the British front to study gas. He proved to be a very remarkable man. He had been working as a urologist, and certainly a urologist would not be the man you would pick out to develop into a gas officer. But he made an excellent gas officer. He organized the medical services of that division and now he is the corps gas officer of the First Corps. He did very valuable and very efficient work. I don't know that any man has done as well as Captain Coghlan has done in that respect.

Each of the new divisions will have a man who can get his medical men in shape in regard to the treatment of gas. Early we found that gas attacks then occurring in the fixed line, and were pretty fierce sometimes. The gas attacks were made with projectiles at a certain point and a group of men would be gassed, and we felt it might be necessary to have teams called to the front at any moment to help out in the treatment of gas cases. Such teams could also be utilized in the care of cases of surgical shock. It was early determined that the need of surgeons would be so great that the care of surgical shock should be turned over to the physicians; that is, men not regarded as suitable to do operating. So now we are forming in each organization two emergency shock teams, gas teams, "shock teams," as they have been called. I hope they may be known as "emergency medical teams." In times when trouble is expected these teams are sent to field or evacuation hospitals or collected at certain strategical points, from which they may be summoned in any emergency. Each leader of a team is sent to Dijon where, in Colonel Siler's laboratory, he is given a course by Major Zinsser and Captain Hussey. They have succeeded in getting a standard method of transfusion so that one apparatus is used everywhere, and each one of these teams carries its own apparatus with it, and the central laboratory is able to supply any number to the field hospitals and places where needed. This may be used in an overwhelming gas attack or for the treatment of surgical shock. In that way they are able to relieve the surgeons, and these men, who are especially equipped men in the treatment and care of shock and infusion, can also help in questions of pulmonary disease and other things that may be necessary in active warfare.

The question aviation is one that came up early. It has been a very interesting question. The medical care of the aviator is a special problem. The British early recognized its importance; the French have been slower. We recognized it at home, but it hasn't been developed as yet here. The aviator is living in a region, if he is flying high, where oxygen is relatively scarce. He is under a very considerable strain, and unless he takes special precautions he is going to get worn out. He must, in the first place, be selected with great care as a man who is able to stand long periods of exposure and long periods of oxygen want. The state of the candidates who present themselves for admission to the Aviation Corps are points of great importance. At the present moment; under Colonel Boggs there is being organized a special aviation service, which has not yet taken form altogether, but there will be a special group of men who know the proposition of examining aviators; and the lives of some of our most important men and the efficiency of our aviation service depends very generally upon the conduct of this work.

Major Webb, as I said, is looking up the question of tuberculosis. He has been going about through the different base hospitals, speaking to the staffs, endeavoring to standardize the work in tuberculosis along the special lines which have been adopted by Colonel Bushnell in the Surgeon General's Office, and already matters are taking good shape. These interesting pulmonary infections that have been occurring in the Army have caused a good deal of confusion, and it was discovered that a great many cases of early tuberculosis were sent back home from France that were not tuberculosis at all. Now, all suspicious cases are sent to one or two designated hospitals, where they are disposed of as the case may warrant.

There are now being established convalescent camps in connection with every large hospital group, and in these convalescent camps there will be many interesting cases that are known as the effort syndrome. Cases of tachycardia, dyspnea, which were known in the Civil War as the irritable heart of soldiers, as described by Doctor Da Costa. The special study of these cases includes a certain portion of these individuals who are otherwise lost to the Army or become permanent invalids, and they present numerous interesting problems, of which Major Cohn will speak. Convalescent camps will do a great deal more. They are gotten out of the hospital atmosphere where they will remember they are still in the Army, where the only idea is that they are going back to the front, where they are given the necessary exercises and the necessary training in a carefully calculated manner without their appreciating it, and thus getting them back into the Army spirit and able to go back to duty.

I have nearly finished my hour. These are the main things the medical service is trying to do. We keep in touch with the different services in the different base hospitals, the special consultants in the different group areas, and in the army corps as well. The consultant in a group area is a man who is the link between our office and the different base hospitals; more than that, also the camp hospital as well. He should be a man who knows the medical officers in the area; he is familiar with the conditions in the base hospitals; he is able to get quickly to the corps or divisions who are supposed to keep in touch with the specially qualified personnel for internal medicine, so that if the commanding officer needs more internists we might be able to indicate them to him quicker. We also communicate with regard to purely professional matters with the chief consultant. The consultant in an army corps in the same way forms a link between the chief of professional services and the professional men in an army corps. Working with the corps surgeon and with the division surgeon, this forms again the same sort of a link. I should say that almost our two main functions are the supplying of personnel through our knowledge of the personnel, and the possibility of giving special instruction in special branches where some instructor is needed. They work in this way. In the First Corps, Colonel Grissinger is chief surgeon and Major Swift is consultant. Through him and through the evacuation hospital and the army surgeon he is able to assist the corps surgeon and the division surgeons to determine at just what points these special shock teams are needed in determining just where men may need special instruction in the shock work or gas work; in other words, helping out the professional side of the machine.

So far I feel very much encouraged with the way things are working out. The effort is, of course, purely and simply to increase the efficient service. It isn't an easy thing to work together with a big thing like this. It seems the more striking how smoothly everything is running.

The laboratory services under Colonel Siler at Dijon are doing a wonderful work. They have a central laboratory which is not only the supply laboratory but there the organization looks out for the establishment of laboratories in divisions and other points where they are needed; it looks out for the bacteriologists as well. Courses are given in wound bacteriology and courses in the treatment of surgical shock. Through the department of sanitation, Major Zinsser has done most valuable work in looking into the outbreak of infectious diseases, and with Colonel Siler, I think, will be able to accomplish still more.

This in a way covers the special medical activities in the American Expeditionary Forces. I do want to say one or two words, more particularly to reserve officers, who are entering into army work. It isn't always very easy for a physician who has been perhaps engaged in more important independent work to step out of his practice directly into the machinery of the Army. He finds himself in a position where he is submitting to a discipline which is sometimes rather irksome. He finds himself often under the command of an officer younger

than he is. He instantly sees the way to all kinds of short-cuts and becomes irritated when he can not follow them. He is very apt to be radical on discipline and be a good deal exasperated by what he has to go through; but as he is in the service longer he learns that the discipline and rules of conduct in the Army were not made for nothing, and when he steps into the Army the first thing he had better remember is to keep his mouth shut and not criticize. It goes without saying that every officer you may be put under may not be an extremely wise man, but when you step into the Army you step into something which is a certain definite organization and discipline; we step in to follow the rules, and we can't do anything but that, and a lot of exasperation might be avoided if only we could stop and see how obscure it is, how little the things are that we often stop to criticize and whine about.

The commanding officers of the Medical Department are men whose only desire is to care for the sick and wounded and to preserve the efficiency of the American Expeditionary Forces. We entered into the service. We stepped into a great machine in which we must expect to do our part in the position assigned. Few of us get in the exact spot in which we would like to be, and that's a point that came up yesterday. I said to a man: "What do you think is the most important thing with regard to the strictly medical duties of an officer in the medical service." After some time he said: "Do you know, I think it would be worth while to say something about contentment with your job." Always. Every reserve man that comes over here is disappointed with his job. He wants to be somewhere else. Very few of us are where we would like to be, and when we are there we can't run it as we would want to run it. If we do our level best where we are, without complaint, we shall do the best service for the whole. If we are constantly thinking of ourselves and our own personal comfort and allow ourselves to be disconcerted, discontented, and to kick constantly, we clog the machine; we are not doing our full duty and are putting sand in the bearings of the machine. Work well done may pass unrecognized, but not often, and with all the difficulties, all the inefficiencies of ourselves, and our faults in the past, and those which we shall certainly commit in the future, the officer who gives his full, his whole effort to filling the duties assigned to him will, in most instances, gain his full reward and will be very sure to gain his name in the Medical Corps of the American Expeditionary Forces.

Army Sanitary School No. 168.

THE DIVISION ORTHOPEDIST

By Capt. R. O. Blood, M. C., United States Army, November 27, 1918

I am going to take up a little of the work of orthopedies from the standpoint of the divisional orthopedic surgeon and also from the standpoint of the orthopedic work done in the division, over which the orthopedic surgeon has full control and is naturally responsible. The division orthopedic surgeon has developed entirely since our participation in the war. We now have a divisional orthopedic surgeon, or did have during hostilities, with each of the divisions, and that man was held responsible for the condition of the cases when they left the division and held responsible for the treatment of cases within the division, and, of course, that meant a lot of work. There was no surgical man attached to the division and, naturally, the man who was doing orthopedies took up a great deal more of the serious surgical work; not that we did any actual surgery in the division because we did not, but we had the shock cases to treat and a good many surgical conditions which are not truly orthopedic but which are under the supervision of the orthopedic surgeon. It has been my good fortune to serve during my stay in France—something over a year—first, with a field hospital, then 5½ months with the Infantry as battalion surgeon, then with an evacuation hospital, and then with a base hospital, and finally back to my own division as division orthopedic surgeon. So I have been fortunate enough to deal with wounded men from the front where they were injured back until they finally recovered. Our division, as you all know, started its trench experience the 7th of February last. On the 7th of February we entered the Chemin des Dames sector. There we saw quiet trench warfare. They told us before we went up—we were all very anxious to know how active it was—that it was quiet; that they threw over 400 shells

a day. I asked a French officer how quiet that was, and he said: "When they tell you how many shells they put over a day you can call it a quiet sector." They had already told us they put over 400 a day. When the activity is figured in number of shells it is called quiet.

In order to understand the work of the Medical Department and its relation to orthopedic conditions it is necessary to know some of the conditions under which a medical officer works. In trench warfare, the conditions we found in the Chemin des Dames, we had good dugouts and plenty of room to do our dressing under safe cover, also plenty of room for equipment and plenty of transportation to get it there. In open warfare, such as we had at Chateau-Thierry, St. Mihiel, and Verdun, the conditions were exactly opposite. There you had no protection from enemy fire. You had no place to carry equipment except on your men, and the best thing you could hope for is to get behind the shelter of some small elevation and out of sight of the Germans. Of course a great many things have to be taken into account in choosing your locations there. It should always be possible to find such a location within a kilometer of the front, and I think a greater distance for litter carry in the open is altogether too great. That is entirely up to the medical officer and has to be decided after a study of the condition of the ground in which you are working. On the field of battle, while the first-aid treatment is given the wounded man, the cases are practically all orthopedic if the casualties are due to artillery fire. If due to machine-gun fire, as at Chateau-Thierry, we do not get so many fractures but a great many wounds of the soft parts. Wounds of artillery are practically all fracture conditions. At Verdun, in the last offensive in which we took part, just before the end of the war, the wounds there were practically all fractures, a great many compound comminuted fractures of the femur, and of course these required very careful attention. The treatment of a man depends largely on his diagnosis. We sort of accept the opinions of the medical officer who sees the man at the battalion aid station; if he makes a diagnosis of fracture it is very easy for a man seeing him later to pass him through with the original diagnosis without attempting to make any differentiation in or confirmation of the diagnosis. I remember one case that happened at Verdun. A man came in treated for a simple wound of the thigh. The man who was on duty treated him and said, "Simple wound of the leg," and on looking at the man it looked to me as though he had a false joint and on closer inspection we found he had a compound comminuted fracture of his femur, and he had been through three hands and no one had discovered it. The first man made an incorrect diagnosis and no one else had taken the trouble to make a correct diagnosis. Of course, the man was at once put in a Thomas splint and sent back to the rear.

Cases should be diagnosed as fractures at the first dressing station—the battalion station—and there, except under extreme conditions in drives, we should apply our splints. One of the great reasons for the success of our department within the divisional area is, I think, due to the limited variety of splints used, thus making it easy to teach every medical officer and enlisted man during rest period the rapid and proper application of splints. We have limited ourselves to the following: Humerus traction arm splint for injuries of the humerus, injuries of the elbow joint, and upper part of the forearm. Its application is very simple and requires only a few minutes. One mistake frequently made is in bending it to the chest. Up at Verdun I saw a large number of cases not properly splinted, although the splints were well applied as far as traction went. When I was in Paris in September we had one case in there which had been splinted for about three days. It was under extreme rush conditions following the St. Mihiel drive. This man had been splinted very well except for one point, and the pressure on the brachial arteries had cut off the circulation of his arm, and he lost his arm because of that. That was not the fault of the division; it was the fault of the evacuation hospital. I don't see what right the evacuation hospital has to criticize anybody; we see cases of poorer splinting coming into base hospitals from the evacuation hospitals more frequently than I have seen similar cases leaving the division for the evacuation hospital. That is certainly due to carelessness or possibly to the extreme rush of work they are laboring under; but saving this man's arm was worth more care than was being paid to the cases. So the one necessary thing to do with that splint is to put a band extending from the chest below the union of the arm bar where it unites with the circular ring around the chest, through the other axilla, and fastens to the back of the splint at some point. That prevents any chance of this ring coming up against the arm. Another thing that they frequently do

is to put in a lot of wadding, thinking they are going to get a pressure there. Then in transportation you bring the arm down to the side. You might as well stick your fist in there and press the arm down against it. You shut off the circulation. That is poor judgment. You are protecting in one case and hindering in another. So never forget when you apply that splint to tie it down with some sort of apparatus. The triangular bandage is an excellent thing for that. It is just about long enough to tie below and back. But the bandage must be strong and fairly wide so as not to cut into the flesh.

Now the question of injuries of the forearm and hand. We tried to get the Jones cocked splint, which is a very good splint, but it has been impossible to get them in sufficient quantities, and we found that the wire-ladder splint, bent to meet the special requirements of the case, has proved equal or even better, if properly applied, than the Jones splint for wounds of this part of the arm. The wire-ladder splint can always be obtained. It comes in about 3-foot pieces. You can keep them in dressing stations. I think they will be good things to keep in our offices back home. I am going to throw away my wood splints when I get back. You cut it in two, make it just long enough to go from the elbow to the fingers. You can make it any angle you wish. You can put up one in front and one in back—fix it just the same as a plaster. Just fasten it with a couple of strips of adhesive and it works wonderfully. I think that is the only proper dressing for anything below the upper part of the forearm. Of course, you want to carry all these arms in slings.

These are the splints we have been using in wounds of the forearm and arm. It is very simple to teach the application of these splints to your enlisted personnel and to your new medical officers, and get them so they can do it perfectly well and perfectly easy and it takes very, very little time.

Now for the leg. For the leg we use Thomas traction full and half ring splints and the Cabot posterior wire. The Thomas full-ring splint has been rather difficult to get and has been taken up generally by the bases. In the last drive we were not able to get as many Thomas full-ring splints, so we used the Thomas half-ring splint. It is much more convenient to carry. It takes up a great deal less room and is not so apt to be broken as the full-ring splint. I would advise that it be used entirely within the divisional area simply because it is lighter, easier to transport, and it is practically as efficient for divisional work. The great advantage of the full-ring splint over the half-ring is that it is a little better provided and you can slip it well over the leg. It is a little bit firmer than the half-ring. The uses are the same, of course; injuries of the hip joint, injuries of the shaft of the femur, injuries of the knee joint, of the upper part of the leg, and also for large wounds of the soft parts. It has been proven that, even if you haven't a fracture of the bone, the man is more comfortable and you get better results. If you have a large wound of the muscle of the thigh, for instance, if you apply the same sort of dressing without any splint, and then over that apply the splint, the splint has a tendency to hold the muscles relaxed and keeps the part from moving; the moving, of course, is what hurts. The three important points of the application are, first, the proper applying of pressure upon the tuberosity of the ischium. Of course, in getting traction you have to have traction on your feet and countertraction at the head, and the countertraction is obtained by the pressure of the ring of the splint on the tuberosity of the ischium. One of the greatest faults is that you allow the ring to slip up over the tuberosity. Then, of course, you lose all your traction. Be sure that you feel your tuberosity and apply the ring to that; then apply the traction and it won't slip.

The second point is the traction anklet. One thing that the men have a great tendency to do, and I don't see why they should, is to remove the shoe. I should think it would be the last thing you would want to do. It takes time, it hurts the man, and there is no excuse for it. The canvas anklet which was developed and carried on every splint was made to fit over the field shoe, and if you don't leave the shoe on you have to use the foot. That is one of the common mistakes made in the application of this splint. They would take off the shoe and wouldn't put in any cotton; the anklet didn't fit, and it caused undue pressure on the foot and shut off the circulation.

The third point is the method of supporting the limb. The simplest and quickest way to apply the Thomas splint under field conditions is with three triangular bandages. Take them and fold them as you would fold a cravette, about 4 inches wide, and apply one of them

behind the middle of the thigh. It passes through under the thigh and over the two side bars, and then down around the back of the leg again, then it crosses and ties in front. That makes support from behind and support in front. Apply one in the same manner at the middle of the thigh, middle of the leg, and at the knee. That's all the support you need; you already have on your little dressings, and you put a circular bandage around splint and leg. Of course, it is necessary to support the leg on the litter bar.

Now for wounds of the lower part of the leg, below the knee, the Cabot posterior wire has been used and we have been able to get them most of the time, and that makes an excellent dressing for anything below the knee. They are kept in readiness at your station. The only points that need to be emphasized are the pressure pad behind the ankle and behind the knee. You see a man coming in with a Cabot posterior wire without pressure pads and he either complains of pain in the knee or pain in the heel. One is due to application with the knee too straight; the other is due to pressure directly on the heel. So be sure to put a pad just above the heel and on the knee.

They have developed three different appliances for applying traction to the foot. One was a shoe hook made with a string and applied directly to the side of the shoe. You cut a bandage in two and twisted it up. That was pretty good. Then they tried all kinds of things, but nothing has been developed to equal the original canvas ankle applied directly over the shoe.

It might be interesting to detail the movement of a compound comminuted fracture of the femur from the front line back through the divisional area. First, he is picked up by the first-aid men, who are with their companies, or by some of his comrades, and there you see all kinds of primitive applications of splints—the rifle barrel on the outside of the leg, a bayonet on the inside makes an excellent splint of the femur. They come in with a rifle barrel running under the belt without a first-aid bandage on, or they will apply it over the rifle barrel. Then inside they will stick the bayonet. That makes a very good dressing and with that dressing they come into the battalion dressing station, and that is where the medical officer first sees them. If the medical officer is not working under too heavy artillery and machine-gun fire, the Thomas splint is applied, usually not by the officer but by well-trained enlisted men. Let me say here that the efficient medical officer in the front line depends on them entirely—on the enlisted personnel. He can not possibly dress every case; he can't do any more than see them. If he is on his job he will train the enlisted personnel during the rest periods and then they can apply them as well as he can. Morphine is given if needed, and immediately he is transported to the ambulance dressing station. There the splint is inspected and necessary changes made. At the triage he is seen by the orthopedist and inspected and corrected after his ambulance ride. Thus you see the wounded man gets careful attention at every station. At the battalion station this attention depends greatly upon the protection from enemy fire and the number of cases passing through, and in many cases it is very meager. At Chateau-Thierry, in July, my battalion evacuated 600 cases from the zero hour (15 o'clock) to midnight, working in a ravine within 1 km. of the actual fighting, and you can easily see how much time was spent on an individual case, for two reasons—first, it was impossible, and, second, not wise because the most important thing was to get the patient out to a safer place before extensive treatment was attempted. Many interesting cases were seen during the drive, and one of the most interesting from a medical point of view was on the 22d, when a detonator from a "77" embedded itself in the bony part of the elbow of a man and remained there. I simply applied a wire splint, bending it to the angle the arm was, and sent him back. As you know, a detonator is the head part of a shell which contains the mechanism which causes the explosion. This usually flies off more or less intact and this man got it. One reason why I didn't remove it was because I was afraid it might be followed by hemorrhage. Besides I was busy and some one else could do it better. Ambulance stations are always larger and more protected and adapted for better work, and it should carry on the work done in the battalion station and improve upon it. Shock should also be treated at this station.

During the last offensive we were located north of Verdun and I saw all the fractures. We were located out of range of the smaller guns, in an old barrack. We also treated shock cases in a specially prepared shock room, and it was great to see the cases come in there in as

good condition as they did and it was greater to see them go out. Occasionally a man would come in with a poorly applied splint. We took it down and properly applied it and sent him on, and he was perfectly comfortable and went out feeling fine.

The work of the division orthopedist may be divided into work at rest and in the trenches. At rest, the divisional orthopedist has a pretty easy job, a sort of consultant to the division surgeon and to the men in the division. We have to see all the orthopedic cases that go through the divisional hospitals, consulting with the men on duty at the field hospitals. We have to advise the division surgeon from time to time of things which are going wrong within the division. In the early days before we went into the trenches the first time, the flat-foot question was a big proposition for the orthopedist during last winter. The cavalry, you know, were changed into machine gunners and the men in the cavalry didn't like that because they didn't want to walk, and we had a lot of trouble with them. So a large part of the early orthopedic work here in France was with flat feet cases, and they developed training battalions for them. When they were on duty they were not carried as sick; they were carried as on detached service, and in this battalion there was a line officer and one medical and orthopedic officer. There they could give them special training. Some were sent home and some were transferred, and the others went back to their organizations cured, and it worked out very well. At Neufchateau last winter, before we went into the trenches, we ran a camp hospital and really did a limited amount of surgical work and a lot of orthopedic work; and as the orthopedic work decreased, the surgeon at this training battalion was the orthopedic consultant of the division. We did almost everything and got away with it. In those days there were only few Americans here and we did a lot of things. The training of medical officers and enlisted personnel is another thing. When the new replacements came in we made sure they were educated in splinting. Men who are perfectly able to do good splinting in civil life may not know anything about it under war conditions, but they soon learn and do very good work. Another way is to check it up. A man comes into a triage and he has all poorly applied splint. It was my custom to see them apply the splint, and if two or three cases came in not properly splinted I took it up and found out the cause. It was surprising to see how quickly they corrected the conditions. It was a good thing for the men, for the patient coming through, and a good thing for the service.

During the time of a drive the division orthopedist stays with the other divisional consultants at the triage. That is the sifting station. He supervised the splinted cases and checked them. You are on duty 24 hours out of 24, and frequently it runs up to 6 or 7 days with little sleep. There every case is gone over, the splints are carefully looked over and reapplied if necessary. You frequently find there cases where the splints have been applied for some time and where for some reason circulation has been cut off, either from tight dressing or some other cause, and these cases you have to take down and reapply the dressing.

As to the equipment of the battalion aid station: The medical supply officer and the divisional orthopedic surgeon formulated from time to time circular letters setting forth the equipment that should be carried by each individual unit of the Medical Department. This was so that every one carried just the right amount of equipment, as far as I was concerned, for splinting.

The most difficult thing that we have had to contend with is the condition of trench foot, which was just developing in our division in the last days of hostilities. Wet and cold are predisposing to the development of trench foot. There developed 35 or 40 cases, which are altogether too many. They wore the shoes too long without removing them; they had been in shell holes for several days where they couldn't move from morning to night, and of course their food was poor, and they also went in some cases from 15 to 20 days without removing their shoes.

Army Sanitary School No. 169.

THE MEDICAL SUPPLY OFFICER OF A DIVISION

By Major Walker, M. C., United States Army, November 27, 1918

Our medical supply depot of the 26th Division, during engagement and during rest periods, had its location, as a rule, in the same town as the sanitary train. We have followed in our division the Tables of Organization in that the medical supply unit is attached as a part of the sanitary train. Most of the divisions I have found have carried the medical supply unit with the headquarters of the division surgeon. Our depot was situated with the sanitary train, as a rule about 8 or 10 km. back of the front line. Our unit was lucky in obtaining in nearly every move adequate quarters for supplies and for the personnel. We were very lucky as a rule in getting out ahead of the other fellows and finding a roof where we could shelter our supplies, although some towns were very destitute of good buildings, and at times it was rather difficult. We carried, in addition to the medical and surgical material, the divisional dental supplies. Our personnel at first was rather large—21 men—due to the fact that the medical supply replacement depot of the 26th Division was the second medical supply unit in France, the first being the base at Cosne, and the second the 26th Division. Thus we had our supplies from the seaport in earload lots, and furnished supplies to the other divisions. I think we furnished the entire supplies for the 2d Division and part of the 1st, and I have helped equip several supply depots since. This was during the latter part of the year 1917, when we were stationed at Neufchateau. The depot at this time was too large for the position and immobile. A medical supply unit should be mobile and easy to handle. Our personnel was reduced to 13 men, exclusive of officers. The personnel consisted of 2 officers—myself and a lieutenant of the Dental Corps—a sergeant, first class, a sergeant, 2 wagoners, a dental assistant, and 8 privates, first class. Our material and transportation consisted of about 7 earloads, or 15 trucks, and that was an unwieldy amount of material, too much involved, too large, that we have reduced it until at the present time we can transport it on two of the 3-ton English trucks. These trucks have done us service since we have been in France and are still running; they have probably covered more miles than any truck in the 26th Division; and, in addition, we have a light Ford delivery car. The lieutenant of the Dental Corps, with his assistant, has charge of the filling of requisitions for material required by the dentists attached to the divisional units and the divisional field laboratory; all supplies for the same being requisitioned for by the medical supply unit, accountability and responsibility being carried by the commanding officer of the medical supply unit.

The first requisite on moving into a sector and establishing is to get a line on your sources of supply. In the early days of our participation in this war the base medical supply was so far away, and the delay in getting requisitions properly indorsed and the French railroad system so slow, which you probably know, great inconveniences were experienced; but as time progressed this difficulty was obviated by the establishment of army medical parks, or dumps, as they were first called, but later changed to parks, 15 to 30 km. in the rear of the front line. After leaving the Chateau-Thierry sector I was able to go direct with my outfit to the army park at Vaubrecourt and get what I needed and consumed only half a day's time in the transaction, whereas before, dealing with the slow railroads and delay in transportation, there is no telling when we would have got it. This cut off the necessity of carrying a large stock on hand. The supplies were supplied on requisitions signed by the supply officer of the receiving unit, simplifying the transaction a great deal. The medical supplies of the supply unit need to be considerable in amount and the supply at times considerably varying, depending upon the number of attached troops. We have had at times as high as 45,000 men to cover. When we were in the Toul sector we had engineers and other outfits, aviators attached, in addition to our men which we covered to make 45,000 troops. So if your base of supply is far away you have to be foresighted to see that you have a fair amount of stock on hand. The essentials of a depot, as in all other cases, are a good sergeant, a good man with the typewriter to keep your paper work cleaned up all the time. Although accountability was supposed to cease in the advance zone of operations, we made it a practice to keep our accounts

just the same, thereby avoiding possible trouble later in life. It is a great deal better to keep it up in the old way than not to keep any accountability and then perhaps two or three years after you get home put in 10 years trying to settle it, and you will have to work quite a while to get enough money to pay for this material; and although accountability was supposed to cease after we left the Services of Supply, yet I maintained it all the time. I can not enumerate all the articles carried at our depot, or the amount of each article, for they vary with the casualties, be they great or small.

I must pay a tribute to the American Red Cross for the assistance rendered me in the way of supplies in the Chateau-Thierry sector. The Red Cross people carried a good stock of dressings, blankets, and 1, 2, and 3 front-line packets, so that every night I went to the storehouse and looked over their stock and was able to cover myself if anything came up in the night and I ran short.

The first important duty is to have the medical personnel of the entire division properly equipped. The work of supply in the sanitary train is taken care of by the supply officer there, he having under him two lieutenants, one for field hospital section and one for the ambulance section; they collecting requisitions from their four organizations and consolidate and turning into him for consolidation, and he getting the material from the medical supply depot and delivering it through his assistants to the organizations under him, thereby doing away with officers from four field hospitals and four ambulance companies or sergeants or messengers running to the medical supply all the time. "You find they like to run down there; it kills time and they like to talk, and it bothers you a great deal. You can simplify matters by keeping everybody out and thereby saving time and patience of too many members to the transaction. The divisional sanitary units, exclusive of the sanitary train, send their requisitions through the ambulance companies and they deliver direct to the line. Nobody in the division was allowed to do business with the Red Cross except through the commanding officer of the medical supply depot. We had little difficulty in getting supplies and practically no complaint from front-line units. All organizations were supposed to be fully equipped before going into combat. Supplies needed during engagement are blankets, litters, dressings, 1, 2, and 3 front-line packages, antitetanic serum, a good stock of 10 c. c. syringes, morphine in ampoules. This is to be used only in front-line work and in ambulance dressing stations. If you have one of the field hospitals operating as a severely wounded hospital, another as a gas hospital, a third as a triage or sifting station, and the fourth as a hospital for slight sick, oxygen, gas equipment, and a line of drugs is necessary. The amount can only be determined by experience and the number of casualties in an action. Sector troops on the offensive need large quantities; troops on the defensive need large quantities, particularly when under constant shell fire. Instruments, ligatures, ether, sterile dressings, adhesive plaster, aspirin, etc., all have their place, but drugs are only a small part and are of secondary importance. A carefully prepared list of splints carried by the ambulance companies and field hospitals and a minimum carried as reserve by the medical supply was proposed by the division orthopedist. Each sanitary detachment in a division had a certain number of different splints which are carried with their combat equipment, and this list was made up by the division orthopedist and approved by Colonel Porter, the division surgeon. The splints carried were the Thomas full-ring leg, Thomas half-ring leg, Cabot posterior wire, the Thomas hinged arm splint, Liston splint, Jones splint, ladder splint and litter bars, foot pieces, triangular bandages, muslin bandages, cotton rolls, adhesive rolls 1 inch and 2 inches wide, straps and buckles, dressings, medium and large paper clips, etc., and every organization had all these. So we were very fortunate. I used to take a little time going around to the supply depots and seeing what they had on hand and find out when a car of supplies was coming in, and if I needed anything I put in a requisition for it and got the supplies as soon as it got in. The things supplied by the Red Cross to the men in the front line were a world of comfort to them, and we should not fail to mention the cigarette not supplied by the M. S. U. The great difficulty is in maintaining a stock of blankets, litters, and splints—three essentials in the evacuation of wounded—and unless you have a good noncommissioned officer on the job at the triage to see that the ambulances bring back from the evacuation hospitals the replacements for litters, blankets, and splints as they go down, you are going to lose your whole stock. He may have to keep right on the job all the time during activities;

otherwise you lose your stock. There are other divisions in the front as well as yourself, and they are entitled to just as much supply and everybody should be fair and square about the supply game, and if you lose out on that you can not get certain splints, because there were times when it was absolutely impossible. We went weeks without a Cabot posterior splint and couldn't find one anywhere, but later, as the supply parks got nearer to us, they were fully equipped with splints, so in the St. Mihiel and in the Verdun sectors we had plenty of splints of all kinds. But if you have some one at the triage looking out for the ambulances bringing back just what they take down on the patients you will keep your stock up, and that's what you have to do. Blankets, litters, and splints are the three things you have to have outside of dressings. Dressings you won't be bothered with, because you can get them from the Red Cross and they have plenty of dressings; but the other three essentials are things that you have to have, and unless you are extremely careful you are going to find your stock gone and then you are high and dry. If the supply officer is alive he will keep after everybody concerned, and when his division goes into repose he will have the satisfaction of knowing that his stock is complete. You must see that the sanitary units do not overstock. There is always a habit in men to get all they can and when repose comes equipment A is all that is to be carried, and the extra supplies will be turned back to you for salvage. So I got to know the medical officers of the division and how far to check over their supplies. As the division advanced in combat it was very necessary to establish an advance depot in close relation to the triage. This depot carried only the necessities for active work enumerated before as essential. All supplies were issued to organizations on memorandum receipt. Some clothing was carried for gas cases, and also material for lights to do night work in the ambulance dressing stations, etc., such as carbide, candles, Prest-o-Lite tanks, etc. Replenishments were made from the main depot.

On the Chateau-Thierry front it became necessary to establish a second advance depot. A one-half truck load established an advance station. It was quickly loaded. Experience told me what was necessary. Dressings, 1, 2, and 3 bandages, candles, etc., sufficient in amount for four to six patients, put up in sandbags and sent up by the ambulances on their return trip to the ambulance head, and these bags of supplies were turned over to the litter bearers who took them to the collecting head. It was extremely difficult with rapidly advancing troops to keep them supplied, but they always had plenty. Our medical supply unit was nearer the front line just before the St. Mihiel drive than any depot before—about 5 miles. When we go into rest the units are reequipped all ready for resumption of activities. The number of litters carried by the division is 1,380. In addition to that, just before we went into action it was increased from 300 to 600 American litters if I could get them. The blankets I used to carry at the field hospitals, at the ambulance companies. They are supposed to have their designated number of blankets, and I used to have requisitions in, as a rule, for about 2,000 blankets and I drew these and handed them out. During an engagement I would probably draw four to five thousand blankets. I know of one division in 10 days in action used 15,000 blankets and 5,000 litters, but they evidently had not had replacement of blankets and litters. At one time I drew 1,710 blankets, and when we cleaned up I had 1,893; so I was long on blankets. Therefore, when we went into the next area I had my stock on hand and didn't have to bother for any supply. Of course, where you carry that amount of stock you have to have a lot of transportation, and if you had to move, you sometimes had to make two trips, unless we went some distance and moved by train. You can carry on two trucks all that is necessary, and what's over you can salvage before you make the next move. We started out with 15 trucks or 7 car loads and we are now carrying two trucks and carry our complete equipment. We salvage practically all blankets, every splint, all the dressings because they are of no use now that the combat is over.

As far as I can ascertain I am the only medical man who is the commanding officer of a medical supply unit; in the other divisions they are Sanitary Corps men; and I maintain, and justly I think, that the medical supply officer of a medical supply unit should be a medical officer. Although you may have your supply officer a Sanitary Corps man, who has been a medical sergeant for a number of years and knows all about supplies, but there is something about it that I believe a medical officer can do better work and keep up the supplies and look out for the future needs of his division.

Army Sanitary School No. 171.

PROBLEMS OF THE REGIMENTAL SURGEON—THE DENTAL SURGEON AS AN AUXILIARY
MEDICAL OFFICER

By Col. Philip W. Huntington, M. C., United States Army, December 7, 1918

When I came down here, gentlemen, I hadn't expected to have the pleasure of addressing the dental class, and I am mighty glad to talk to you. I haven't prepared any notes for a lecture to the dental class and what I have to say is mostly in regard to the medical work of the division in combat, but I think it will have considerable value in connection with the Dental Corps because—at least in my division—the dental officers during combat performed exactly the same duties as the medical officers. In the 79th Division the dental officers during combat serve as auxiliary medical officers. They were attached to the battalions and they went forward with the battalions and functioned in the battalion aid posts, regimental aid posts—or wherever their services might be needed—and performed exactly the same duties as medical officers, and I might say, as I told Colonel Boak, they performed very satisfactorily, very creditably, very well. I have been division surgeon ever since the Seventy-ninth was organized and am still, and the work of the dental surgeons has not been confined to dental work entirely. They were used in a military medical sense; I had that idea from the very beginning; I felt that if they were going to be called upon to do the duty of auxiliary medical officers they were entitled to training, and I proceeded to give them training ever since the division was organized. I commenced training the dental surgeons along the same lines for field work as the medical officers. They were given all the training possible without forgetting their specific professional duties.

I thought it might be of interest to you to tell you of one fight my division was in. On the 15th of September we were moved up into line just on the edge of the Argonne Forest. We took part in the big drive up there commencing on the 26th of September. We were in the Fifth Corps. There were three corps in there, from the west bank of the Meuse to the Argonne Forest, and our division was the middle division of the middle corps. Although it was our first time in the line, and some of our men had not had a shot fired over them, we were fortunate to be assigned to a central location in the attack and to take as our objective the strongest and most fortified town in the whole line, the town of Montfaucon, which was afterwards taken by our division, and I think it may be of some little interest to you to tell you something about this engagement and in that way possibly I can make it a little plainer and a little clearer and show you just exactly what the situation is with a division in the field in combat, in open warfare. I have drawn a little sketch here to show you as well as I can some of the salient features of that particular fight.

The First Army at that time had 9 divisions—3 corps of 3 divisions each, and the army was occupying a front of about 20 km., so you can see that each division had a front of only about 2 km. or a little over on an average on the jump off. Our division, like so many American divisions, became separated from its artillery brigade. It came over here but has never joined us. But this time we were furnished French artillery, and such a concentration of artillery I have never dreamed possible. It was stupendous. I never saw anything like it. It was one of the most impressive things I have ever seen, to go up there through those woods in back of our line and see the artillery in there. This was a woods in here [indicating]; it was just jammed full of French artillery. I never saw anything like it in my life. We had behind us about 300 guns and most of these were long 155's—6-inch rifles. It was extremely interesting to go through there and see them—to see the French, their way of living, etc. These 6-inch guns were manned by bluejackets, officered by French Navy officers. Well, this was the situation with our division. This little town here is the town of Avocourt. This is the town of Haucourt, and this red line I have drawn here indicates approximately the position of our first line at the time of beginning of operations, on September 26. Before that time we were back down over here and our division post of command was at a little place called Caesar, which I have indicated here by this red mark. On Monday the 25th and the morning of the 26th, the artillery barrage began at 11 o'clock on the evening of the 25th and continued right up all night long. We were living here and the artillery was all

around us. There were 12 or 15 of these 6-inch rifles within 100 yards of us and they nearly lifted us out of our dugouts. They were laying down a barrage across the German lines here and they were also punishing this town of Malancourt and Montfaucon, while on the morning of the 26th, when the troops made a get-away, they got across here and met very stiff resistance, mostly—as the Germans have been doing all along there—from machine guns, and we had some very heavy losses going through this No Man's Land and going up through the edge of these woods in here. You notice these woods give a fire almost directly against our front line, and when our troops got up here [indicating] they got enfilading fire from this place. It was a very hard proposition indeed. Well, we went along and by the evening of the first day we had gotten up about where I draw this line here [drawing line], in the northern end of the Bois de Malancourt. Of course, I had to make other sanitary dispositions, different from those we had needed in trench sectors. I had my sanitary units all placed, but as we advanced I had to make other dispositions, which I did, and the farthest fixed unit was an ambulance dressing station just north of Montfaucon, just side of this road. The wounded were coming in in very large numbers and there was a great deal to do. This road from Malancourt to this junction was used not only by our division but also by the division on our right, the 4th Division. The traffic was very, very heavy and made the roads almost impassable. The next day we went along and took Montfaucon. We had again very heavy losses, particularly from machine-gun fire. This town (Montfaucon) the Germans called the Gibraltar of the Argonne. It was extremely heavily fortified. It is a perfectly round hill; slopes up like this [illustrating], and was originally was quite a large town. It has been under artillery fire for a long time, however, and is knocked to pieces. It was full of reinforced concrete machine-gun posts, observation posts, and all kinds of strong places. Incidentally, there is an observation post in the ruins of a church, a very remarkable one which is said to have been occupied by the German crown prince during the Germans' attempt to take Verdun. It has a wonderful view; you can see the country for miles and miles. I have been in it a number of times. Well, as I said, we suffered very heavy losses here. The Germans had just plastered that town with machine guns and all around it; and, incidentally, gentlemen, as I was saying to Colonel Boak last night, you may have read in the papers about the morale of the German Army being destroyed and being down in spirits because they were licked. It may be so—I don't know; but those we had up there had all the morale that was necessary for them to fight and stick, and they did stick, and don't let anybody tell you anything else. You have to hand it to them; they are the greatest machine gunners in the world. When a crew will stick with a machine gun and let two or three waves of Infantry go over them before they turn loose, they are "there" and they will stick and fight it out.

Well, we kept on going and got past this town. We were in the line altogether six days. Now after we got up about here the traffic over these roads bringing up material, bringing up ammunition, bringing up food, etc., became so heavy that the roads just simply couldn't stand it. This road from Avocourt to Malancourt—you hear of roads being a series of shell holes; this was a ditch, it was all shell holes, many of them overlapping each other. Our division engineer estimated that it would take 8,000 tons of rock to rebuild that road. But they had to run over it, and then ran over it anyhow, as it was. The traffic came up this way from Montzeville to Esnes, to Haucourt, to Malancourt, and going back it went down here to Avocourt, and so on. That is, theoretically it did that; practically it flunked. We had one traffic jam that stands out particularly in my mind because it lasted 48 hours. Absolutely. For 48 hours solid there wasn't a wheel turned either way. Now if you can imagine any more hopeless and helpless feeling than to be a division surgeon and have two or three thousand wounded on hand and have sent your ambulances full of wounded 24 hours ago and not see any of them come back, and have a complete road block on your hand—I don't know what it is. That's the proposition we were up against. Now this is getting pretty far away from dental surgery, but it has a bearing just the same. Now that road block was due to two things: One of them was that we didn't have enough engineer troops to build and repair these roads quickly enough; the other was that we didn't have an efficient and properly instructed military police force. I don't know whether any of you gentlemen have had very much in the way of experience with military police matters, but unless we can improve on our system of military police, traffic control, before another war, I am in favor with doing away with

them altogether and putting some of these wooden Indians on the job. We have got to have something done in order to control this traffic, and it isn't just enough to just post these men at crossroads. My idea is that we should have men making constant trips up and down the roads so when a traffic jam starts there will be somebody to handle it. Here is the way it starts: A truck tries to go around a wagon ahead of it and another truck is coming the other way and they meet. Neither will back up, and they commence to swear at each other. Other trucks come up and there is a traffic jam. Now, if there is somebody there nine-tenths of these traffic jams can be eliminated; and I speak feelingly of it because these traffic jams were responsible for the loss of hundreds of lives. Absolutely.

Well, as I say, we were getting lots and lots of wounded and we had a large number of them in this wood right here, just east of Montfaucon, and as I told you a minute ago, all my ambulances had gone back to my field hospitals down here. It took them 60 hours to get back. They don't tell you about that in the book, but that's what happens, and I didn't have a thing, not an ambulance—not one motor ambulance, but, luckily, Heaven be praised, luckily I did have some hard-tailed mules. I have been a strong advocate of the animal-drawn transportation in the Medical Department ever since I have been in it. I knew I was right then, and I know I am right now, and anybody that tries to talk me out of it has got to throw me down. They will and can go where motor ambulances can't. Some people say it isn't so, but I know it is so—I have done it. These little Ford ambulances work under certain circumstances and will go over rough ground, but there are places where a Ford can't go. Well, I had these mules. This road jam showed no signs of opening up. I had to do something. I couldn't send them back to the field hospital and what I had to do was to bring the hospital up to them, and I did. I sent back to my advance medical supply depot—by the way I had my medical supply officer move all of his divisional medical supplies up to this place here—and I sent back word to get two field hospitals equipped and loaded in these animal-drawn ambulances and brought it up to the crossroads—over barbed wire and through shell holes; while this road block was on we came across No Man's Land here—and that was a hell of a place, too—and we came on up to here. By that time our division post of command had moved up to this junction of the road to Montfaucon and Cuisy—Cuisy Junction. I brought this field hospital to this place, the southern edge of a wood, and I put them in tents. Luckily I had a hunch before this thing started, and I got a lot of paint from the Red Cross and drew on the top of the ward tents big red crosses. I got these tents pitched and I put the wounded under them. We had about 600 wounded, and I got started in the evening. Just about 15 minutes later a hard, cold rain started in. I don't know anything that made me feel more relieved than to know that these poor wounded men were under shelter, out of the rain, and getting attention. We were evacuating down to Malancourt and from there we carried them on litters to Avocourt, about 6 km. That's the way we got them out. Well we had been running these two field hospitals here—by the way, the road went along like this [indicating] and I had my hospitals pitched about like that [indicating]; this representing the white tents, and back of them I had some small conical tents and some wall tents that I was using for dressing, operating, etc. These tents [indicating], as I say, had big red crosses. Well the next day—I got it working about 4 o'clock in the afternoon—the next day at about 2 o'clock a boche airplane came over and—incidentally, I don't know whether you gentlemen have read in the papers about the supremacy of the air. You have probably read about that; and while this is another thing that I don't question—it may be so, but I have never seen it—the allied supremacy of the air doesn't happen whenever I am around. It may be along other parts of the front, but I haven't seen it. Well, anyhow, this boche aviator came over about 2 o'clock and he wasn't 100 m. in the air; you could see him very plainly—I could see him looking over the side. Well he flew around there for about 15 minutes. There wasn't a combatant unit closer to us than a kilometer; there was a machine-gun battalion in here; that was the closest thing. About 20 minutes after this boche aviator flew away the shells commenced to come in over here. Now, those people can shoot; they hit where they shoot. They weren't shooting at these little tents; they were shooting at the ward tents and they hit them every time. They threw 35 high-explosive shells into that hospital in about 15 minutes and they made direct hits. They didn't hit these [indicating]; they weren't shooting at them. Well, I don't know whether any of you

have been in that situation. It is bad business. We had about 600 patients in there and I imagine, roughly, about half of them were walking cases. We told them to go and they did. They came across lots here. They hiked right out; they didn't wait to be told again. But we had about 300 patients who couldn't walk—severely wounded, fracture cases, etc. Of the patients in the hospital the boches killed 16 and they killed part of my personnel. And if you can imagine a more complete pocket edition of hell than what we had there—I can't, that's all. It was the worst thing I ever saw in my life. Well, it is a perfectly remarkable thing to see how a stunt like that brings out what's actually in a man; what's really and truly in him. It was most remarkable. There was one of my sergeants—I was right close to the place at the time the thing commenced. I was right here at the division post of command when they commenced shelling and I came out and saw what was taking place and got there just before it was over. This sergeant said "Colonel, I am yellow as hell; I am scared to death; give me something to do." And I did. I told him what to do. He was one of the bravest men I ever saw, as a matter of fact. There was a little French interpreter—I don't know where he came from, an officer of the French service—he came galloping down this road and jumped in and carried patients on a litter all afternoon. He was all polished up, shaved, clothes brushed, shoes shined—prettiest thing you ever saw—but he was right on the job and he worked. There was a little second lieutenant of engineers. I don't know where he came from; the first thing I saw of him he was working. These machine-gun fellows, as soon as the shells commenced falling, ran right across and commenced carrying. I sent up here and got trucks, water wagons, and the machine-gun battalion took them on litters down to here and so on, down to here. Well by that time it was dark, raining of course, and everybody was more or less scattered, but I had given orders to have these patients taken down to the old dressing station just north of Malancourt, and we did. We got them down in horse-drawn transportation that could squeeze down along the side of the road.

More troubles. There was a field in here and a battery of American rifles in here firing, and we no sooner got our patients down here than the Germans commenced throwing gas; they just completely filled that place with gas. Well, we were tired, but we couldn't leave these poor devils there—that's all there was to it. We picked them up and carried them down by hand, way down here [indicating] and established a field hospital there. Well about that time this road jam commenced to break up and my ambulances came back to the station and we were able to function. I established an aid station here [indicating] and another here on the road to Montfaucon, and the thing ran along a little better. This is a rather rambling narrative of the way the thing goes, but I wanted to tell you, to impress upon you the fact that these things don't go by diagrams. You can draw all of them you want to and it is the plan to work if it will work, but it don't always work, and when it don't you have to do something else. That's the point. It is up to you. And in my division, not once or twice, but lots of times, you gentlemen of the Dental Corps have been up against that proposition. It has happened time and time again that the only medical officer with a battalion was the dental officer and he would be entirely responsible for the organization. One of our regiments went in with a full quota of officers and came out with 2; one regiment lost 4 majors in two days. When you get in a thing like that you can not sit down and wait for somebody to come and tell you. You can't fall back on theory or what you have learned from books or diagrams. You have to say what's to be done and do it. Don't wait for somebody to come around; it's up to you individually and personally.

Now, there are several little points here that I want to bring out in regard to combat. This is very rambling, indeed, but some of these things are of interest, and from my point of view they are of importance. Now, you will hear a lot about gas. Well, of course, in this open war—and everything I am saying pertains to open warfare; please get that straight, I am not talking about trench warfare at all. In open warfare the conditions for the use of toxic gas are not as favorable as in trench warfare. You won't have projector attacks. Now among green troops particularly you will have a very large number of gas casualties that haven't had anything to do with gas. Very large. The men get tired, and I mean really tired—they are exhausted—and then a high-explosive shell bursts near them. They get a smell of the acid, which is very irritating, and they think they are gassed. They go to the medical officer. They are worn out. He thinks they are gassed, but they are not.

What they need is 24 hours' sleep, a meal, hot food, and they are all right. But you want to watch out for these people and don't send them back with an improper diagnosis. If you think they are exhausted, put down "exhausted." It is perfectly proper to evacuate a man for exhaustion; but, on the other hand, don't overlook the gas casualties if you can help it. It is very easy to overlook phosgene and mustard gas when they are new; it isn't after a couple of hours. Incidentally, if you are in a battalion aid post and the boche commences to put mustard gas in there, there is just one sensible thing to do and that is to go somewhere else. Move your patients out and go away. You don't want to stay around mustard gas. The only preventive against mustard gas is to go somewhere else. Now; you have probably heard about battalion aid posts and you may have to run one. I hope you won't, but you may. Our battalion aid posts were nothing except places. We had no shelter; no dugout. They were as flat as this floor and as open as this room. It was a place as favorable as you could find, a place to sort out patients—that's a battalion aid station, out in the open. So don't think you are going to have shelter and concrete dugouts and things like that, because you won't. I don't know whether you have or not, but I guess you have heard a lot about liaison in the field. They will talk to you about the necessity of maintaining liaison, which means nothing more nor less than communication. It's a necessity, it's a valuable thing, and ideal to be striven for; but it is exceedingly difficult to maintain liaison in the field in battle. On the other hand, if your division surgeon tells you that he wants you to keep him informed of where you are at all times, please don't think that the division surgeon is doing that to satisfy his own personal curiosity, because I assure you he isn't. It is merely that he may keep you supplied with material to do your work. Absolutely. It is perfectly astounding how hard it is to realize that if the division surgeon don't know where you are he can't send the stuff to work with. They used to come kicking, "I haven't this; I haven't that." I said, "Where are you; where's your station. If you let me know where it is I will send you supplies." Don't forget, if you are a battalion surgeon, to keep your regimental surgeon informed where you are. Then map reading. Learn to read a map and coordinate, so you can send a report to your regimental surgeon and tell him "Battalion aid post, 3d Battalion, is located at 26.7, 35-5," and he can find you. If you do that half of your problems will be solved because they know where you are. The division surgeon is more than anxious to keep the officers supplied with material and men to do the work properly, and if you let him know what you want he will get it for you if it can be done under heaven. Now responsibility for that rests with the front-line units. The division surgeon has only a small office, he has no runners; he can not send a runner to the battalion; it is up to the battalion surgeon to send runners to the regimental surgeon, and from him to the division surgeon. Now one of my regimental surgeons didn't let me know because the telephone wasn't working. If the telephone isn't working send a runner; if you haven't one send a lieutenant, and if you haven't a lieutenant come yourself. If the situation is such that you haven't any runners and there is no one to send, come yourself personally. You must let them know; if you don't you won't be able to do the work.

Now, another thing is the question of supplies. When you get in a moving engagement such as this one, you have such a chest to carry things in. That's very nice, but you haven't transportation for it. What you have to do is to take the stuff with you. Now you gentlemen in the dental service, you are going to be up there doing first-aid work, and you won't get much in the way of dental equipment to carry. You carry your emergency equipment in a little haversack. You need it. If you have a medical cart to put it on, put it on there. If not, you have to pack it on your back. The same way with the medical supplies. Some of my medical officers walked off and left the litters lying on the ground. They didn't have the medical carts. They had 48 men to take them up. If you can't do anything else, you can try what we did, and I think it a practical and good scheme. We went to the division engineer officer and got two bales of gunny sacks and I gave them around to the regiments, and when they went up they put some Thomas splints, bandages, A. T. S., iodine tubes, and things like that in them and carried them up. That was my ambulance dressing station. They carried the things in their hands, and they moved faster and did more work, and better work, than the outfit that tried to carry their whole equipment on transportation. So when you can, carry what is necessary. If you don't know what is necessary, ask the regimental surgeon. If he don't know, ask the division surgeon. Take what is necessary and don't let it get away from you.

Now that brings up the question—what was the burning question in movable warfare and that is A. T. S. and glass syringes, which are easily broken. Of course, you can give the A. T. S. with a hypodermic syringe, because we did it. But in my judgment A. T. S. should not be given by the regimental personnel at all. I don't think they even ought to try it, because when they get in a rush they don't do it; they can not do it, they haven't time; and half or more patients get back to the field hospitals without A. T. S. and you can give it to them there. Now why not give it all at one place, where you give half of it anyhow?

Colonel BOAK. Suppose you can not evacuate your patients for 36 hours?

Colonel HUNTINGTON.—Well, that's a good point, of course. There will be times when that happens. You will have a number of other dangers, too, which it is not pleasing to contemplate; but I believe in the thing, I believe it would be just as practicable as anything else. As a matter of fact, they don't do it, the glass syringes break, the A. T. S. gets busted in the ampules, and they have a deuce of a time trying to give it. It just falls down where you have a lot of casualties

Now that brings me to another thing, and that is the question of shock. Now, gentlemen, if you have a tent, if you have three litters and some blankets, and some solidified alcohol, which you should have in your gunny sack, you can treat these shocked patients. You probably have seen and have had explained the deshoeking apparatus. You can make a deshoeking bed out of three litters. Stand two litters up on edge and put another across, and put a can of solidified alcohol underneath and light it, with blankets over the patient. It works just as well as elaborate and expensive things. Now, I don't know how much experience you have had with surgical shock, but I want to tell you that from my point of view that is the most serious condition that we have in regard to wounded. If we can successfully treat our shock patients, including proper splinting, we will get away with our medical services pretty well. Lots of patients in our division died from shock—that's all there is to it. Personally, I didn't see but one death from acute hemorrhage, and he had his artery cut by a shell splinter, but I did see a good many people die from shock, and, believe me, shock kills them and don't think it doesn't. They died from it, over and over again, from comparatively trivial wounds. On the other hand, if you have proper antishock treatment you will save people whose lives you wouldn't believe it possible to be saved. It is perfectly astounding. When we had this field hospital up here I saw 50 patients in there for whose collective lives I wouldn't have given a nickel; I didn't think there was a possibility of their living; and five or six days later I saw 35 of them in splendid shape—lying in bed, smoking cigarettes, and just as happy as could be. I didn't think there was a possibility of one of these men living. Certainly three-fifths of them pulled out. What their ultimate fate was I don't know, but they got through the early stages, and just simply because they had proper deshoeking treatment. If they didn't they would have died. Now the contrast was impressed upon me very strongly at the time of this road block. I had patients all the way from here to here [indicating] in trucks and didn't have any ambulances, and they laid there for 48 hours in those trucks. I personally spent two nights walking this road from here down to Malancourt trying to look after these poor chaps. We brought up kitchens and gave them soup, coffee, cocoa, etc., and I took my director of ambulance companies and some men and we put in two nights there trying to fix them up. But I would hate to tell you how many we had to take out of those trucks and lay alongside the road. It was the most heartrending thing you could imagine. Every one, I think, died from surgical shock; every one of them. Don't forget it. We had one instance. One of my little Ford ambulances started from up there with three litter cases and when they got down here two of them were dead and the other died shortly after. And they died from shock. If you can get these people into a deshoeking cabinet, if you can get them hot food, preferably soup and bicarbonate of soda, and rest, and proper splinting, it is perfectly marvelous to see the way they come up; and, incidentally, they take soup or coffee much better than cocoa. I noticed a very considerable number of these shocked cases became nauseated after taking cocoa.

Now in another sector, in stable warfare, we were just north of St. Mihiel, at Troyon-sur-Meuse. There was a big ridge of hills there, and up here [indicating] is the valley of the Woivre, and our lines were on top of a hill, where you can look out over the whole world. The boche were down in the valley. It was the nicest thing to hold you ever saw, and that's all we were doing. I had an ambulance dressing station in a church at Dommartin, and by some strange

freak of fortune the boche had never hit that church. We had our dressing station in there, gas washing, two or three deshoeking tables, nice ones, and always three galvanized-iron tubs, filled with soup, coffee, and cocoa, and everybody that came in got some, whether they wanted it or not, and they likewise got a big, heaping tablespoonful of soda in the solution.

Now Goldthwait and Baer will tell you to train your enlisted men to put on splints. So you should, but that splinting has got to be supervised by an officer, and if you think that isn't so, you are wrong. If you don't you will have an inspector along asking why this man lost a leg from gangrene. That's a fact. But it's all right to teach your enlisted men to do it; they should know; but it is exactly like everything else. Take your paper work, if you sign your name to a report, you are responsible for it no matter if the sergeant did make a mistake; and if a man putting on a splint does it wrong you are responsible for it. Don't forget it. You have to check up every bit of that splinting and see that it is done right.

There is one thing that I do not want to impress upon you. We may some time get into this stable warfare again; we may get where we have battalion aid posts in dugouts or shelters, or something of that kind, and one of you may be put in charge of one of them. When you do, don't—please, gentlemen—don't sit down and wait for somebody to tell you what to do. But get busy and fix it up. Put in some deshoeking racks, build some racks out of scrap lumber to put your litters on, so that instead of having space for only one litter you will have space for four. Get your food situation fixed. Some one said something—I think it was Napoleon who said once, "There is only one military mistake which is unpardonable, and that is inaction." That's the only one. You may make mistakes; you may do wrong; but do something anyhow, because if you do nothing it is a hundred per cent bet you are wrong, but if you do something you have a 50 per cent shot at it. I can't tell you that with enough earnestness. I have had battalion surgeons of all kinds. Some of them would go in and sit down and think their responsibility was ended merely by the fact that they were there. And I have had other people who, as soon as they got there, would commence to use their head and see what they could do to improve their facilities so as to better help the patients when they were brought in. When you are in that situation try and figure what it is going to be for these people coming in and try to provide for them beforehand. I can not emphasize that too strongly.

Now, another matter that I think is a very important thing, and that is do not unnecessarily expose yourself or your personnel or your patients to enemy fire. There are lots and lots of times when you can not get shelter, but there are times when you can. But if you can not get material shelter in a dugout or something like that, try and get concealment. Very often a thick hedge is good protection against rifle fire as anything else because they won't see you, and it is your duty to protect the lives and limbs of yourself and your enlisted assistants and patients at every possible cost. Now right in that line there is another little point that I think is very important, and that is when you get out in this open warfare, when you walk across an open field, like this one here [indicating] and there are wounded lying all over, don't make the mistake one of my medical officers made. He started going around from one wounded man to another dressing them. By the time he got to the third one they commenced coming to him, and then he had seven or eight, and then had a hundred, and there he was—stuck; he couldn't move. Don't do that. When you have wounded to treat go and pick out a place. Don't look at them all. Pick out a place and stay there and have the wounded brought to you. If you start dressing them on the open field, before you finish with one you will have more, and you will have such a mess you can not do anything. This may sound trivial, but it isn't. Our experience has been that the Germans do not use artillery fire against one or two men, but they do against three or four or more. In all this sector you couldn't get out in groups of three or more without getting sniped at, and it was mighty uncomfortable.

Now it may happen that some of you may be on duty in a field hospital. In one division the dental surgeon was the triage officer. He received all patients, sorted them out, and said where they were to go. If any of you are responsible for that, use your utmost endeavors to see that the blankets and litters, hot-water bottles and splints that come in with these patients are replaced and sent back by the ambulance to the front. If you don't

the next day the poor devils are going to be out of luck, that's all there is to it; you have got to do it. The ambulance companies bring these people in there on litters. They are blanketed. They frequently put hot-water bottles on them, and they almost always have splints on them, and they came from somewhere and they came from the regimental surgeon, and he got gray hairs getting them; and if you don't send them back, if you don't replace them, the next day the wounded are going to be out of luck; they will be coming down without blankets, without splints, without hot-water bottles, and then there will be hell to pay.

Now, gentlemen, you can not do this business—all that I have been telling you about; you can not do it and get away with it successfully unless you have discipline. Discipline among your enlisted men. That's all there is to it. And let me tell you first of all the basic source of discipline is inside the officer himself. The officer himself must be conscious of his duty as an officer, conscious of the necessity of performing his duty to the best that is in him, and by setting the proper example to his men. If he don't do that no system of punishment will get discipline for him. So the primary thing is for the officer himself to realize his duty to his country, to his division, his regiment, his battalion, and his duty to himself; to maintain the very highest ideals of professional ethics and professional treatment of your patients. If you don't do it you will never get discipline out of your men, and I tell you you need all the discipline you can get. Absolutely. Don't forget that warfare—combat—is destruction; destruction of a personal and material nature; moral destruction; destruction of everything; and troops in combat do lose their personality, they do lose their material, and they do lose their morale. You take the best division that ever was and put them in a hard-fought battle and they lose the men killed, they lose material destroyed, and they lose morale. It happens right along. And unless you have discipline, which is not only the recognition of outward forms but really rests on the consciousness of a man's duty, you will never get by with it; you break down right in the middle of the thing. It is up to us as officers of the Army to do every possible thing we can for our detachment, to put discipline on that basis. Absolutely. I tell you you can not realize until you have been in the service long enough, you can not realize how much the enlisted man depends upon the officer under whom he serves. For example, when this hospital was shelled I venture to say that if the officers there had broken and beat it, and run out of there, I venture to say there wouldn't have been five enlisted men who would have stuck. As it was there weren't five of them that didn't stick. They didn't like it; neither did I nor anybody else, but they stuck and stuck right straight through and they did the job absolutely.

Now one thing that I was lucky enough to get in my division was assistance from the line. You know when you get a big mass of wounded the personnel you have in your regiment isn't big enough; you haven't enough men to handle it. So I got a division order in my division assigning eight men from each rifle company to be used as litter bearers during combat. They would be available on the call of the regimental surgeon. We called them out and used them and they were all right. They did the job and did it well, but don't forget that you have to have reserves. Now before you go into the battalion—if you are battalion surgeon—ask the battalion commander for them and he will probably demur and say he can not spare them. They say, "If I give you men for litter bearers there are that many less rifles." That's absolutely true. You can not argue that point. But tell him it is his soldiers they are working for—not you, and that you need them to take care of his personnel, and if he doesn't see it then, wait until after you got in combat. Then he will see it. I have had it happen both ways. But get the men if you possibly can, and use them.

Now there is one man in the division who has the hardest job to my mind of any medical officer in the division, and that is the director of ambulance companies. The direction of ambulance companies is a very difficult, very arduous, and very trying position; and the man runs around in a side car all over the place trying to make liaison, as they say, between the ambulance companies and the regimental medical personnel, and it is up to battalion surgeons to let him know where they are. Let the division surgeon know anyhow, because he can eventually let the director of ambulance companies know; but if you can get in touch with him directly, do it, because he is the man who moves wounded for you and he can not do it if he don't know where the wounded are. He is the man who works all day and all night and

he has the hardest job in the division. My director of ambulance companies says he can tell where he is in France by the taste of the road. But don't forget his troubles, and try, so far as you can, to make them as light as you can by keeping in touch with him and notifying him where you are, and how many wounded you have, and what class of transportation you need.

Incidentally that brings up one little thing and that is the subject of messages. I don't know whether you have had any instruction on that, but when you write a message use that little book for the purpose. The Signal Corps issues it. Gentlemen, when you send a message to the division surgeon to let him know where you are, or to the director of ambulance companies, or whoever it may be, make it explicit, and don't ever, ever send messages like this: "Send some ambulances to Haucourt for wounded." Now I knew where Haucourt was, but I didn't know how many wounded there were. I didn't know whether they were sitting or lying cases. Now that message, therefore, gave me no information. What I had to do was to get the director of ambulance companies to go up there and find out how many patients; how many were sitting, how many lying. What he should have written was "At 25.3, 75-6 I have 14 patients, 6 lying, 8 sitting." That's all I needed to know. That covered the whole thing. I could have handled the situation and would have sent up ambulances for his patients right away. When you write a message of any kind, put yourself in the place of the man getting the message. You know what you mean, but he doesn't. Make them explicit. You can send them by runners, by telephone sometimes, by these so-called buzzer phones; carrier pigeons. You don't hear much about carrier pigeons, but as a matter of fact in this Montfaucon business our best liaison in divisions was maintained by carrier pigeons, and it was the only way in which we were in touch with corps headquarters for two days. But if you can't send any that way you can always send by ambulance drivers, and this is the best way of contact. When we went into this fight my chief of staff ordered me to divisional headquarters, and I ran the whole thing from there, in a Dodge car. I didn't have a soul there except the driver—no clerk, orderly, officer, or anybody; none of my office, none of my assistants. That's the way I worked it—by stopping ambulances, giving the messages to the driver. Now, as I said, whenever you write a message, no matter what it is, make it explicit, giving your location, and make it definite.

Now a minute ago I skipped one thing in talking about discipline. There is one thing that you do want to do. If in an action any of your men have one particularly or markedly good work tell them about it. Don't forget it and don't forget to tell them, so somebody else will know about it. Get the men formed in rank and call the man out in front of the formation, and tell him about it right there. There is nothing that works so well for discipline and esprit as properly distributed discriminating praise for work well done, and if any of your men distinguish themselves in action recommend them for the distinguish service cross. I recommended some of my men and they are going to get it. The beauty about it is this: It is not only good for the man who gets it, but it is good for every fellow who didn't get it. He says, "You watch me; next time I will get it, I am going after it." It is the finest thing in the world, and after this Montfaucon business I took occasion to recommend several of my officers for the D. S. C., and others that I didn't think quite deserved it I asked the commanding general to write them a personal letter and he did—a fine personal letter; and we had them all lined up and I called out the noncommissioned officers and privates and shook them by the hand and told them I appreciated their services. I want to tell you about one case. By the way, I had five medical officers and two dental officers killed in this action. One of my medical officers, a graduate of this school, Lieutenant Marks, battalion surgeon; on the third day a shell splinter came along and cut off his moustache and bit a hole in his upper lip; didn't take it all off, but cut right through here [indicating]. He got down in a shell hole and put a couple of stitches in it and took a dose of A. T. S. and went back to work. The next day he got a machine-gun bullet right across the back of the head—practically through the muscles of his neck. There was a gutter in there about that long [indicating]. He got one of his corps men to put a dressing on it and he went to work and stayed with that battalion, and when it marched out he marched with them on his own legs. He is going to get the medal of honor if I can get it for him. One of the dental officers in the division was recommended for the distinguished service cross and he is going to get it.

Army Sanitary School No. 172.

THE DUTIES OF BATTALION AND REGIMENTAL SURGEONS

By Maj. S. Bayne-Jones, M. C., United States Army, November 25, 1918

In discussing the duties and the work of a battalion and regimental surgeon, I mean to take up the work both from the standpoint of a battalion surgeon and the somewhat larger standpoint of a regimental surgeon. I will limit the discussion generally to a regimental surgeon or battalion surgeon during an advance, during an attack, rather than spend much time talking about the work of a medical officer of that class during stationary action in occupation of trenches.

We have two distinct phases of work. The work of the medical officer in trenches in a fixed position is generally sanitary, and the same rules that you had for ordinary sanitation in the field apply in the trenches, modified by common sense as they are in the field. The principles of your conduct in an operation such as attack will be brought out more by telling about advances than it will be in telling about trench work—that is, if you know how to get along in what is called “open warfare” you can certainly attend to the evacuation and handling of wounded when in intrenched positions.

To speak about the duties of regimental and battalion surgeons in action, in advance, will be the chief purpose. Perhaps it would be well to relate briefly just what a battalion surgeon has to work with in the way of personnel and equipment, and what the regimental surgeon has to work with. A battalion surgeon, has with him a medical officer, an assistant battalion surgeon, and in our battalions 13 soldiers from the medical department. He has 1 sergeant and 12 men; and these 12 men with us, are divided as follows: 2 first-aid men to each company; that leaves 4 men of the Hospital Corps, and we divide these 4 between the 2 battalion surgeons, so that the chief battalion surgeon has with him a sergeant and 2 men; the other battalion medical officer has 2 Medical Corps men. The 2 Medical Corps men with company generally are attached to the company headquarters, and keep in close touch with the company commander.

In addition, the litter bearers are an essential element of the medical personnel of the battalion. At first it was difficult to obtain an adequate number of dependable litter bearers. Until an organization has suffered casualties, the need of numerous good litter bearers is not realized by the commanding officers. When we went in at first—early last year—the litter bearers drawn from the companies were, in many instances, men whose physical and moral defects were often sources of trouble to their company commanders. These litter bearers for several months were made to carry arms. They carried rifle and ammunition, and naturally were used for the duties of armed men. For example, two men were placed on sentry duty in a shell hole post for 36 hours, and were expected to carry wounded men 2 km. Under such conditions the evacuation of wounded was disorganized, as there were no men definitely available to be used for that purpose. One of the duties of a regimental surgeon, therefore, in an organization which has not had casualties or does not realize the need of dependable litter bearers, is to do everything in his power to obtain the assignment of a sufficient number of strong and courageous men for this work. In the 26th Division, after a good many hard experiences, General Edwards issued an order, which I will pass around, allowing to each rifle company 12 privates, detailed as litter bearers, with 6 litters. These are not Hospital Corps men; they are not Medical Department men at all; they are men drawn from the fighting strength of the unit. This order provides, therefore, for 48 litter bearers per battalion. The best way to distribute these bearers has been found to be: 2 per platoon, 4 with battalion headquarters, 8 with battalion surgeon, 4 with assistant battalion surgeon. Two litter bearers in each platoon are sufficient to take care of the ordinary evacuations of the usual number of wounded. It is important for the battalion surgeons to retain reserves of litter bearers at their aid stations. Sometimes one platoon runs into a little more trouble than another. Then a message is sent that more litter bearers are needed there. Now if we have all battalion litter bearers spread out among the companies and platoons, the surgeon can not help that local situation. If, however, the surgeon has a reserve of 4 or 8 bearers, these can be sent out as needed to some particular area. They return to the surgeon's reserve again when they return with the wounded. These litter bearers are also very useful in an advance to carry forward supplies.

It has been my experience that litter bearers drawn from ambulance companies or hospital units and put into platoons and line companies in trenches, or in attack, don't do as well as the men taken right out of the line. When a man's "buddy" is detailed as a litter bearer he is going to take better care of that particular group than a man not quite so personally interested. Litter bearers are drawn directly from the platoon which they serve. They live with their platoons, know their men. They are devoted to their platoons, and if they are courageous men they are highly respected. The service from such men is beyond praise.

The personnel of the regimental surgeon's office usually consists of a sergeant, first class; a sergeant, and 3 or 4 enlisted men. In an advance it is best to leave the sergeant, first class, at the rear echelon of the regiment, where he will be able to compile reports and keep up the paper work of the office. The remainder of the regimental surgeon's personnel should accompany him in the advance, to carry supplies, assist in dressing wounded if there is a regimental aid station, and to act as messengers.

Now for equipment. The battalion surgeon has a very heavy medical cart which usually can't be pulled by the mule hitched to it. It is filled with a great deal of equipment which in actual experience can not be brought up to the front line in an advance in time to be of use. We found it necessary to carry equipment forward by hand. The amount of this material, therefore, had to be reduced to a minimum. Splints were tied together in bundles and dressings and other necessities were packed in sandbags. In most cases each battalion surgeon with his party of Medical Corps men and litter bearers carried forward the following supplies: 4 or 6 Thomas leg splints, 4 hinged arm splints, 12 wire ladder splints, in 4 or more sandbags, dressings, such as medium shell dressings, first-aid packets, doses of antitetanic serum, triangular bandages, packets of gauze, safety pins, bandages, rolls of cotton, adhesive tape, iodine swabs, packages of sodium bicarbonate, and tubes of chloride of lime. Now with these splints tied up, these dressings packed in sandbags, you are ready to go forward; you have your equipment with you, you don't depend on any cart that will never get to you, and you have enough to work on until supplies begin to come forward from the rear. In addition our division surgeon has ordered that each litter bearer be provided with a corps belt, in which he can carry a lot of supplies that you see there:

Contents of litter bearers hospital belts

Pocket 1 (front compartment):	
Plaster, adhesive, 5 yards by 1 inch.....	1
Tourniquet, field.....	1
Ammonium hydrate, ampoules, 4 in box.....box..	1
Pocket 10 (front compartment):	
Safety pins.....dozen..	1
Bandage, gauze compressed.....	4
Pocket 2: Iodine swabs, 6 in box.....boxes..	2
Pockets 3, 4, 5: Individual dressing packets (par. 949), 2 packets in each.....	2
Pockets 6, 7, 8, 9: First-aid packets for shell wounds, 1 in each.....	1

With this material you can do pretty well for a day or so until things begin to come forward.

The duties of a battalion or regimental medical officer are about 1 per cent purely medical; the rest of the work is almost entirely nonmedical. There are more military than medical matters that are of the greater concern to the surgeons. What I would like to emphasize chiefly is that the chief duty of a medical officer is to get all the information he can about his regiment or battalion. It seems hardly necessary to say it, but the regimental or battalion medical officer must live with his battalion or regimental headquarters. I have known one case of a regimental surgeon who didn't live with the headquarters. I have known battalion surgeons to live with their headquarters. If you don't get along with the commanding officers in an informal way you can't do anything. This regimental surgeon I know of wrote excellent letters; he would "cover" himself with any amount of paper, but he never received any information except when his letters were answered, and that was generally a day or so

too late. I speak of that because the surgeon must have all possible information at all times. You have to know the regiment. The regimental surgeon is the chief one to get information for the medical department of his regiment. He should know if possible the plans of the division; he should know the plans of his regiment in battle; he should know exactly which battalion is going to make an attack, which in support, which in reserve; what organization is going to be on his right and on his left; what his communications are to the rear aside from simple communication to the rear by ambulances, because his messages usually must pass through the message relays of the line organizations, through the military commanders. The best policy is to be as good a friend as possible with the intelligence officers. There is one in each regiment and battalion. All the operation plans and orders for advance come to this intelligence officer. He is also the man that distributes the maps. Now nothing is laid down in the usual divisional distribution of maps that will allow medical officers to have maps. Unless the surgeon is in close touch with his commander or the intelligence officer, he will have great difficulty in obtaining maps. Lately by working with the intelligence officer, going with him to division headquarters when he went for the issue of maps, and by keeping in touch with the intelligence officers we were able to get a map not only for the regimental surgeon but also for the battalion surgeons.

Speaking of maps brings out a matter for medical officers that should be well taken care of in preliminary training; namely, the ability to read a map. We have had medical officers who really couldn't go out of a dugout without getting lost although they had maps in their hands.

Obtaining information of the plans of the regiment, plans of the battalion, is a primary duty, and the regimental medical officer can get that best from regimental headquarters. It is his next duty to pass on this information to the battalion surgeons. This can be done best, not by writing letters, but by seeing the surgeons concerned and talking the plans over on the map and on the ground. The surgeon's next duty in the collection of information is to know the sector. The regimental surgeon should know every bit of the sector occupied by his regiment. He has got to get out and go around there and by personal reconnaissance obtain information about the sector. This personal knowledge, in the first place, will fit him to correct the maps. A lot of the maps for regions over which you might advance have very pretty roads marked on them; when you get to the ground, however, you can't find the road. Lots of maps will show roads running through No Man's Land since 1914, and I have seen routes of evacuation planned over those roads when the roads didn't exist. Unless you have been over the ground you will presume that many impassable roads are open. I saw a battery commander in the St. Mihiel battle with a map showing a road due east nicely marked out. He was attempting to take his battery down that road. But for three years the French had a trench along that road, which has been bombarded so that the road was almost obliterated. You have to know the sector, the ground; you have to know where everything is, just what the ground is like, and have direct information from observations. The regimental surgeon must know also where every important unit in his regiment is located—not simply where his aid stations are, but he must know where platoons are located, where small posts are, and then by looking over the ground he will nearly always be able to pick out a suitable location for the aid stations. There are a number of things of this kind which you can only learn by direct observation.

The arrangement of aid stations preparatory to an advance must be made with two objects in view: (a) Ease of access to wounded coming in from the front, (b) ease of evacuation to the rear. The advance aid station should be in the point of departure of the attack. The battalion before an attack is served already by an aid station which may be a little in the rear of the front line, but it is necessary to have an aid station in the very front line when they go over the top. When the attack begins, this station will be ready to take care of the casualties which occur at the start and will receive casualties occurring during the first 500 or 1,000 yards of the advance. It should be placed conveniently to the route of evacuation to the rear, convenient to a wide trench, convenient to a path or an old road, so that litter bearing to the rear will be as easy as possible. But if you have a choice between a place in the center of your troops that was not on a road or path or an easy route to the rear, and one over on the flank near a good road, it is better to put the aid station near the

center of the sector. The position of the aid station should depend also on the direction of the advance, because men and wounded, walking wounded, and litter bearers, will tend to come back over the road they have taken forward. All the men, stretcher cases and walking cases, will automatically go back over the direction of the general path of their advance. It is most satisfactory to get an aid station in the line of natural drift to the rear. It is also useful because prisoners are brought back generally over the line over which the battalion has advanced. These prisoners should be used to carry the wounded back to save your own litter bearers.

It is necessary in preparing for an advance to arrange portable equipment for the establishment of advance aid stations. The necessity for carrying forward this equipment by hand is apparent to any one who has seen the ground that you have to go over. You can't count on any wheeled traffic getting forward of old trenches or of any service at all for nearly 24 hours. The orders are generally issued for the engineers to begin immediately clearing roads, but they meet a lot of obstacles that can not be removed quickly. Shell craters take a long time to fill up; the boche now have a habit of digging holes in the road about half as big as this room to stop tanks; some of those things it takes days to overcome. You can not count on any wheeled transportation coming nearer than 3,000 yards of your advance within 24 hours after you have moved. It is necessary, therefore, that the battalion and regimental surgeon plan ahead and actually carry supplies in bundles and sandbags.

The other proposition that I haven't taken up yet is the liaison with ambulance companies working in your rear. With us the ambulance company furnished litter bearers to work back from the battalion aid stations to the ambulance head. They furnish a large number of litter bearers. The group we regularly have is three squads under noncommissioned officers; that is, 12 litter bearers with 3 litters under a noncommissioned officer drawn from the ambulance department. The duty of these men is to carry patients only from the battalion aid stations to the nearest ambulance that can get forward. Sometimes their carry is very short; sometimes (during the last month or so) they had to carry, at one time, nearly 6 kms. It depends on where the ambulance arrives. You should arrange with the ambulance company, the commander of the ambulance section, to have 1 noncommissioned officer and 12 litter bearers go with the battalion surgeon to evacuate his dressing station. The regimental surgeon keeps with him one or two squads of ambulance litter bearers so he can follow when necessary. It is the duty of the battalion surgeon to see that these men are with him, that they are properly taken care of, that they have shelter and do their duty. The duty of the regimental surgeon in that respect is largely to keep the ambulance companies posted on the moves of the regiment, giving the ambulance company commander every bit of information possible as to where the regiment is, how many casualties, and so on.

The duties of the regimental surgeon so far stated have very little to do with the actual handling of cases. My idea of the work laid out for the regimental surgeon is that he should not be a dresser of wounds during an advance but a supervisor of the work. He should be free to go about to see whether the battalions are properly supplied with medical materials, to obtain and circulate information to the battalions and to the rear. This brings up the question of the regimental aid station. Some surgeons prefer to have a regimental aid station; that is, a station where the wounded from the regiment are brought after they have been attended to at the battalion station. This is generally not necessary. A regimental aid station is generally a useless block in the line of evacuation between the battalion station and the ambulance dressing station. There is very little that a regimental surgeon can do in this way to aid the battalion surgeon. Occasionally, however, a regimental station is necessary as a sorting station. Last July we had such battalion aid stations that the wounded could not be gotten into them properly, and the battalion aid stations were places little larger than fox holes. Most of the time it was impossible to light a candle or to have any light at night because there wasn't sufficient shelter to cut off the light. In a situation like this the regimental surgeon, who is generally in a more protected spot, should have a place where there is more shelter in which wounded can be properly handled. In most of the conditions, however, a regimental aid station is a useless block in the line of evacuation.

The duties of the battalion and regimental surgeon, as I pointed out, are a good deal more military than medical.

STUDENT. I want to ask how many Thomas splints do you supply yourself with?

ANSWER. Each battalion surgeon carries 2 or 4.

STUDENT. Is that sufficient?

ANSWER. Yes; we can generally handle the start off with that. By the time you have used two Thomas splints per battalion surgeon you have other material coming up.

Army Sanitary School No. 174.

ORTHOPEDIC PROBLEMS OF THE AMERICAN EXPEDITIONARY FORCES

By Col. Joel T. Goldthwait, M. C., United States Army, senior consultant of orthopedic surgery, A. E. F., December 2, 1918

That which I have to talk to you about this afternoon has to do, of course, primarily with the Army organization and that which the division of orthopedic surgery has to offer the Army—the Medical Corps—but I also want to try to interest you in some of the principles that have been worked out, because of the advantage which these principles are bound to exert upon civil practice. It seems to me that one of the most obvious things in connection with this war experience is that we are never going back to the same conditions in our civil practice that we have been willing to follow before. Certainly the treatment of the industrial accidents at home is never going to be on the same plan that it was before, and if I am not mistaken the experiences that we have had over here mean that the services in our civil hospitals have got to be pretty much revised all the way through. Now the reason for a good deal of that is this: The one thing that the Army is interested in, and the one thing that the public is really interested in, which concerns pensions and all sorts of other things, and the one thing that the man is interested in is, What can he do with himself when he is through with that which the Medical Corps can do for him?

Now once upon a time, of course, in the Army organization, the policy was simply to get the man out as soon as you could after he had been injured, but with the immense number of casualties which the British and the French Armies had—the German Army also—of course it became absolutely necessary for them to think in terms not of just the immediate treatment of the wound but of such treatment that would insure that man being the least burden to the nation and also to insure to the Army the return of the greatest possible number of men to the ranks for further service. Now it would have been absolutely impossible for the British and the French Armies to have been maintained at their proper strength—the same thing is true of the German Army—it would have been entirely impossible for them to have maintained their Armies at full strength had it not been for the work of the orthopedic corps, which took on its new function of getting these men as nearly perfectly well as possible. In the British Army it was demonstrated that nearly 75 per cent of all the wounded men were returned to the line or returned to the Army for duty after their treatment had been completed. That made it necessary to plan treatment and care entirely different from the ordinary care which the Armies had previously considered necessary; and in the British Armies after two years of experience with a great many noneffectives, the British turned to Sir Robert Jones, the orthopedic surgeon at Liverpool, and gave to him practically the whole responsibility for trying to fix over these smashed-up men and to see if he could not do something in the way of returning these men to duty. Entirely apart from what it meant to the man himself, the British nation needed man power, and it turned to Sir Robert Jones to work it out. He took it up, with the result that nearly 75 per cent of the wounded men were returned to the service.

Now when war was declared by our Government against Germany, so that we were really in the game, of the two first requests that came for help from this side, one was that our Nation send over to help the British, base hospital units, and the other that we send over to help Sir Robert Jones, orthopedic surgeons. These were the two greatest needs which the British Empire had at that time. It was my function to be asked to get together a group of orthopedic surgeons and come over with them, study the situation and then plan the organization for our own Army; and 20 men sailed to England within a month of the time war was declared and were assigned to British orthopedic centers; and that group of men has been the nucleus

around which practically all the structure of the orthopedic organization which we are using in the American Expeditionary Forces at the present time has been built. We picked our men in the first place because of unusual fitness, and then the training which was given them which they have been able to offer to the American Expeditionary Forces was derived very largely from association with work carried on by the British.

Now, as you will see as we go on, the work of the orthopedic surgeons in the army game is of very different importance from that which is considered true in civil life. In civil life the number of cases that are orthopedic cases are relatively small, while in a military sense, especially in combat, the number of cases that are orthopedic is very, very large.

Now the work of the division of orthopedics divides itself quite clearly into two parts; one of which has to do with getting the men fit for combat or full military duty, and the other for taking care of the men and restoring function after they have been wounded. There are two perfectly distinct parts to the work. In the first part—that which has to do with the precombat or training period—the problem there consists in getting men physically fit, so that the human machine, which if used rightly will stand a tremendous strain, is ready for the strain when it is put on. In a nation that has developed as our Nation has, with its educational system based practically entirely upon the intellectual side, paying no attention whatever—except in isolated cases—to the physical training, physical education, of our people, it resulted when war was declared in our having a group of young men whom were physically far from being fit for anything like the physical effort that would be required for military training. As you probably know, if you remember the figures, in the first draft that was made, the first draft of the Army, 19 per cent of all the men that were examined were considered unfit for service because of flat feet alone. This is just one physical defect. Nineteen per cent—nearly a fifth of the total of our young manhood. Of course, besides that there were a lot of other conditions.

The way in which the problem over here developed was as follows: The first units that were sent over here—the 1st, 2d, 26th, and 42d Divisions—were made up partly of so-called Regulars; and of course the Regulars were simply skeleton units of regiments and the personnel was largely volunteers, some of whom had not had a gun in their hands until they were put on ship. They were not trained men; they were just volunteers. These four units that were sent over here were in such condition and had so much difficulty with feet and backs that unless there had been some method worked out for handling the conditions we would have had just about as many going back to the States as coming over. Of course not literally so, but the number that would have been scrapped because of feet and back troubles would have been such a large per cent that it would have been very difficult to maintain the units. That led to a study of the problem and deciding upon a plan that was applicable, not to an individual, but applicable to groups of men, where you were dealing with them by the hundreds and not by fives and tens. It became quite obvious as the thing was studied that the flat feet or weak backs which so many of our young men have is nothing but a question of the use of the body, and flat feet is only the result and not the primary condition of the way the body is used. If you will study the anatomy of the human body you will see that if a person stands fully erect the muscles of the feet and lower leg are in such position of physiological tension that the bones of the feet are held in position and you need have no anxiety or concern regarding weak or flat feet. Flat feet are due entirely to the way the body is used, and the treatment consists in showing the man the proper way to use his body. If you view it that way your problem is a simple one. A man with flat feet should never be on sick report; he should not be in hospital because of that. It is a question of training and not of medicine, and the moment you put it there you relieve your regimental surgeon of an enormous amount of work which otherwise comes on sick call. You put the soldier where he should be; you make him understand that it is his own fault; that if he will only do certain things he will get over it. If he has trouble with his feet he should stand up straighter, and you eliminate him from that group of weak-footed, flat-footed men that have been such a nuisance in the Army up to the present time. Now the problem was presented in such magnitude last winter that it became necessary to do something—not for individuals, but groups, and after working the thing over it became obvious that the best thing to do was to take in charge these men with weak feet and badly poised bodies; the chap that we have seen so much at home that we have

rather prided ourselves on; the college man who has stood straight and hasn't acquired a slouch has been considered a crank, the man who stood up straight was the man made fun of. Now the human body was never made to be used that way; and if it is, it isn't a question of him having flat feet, it is a question of inevitably having flat feet.

Now the problem as it was worked out was this: The men were assigned as they came in, those with trouble with their feet were assigned to special organizations; they were segregated put in by themselves, and a camp was started to see what could be done with that group of men. To give you an idea of the magnitude of the work in these early units; there was one 28-hour period of military maneuvers last winter with one battalion, and after the maneuvers were over—only 28 hours—there were 138 men sent to the hospital out of one battalion, with trouble with their feet. That was out of one battalion alone, and it was not a whole battalion at that. One hundred and thirty-eight men after only 28 hours of manuevering, and they were not hard maneuvers at that. The commanding general said they were only simple maneuvers. Well, if our Army was going to be based on that type of manhood there wasn't much question where the end was going to be. Now these men were put in a special training organization. It wasn't a battalion organization, and that name for it was not right, but that was the best we could do. They were there told how to use the body, told the way the human body should be used when a man is standing up, with his body fully erect, with the chin pulled in, with the weight on the balls of the feet, as it inevitably has to be if the man stands erect with his chin pulled in. If you stand that way you get the spring and the stretch of the feet and the muscles in such physiologic contraction that they hold the bones together and it is the position of ease and not of strain once you have learned it. It was explained to the men and they were told why. They were made to realize that the way they stood was the cause of the trouble with their feet and that the cure was to get the carriage of a soldier. We told them to pull in their chins and explained that they can not "suck up their guts"—which the drill sergeant is always talking about—unless they pull their chins in. You can hold your head forward as much as you choose and you can not suck or pull in. On the other hand, you can not pull your chin in without pulling yourself in here [indicating] because the suspensary ligaments of the diaphragm are fastened to the base of the neck or pericardium, these ligaments come up to the sides of the cervical spine and are fastened to the center of the diaphragm, and you can not pull yourself up here [indicating] without pulling the chin in, and you can not yawn with your head forward; no matter how hard you try, you have to get your chin back. You can not sigh with your head forward. Now this is explained to the men as a simple piece of mechanics, to breathe rightly, to get the digestion to work properly, to stand up straight. We worked out a short talk which the men could understand, and the orthopedic men gave that talk to the group and they went over the units, and these men that had actual trouble with their feet we put by themselves, and they were worked specially. They had snap parades, with manual of arms, squad drill, all the other things, always from the proper position, keeping the men standing up straight, and starting from that position, with the body rigidly erect, quick, snappy movements—hep, hep, hep—quick, snappy actions, making the man realize if his feet are weak he must make an effort to "toe in." If there is much difficulty and his feet have spread very much and you have marked weakness, the heels are raised so that the man stands with his feet inclined down. From that position the man walks properly, and you make him realize that in walking he should walk with his feet pretty nearly straight ahead. With the cases that already had flat feet, there, of course, it was a question of treatment. What could you do to correct that? Of course, the man with the flat foot wasn't the man who could be depended upon for a long hike. Therefore, he had to have some special treatment, and the treatment that was worked out for him had to conform to military needs. You couldn't make foot plates, even if you wanted to, and if the foot plate is worn once it means forever; and the Army, in the first place, couldn't provide foot plates, and, in the second place, the principle is all wrong anyway. While in civil life you may have to do that because people will not pay attention to instructions, here we had that large group under authority where we could say, do such and such things; and the result was that after the period when we were in training over here, practically all these men were returned to duty without flat feet and fit for whatever service was required of them. Now the treatment that was given the whole body together, as I said, had to be in accordance with the military

idea and with the materials that we could get over here at that time, and the thing that was worked out was an ankle strap, like this [showing].

Now, of course, when the weight is on the foot and the foot is relaxed, the foot inclines to the inside and the cuboid will be pushed to the outside. Now the cuboid is the bone that represents the corner stone of the body; it should be under the tarsal bones and the weight should come on this [indicating], and with the cuboid in place you never get flat feet. On the other hand, if the foot spreads, as it does when the arch drops, the cuboid is pushed back to the side and then you can not help but have flat feet, and you will never cure the condition as long as the cuboid is there. It is absolutely impossible. If the cuboid is out of place you will always have the foot wrong mechanically. Now to cure that we simply made a strap that would go round the foot—of course the strap is worn right over the stocking. This is an ordinary piece of goatskin which was the only thing we could get at the time. These are made of pretty much everything, and I can't tell you of the number of straps that we have made that have been used by our men. This simple strap comes directly over the cuboid, comes up past the fifth metatarsal, and then comes round the ankle directly behind the inner malleolus. There is a depression beyond the inner malleolus. There is nothing that will do the man more good. He can march all day with that; every time he steps he steps into a stirrup; it does not interfere with the muscle action, but it is simply giving him a little added support, taking the stretch off the ligaments, giving the muscles a chance to do their work, and little by little the foot comes back to proper shape and the condition of weak feet or flat feet is corrected. Now that simple strap, which we call the figure eight, is the best thing for flat feet, and it doesn't matter whether it is in the military game or civil practice, because that gives you reason to believe that the thing will ultimately be correct, the foot-plate acting only for the time being. Some of our men who had flat feet themselves were put to work making these things, and that is resulting in a saving of thousands of men for work in the American Expeditionary Forces that would otherwise have had to be scrapped.

There is another type of foot difficulty that is very common and the result of the type of shoe that has been worn so much with a pointed toe and especially with a short shoe. This type of foot is spread across the front and affects the big joints and causes more or less crumpled toes. These men always get sore joints; they have to wear a shoe which is much too wide for Army conditions and they also have callouses on the balls of the feet, a very troublesome foot, and the source of a great deal of difficulty to the man and a nuisance to the regimental surgeon. Now that represents, when you analyze it, simply a spreading a stretching of the ligaments that hold the foot together; and all you need is something to hold the foot together that will not interfere with the use of the foot for marching, and that was worked out with these little straps. Now a strap of that kind applied around the front of the foot, just behind the joints, with the buckle placed in the hole which there is just back of the head of the fourth metatarsal, and that buckle will rest there, and the foot is simply held together with no pressure over that joint; the support comes directly back of the joints, and the man walks all day long with his foot held together by the strap, and the mere holding together lifts the three metatarsals off the ground. You can not hold the foot together without lifting the bones in the middle. So if you have the strap there you solve the problem of callouses at once. The moment you hold the foot together you bring this part in [showing] so it don't shift any more. So with these two straps—this for the long arch—you have two simple measures which make it possible to really cure conditions—not only relieve but really cure conditions which have represented one of the most troublesome problems in the Army previous to this time. When you realize that 19 per cent of the first-draft army was exempted from service because of that, I think you will realize what it means. The number to be exempted would have been twice as much if we had only used medical treatment. As it was, before these measures were tried they went to hospital, stayed there a little while, and then back to their outfits. The next hike and they went back to the hospital again. It was a ludicrous proposition—back and forth to the hospital, to the organization, to the hospital, until they were a joke. But neither would keep them. Then the training battalion was organized, and after it got started, these men were all sent there and trained. They were not on sick report. They were drilled, and the drill was military drill, so they were being made soldiers

while being made well. We had some snappy drill sergeants—one was a British sergeant major who was considered the finest thing ever when it came to bayonet drill, and they got into such shape that the commanding general of the 26th Division said, right off, "These will be my best soldiers because you are putting so much emphasis on the form in which the movements are being made." Snappy, quick movements, everything precise; all the flat feet were eliminated practically by that. Of course, with the strap we sometimes had to use the deep heel to throw the man over on to the cuboid bone until the ligaments and muscles had gotten strong. For that reason we had at the camp a cobbler shop, and at one time we fixed a hundred pairs of shoes a day in order to have them for the men when they came in. When these men left the battalion they were expected to take three pairs of shoes fixed that way. One they wore, another went with their pack, and the other to the quartermaster stores. If the man used these he would be fully well and would require no further supervision. That idea has been continued and the necessity for a cobbler shop in connection with the camps has been recognized. The men need them, and if you recognize that idea a great many men and officers who otherwise would be on sick call will be on duty.

Now, here is a longer strap on the same principle, where you make a double turn around the front of the foot and around the ankle, where you want the support before the longitudinal arch on the transverse arch. This makes it possible to get into the narrow-sized shoes which most of our men need, and with a proper use of his body the man in a short time becomes physically well.

Now, the other condition which you find commonly in the period of training or preparation is weak back—the fellow with the crick in the back, backache, and all that sort of thing. This, together with flat feet, are the two natural weak parts of the body. The spine is held together by muscles and ligaments. The bones in the foot are held together by muscles. Therefore, if the muscles of the body are not used rightly, it is an inevitable thing that you will have low-backed men. Not that you may have it; it is inevitable. Just the same as if you use the body wrongly you will have trouble with the feet. One is just as much a mechanical certainty as the other. Now, if a person stands as I am standing now, the abdominal muscles are entirely out of commission. My belly wall is entirely relaxed. If a man hits me a very light blow in the abdomen it will knock me out, because there is no protection, and in this position now the back muscles and the muscles of the spine are holding the entire support of the body. I am now just sticking on my back muscles. Now, the muscles in that position are under strain, and no muscle can hold for more than a certain length of time. You have the same condition if you try to hold out your arm. In spite of your will you can't do it for very long; it will fall of itself. If you stand as I am standing now the muscles of the back are under strain; in a short time they become tired and you change to the other side, the muscles getting more and more tired until the strain is put upon the ligaments, and no ligaments are made that will not stretch after a time if undue stretch is put upon them. Then you begin to have aching in the back, the back being tired, and difficulty in sleeping because of backache, and extreme weariness in marching. You have a large number of men that you see in any military organization with weak backs and feet. These are the two most common things. If you can eliminate them, you needn't worry much about the other conditions. Now, the same things that apply to feet conditions apply to back conditions. The men with weak backs were sent into the training organizations the same as the men with weak feet, and it was explained that the trouble with the back was due to the way the body was used. If you stand erect the muscles and ligaments of the back are all in physiological position and condition. Every movement is made from the correct position, and that position can be maintained for an indefinite time almost free from weariness, especially if you stand with the feet apart a little; a man can keep that position for almost an indefinite time without weariness. Once that is gotten into the mind of a man and he realizes it, he comes in from his hike much less tired than he was before, and it doesn't take long before he carries himself that way naturally. Now, remember that the question of posture is just as easy to train a man for as it is to train a man in any other thing that requires physical effort. The shaping of letters as we train the children is just the same question as training a man to do the manual of arms, just a training of muscle effort, and after he has performed the movement a few times it is done automatically. It is the same with the use of the body as a whole.

Once a man has been well trained he uses his body automatically, it becomes automatic, and he becomes conscious of doing it otherwise rather than conscious of doing it properly. And one of the great things this Army of ours is going to do for our Nation is to put back into our population a large number of strong, healthy men—well poised, vigorous specimens, who are going to be the fathers of the next generation. One of the best things that is coming out of the war is that our manhood are going back to the States and our men back to their homes strong, healthy specimens. There is no question about that at all; and their children will be strong, husky; and we won't have a lot of these poor little kids born into the world that means a constant struggle to keep them here. When you realize the way it has been handled at home you will see many good things coming out of this.

You saw in the paper the other day that among the units first to be demobilized were the development battalions. They said no man suffering from flat feet would be exempted from the service in the Army; they should be taken in and trained and not scrapped, and given a chance; and that idea developed at home into developmental battalions, as they have been called. And now among the first units to be demobilized are the developmental battalions. When you analyze it, that's the wrong thing to do. These men should be kept in longest. But that isn't our affair, and some one missed the real opportunity, but nevertheless the opportunity was interesting. It said 93,000 men in the developmental battalions would be among the first demobilized. In other words, among our camps at home we have 93,000 men who have come in the last draft, and put in there because of weakness. They have had it preached to them that they are just as good as any other men if they go at the thing rightly; they can be made strong, fine physical specimens of mankind just like any of their mates.

Now, just one word on an instance to make you realize the thing I have just said—that once a man has learned to use his body rightly he will never forget it. Now, a number of years ago, a broken-down physical wreck of a man was under my charge at one of the hospitals; he was all shot to pieces, but after a couple of years the man was well enough for duty and he was given a job in our office as doorman and porter, and there he worked for a good many years. One day a British lieutenant general, an old-time British war-horse type of general, came to the office by appointment, and this man opened the door and let the general pass on and indicated to him the room in which he would find me. That was the only intercourse these two men had. The general came into my office and said, "Where did you get that fellow?" I didn't know what he meant at first, and he said: "That fellow on the door"; and then I told him hurriedly what I knew about him, and he said, "I don't mean that. He has been in our Army." I said that I didn't think so; that he had been in our country 13 years, and the general chuckled and said "He has been in our Army"; and nothing I could say changed his opinion. When he went out John opened the door for the general to go out, and when he passed him he said, "What regiment were you in?" John snapped to attention, saluted and told him. John said to me, "How did he know?" I said, "I don't know; he had you spotted all right"; and I asked the general the next day how he could pick a man out that way, and he looked at me with an expression of infinite pity. "Why, once a man has been trained in our Army he never loses it." The only interest he had was the way John was carrying himself. He had been a cripple a long time, but the general saw something that meant only one thing to him and that was that he had been in the British Army; and the only thing that interested him was what regiment he had been in. Now, this war has given us the opportunity to get our men trained so they will not have lame backs and flat feet, and when the country needs them we won't have to scrap 20 per cent right off before we can make them fit for combat. President Lowe the other day made the remark that if our Nation does not see as a result of this war experience the need of putting into our educational system that which has to do with proper physical training of the body, as well as intellectual training, we have missed a very good opportunity. Now, when that sort of thing is realized it means that we are going to have something that will make our men go round, not in a swaggering attitude, which they have been encouraged to do. It is just as much a lack of education as if a man should use an ungrammatical expression. We see it every day, and our medical men have been one of the worst classes—slouchy, setting poor examples. And it means that if we go round setting the proper example we will see an improvement in conditions, and flat feet will cease to be, weak backs or knees will cease to be, and with that a lot of other things. But

this is not for us to talk on now. The problem is to keep a large number of men fit for military service, so they can be counted upon when the march is on, and not fall down the first time.

Now, to give you an idea of the difference between organizations in which such methods are followed and those where they are not. One regiment had had regular training of this general sort; another regiment had had no training. They were sent out on hikes, a 10-mile hike. The regiment that had been trained came in almost to a man; the regiment that had not been trained brought in over 300 men on ambulances and motor trucks—on a 10-mile hike. Now, it hardly needs any further argument than that. One is a common nuisance and the other is not.

Now, a man going over the top doesn't want to be a man slouchy and relaxed; he wants to be up on his toes, ready to jump, run or hide, or hit; a man isn't at his best if he can't jump or run quickly, and he can't do it there if he can't do it elsewhere. He wants to be up, and then he can hit a blow that has the full power of his body behind it when he strikes.

On the strength of that a great many men have been saved for the American Expeditionary Forces all last winter when there was relatively small call for our men for combat; we were then able to accomplish things and really send these men back as A men, not as C men. In the last four months, however, we have had to change our policy and make a compromise. It doesn't change the principle at all, but it was because of the military necessity. Now, since last July there has been such a demand for men for military units, and there has been such a constant stream of men going through, that we haven't been able to keep the men in training battalions long enough to make them well. So we have had to take the men there and fix them up, and recognize that all we could do was to make them class C men and be sure they were fit for class C. We couldn't make them well; we didn't have time. That meant fixing their shoes, giving them straps, giving them a few talks. They worked by themselves. You couldn't have chosen them for battle, and as soon as we could get them started they were sent back for some duty of C type. Now, the Army began its active offensive in July, and of course it has been kept up ever since until now. It has meant that great numbers of C men could be used where A men could be released to fill up the combat units. For instance, in a very short period 1,200 men were sent at one time in one group to staff the hospitals in the Toul area, men who were not equal to the long strains of combat. One thousand men went for prison guard duty; another thousand for extra personnel duty around hospitals; a lot of these chauffeurs and motor mechanics have come from the training camp, men who have had suitable technical training but whose physique was not up to combat. So we had to use the camp not as a place to make them fit but to show them how to get fit, and a sorting station for work they could do. Then the men were used for our splint teams, were taken from the training battalions; not equal to combat but perfectly satisfactory for the kind of work we were giving them to do. Now, the average man, you see, isn't yellow; he isn't a quitter; he wants to do the thing, but he physically hasn't the stuff in him. The minute you put the thing up to the man and make him realize that it is a weakness of which he ought to be ashamed as much as any other weakness, and take him off sick call, the quicker he will overcome it.

There was a remark made to me a few days ago by a man who has studied the situation quite fully: "That while we have lost a good many men over here we have undoubtedly saved a much larger number than those killed, by getting men physically well who would otherwise have been lost in a reasonable period of time." I think that's a very fair statement.

Now, when it comes to the question of combat and the injuries of combat, certain principles have been worked out for taking care of the problem with reference not only to the immediate treatment but with reference to the ultimate condition of the man, and when the thing was studied a year ago last summer the director general of medical services said to me several times, "Remember that your reconstruction work begins in the trenches," and that led to the organization which we will describe. In the first place, in order to meet the needs of the Army that was being planned for us, it was necessary in the first place to have some standard system of splints, or a standard type of splint, that would be used by everyone. You can see it would be useless and hopeless if Smith, Green, Brown, and Jones had their own special splints. The supply department, in the first place, would have found it impossible

.

to meet the demand and the wounded man would have suffered, because if he were moved from hospital to hospital and the splints were changed every time, it would be highly harmful for him and he would soon get the idea that nobody knew anything about it. In June, 1917, a conference was held in one of our hospitals then serving with the British, and recommendations were made for standard splints to be provided in our Army, and they were provided in October. Now, in order to make it possible to treat our men properly it was necessary to have splints that were the simplest possible for construction; they had to be made over here and we had only certain materials available. We had to have splints that could be made by any labor and they had to be made by the thousands and hundreds of thousands; and they had, also, to be easy to transport and simple to apply. Of course, in this proposition we had the benefit of the immense experience of the British and the French, and we finally decided upon but seven types of splints, which were to meet practically every need that would come in an army in combat—seven. Now, when you see in the museums the number of patterns of splints that have been devised and realize that it has been reduced to seven, you appreciate what an immense saving that has been to the Army, and what a great advantage that has been, not only to the wounded men but to the cause of medicine in general. Because you see this is a principle that we have got to respect, and we ought to take it back to civil life with us again—that there can not be six or more different ways of doing the same thing that are equally good. That's what we have done in civil life. We have had any number of ways of doing things, and each man thought his was the best. But here, with the help of the experience of the British and the French, we said, "These are the ones we will agree upon." Now, the principles of the splints come down to two very simple ones. One is simply that of fixation of the wounded member so that undue pressure will not be put upon the tissues in handling, and the other that of contraction or the pull on the muscles which have been bruised and are thrown into a state of spasm—contraction; state of the member. So that the two principles of fixation and contraction were the basis of the attempt to get our splints, and the splints which we have adopted have been pretty much the same as those used by the British organization. For the leg we have adopted the Thomas splint, which without question has saved more lives than any other one appliance that has ever been devised. Sir Anthony Bowlby, who has had charge of the British service in the field, said to me the other day: "This is still called the Thomas splint, but some one the other day called it the St. Thomas splint, and I think that's just what it ought to be." Now this splint is adaptable for almost all injuries of the leg from the hip joint down, except conditions of the foot; you have to have something else for that. It consists, as you see, of just this ring and these rods. This brings the pressure down on the tuberosity of the ischium, and this long piece, which can be bent; this is placed on the bottom, to which you tie the extension, which is fastened to the leg. Now, the British have used this splint not only for the treatment of fractures in hospitals but they have used this in the transport of patients, and this splint is put on in the field. We have adopted for our field splint a different pattern because it is easier to apply and meets the needs almost as well—not quite, but almost as well, and well enough so that it is satisfactory. This is a pattern of splint devised by Keller, of the Medical Corps, and by Blake, who worked it out, so it is called the Blake-Keller modification. It is a half ring, so you can use it on either side. It is simpler for packing and transport, and it is quite the thing in the forward area. For the stretcher cases in the battle field this is the splint that we have made standard, and it has been used in all our work since the 1st of last January. This type of splint is very simple, as you see. It is fitted in the back, strapped to the rods, held in place, then the extension is put on the ring. This is used only in the field where the man is picked up, and it must be a splint that can be put on in a hurry, for your stretcher bearers are exposed and you want to save as many of them as you can. You have with a splint like this a splint that can be applied in a very few moments, and with that the man can be handled and gotten to the rear fairly easily. Now, the importance of this is of course tremendous, and you who haven't been at the front and seen the work and studied the thing can hardly appreciate just what it has done.

Previous to the Battle of Arras, in 1917, the mortality for fractured femurs alone in the British Army was 80 per cent in the forward area; 80 per cent of all femurs died in the forward area. Because of the great mortality, just before the Battle of Arras the British started to apply splints in the field. That was the Thomas splint, and trained their stretcher bearers

so that a man could apply a splint like this with extension, with a field dressing, and get away with it in no more than two minutes' time. Now I fancy there aren't many men in this room who can put that on a man with a broken femur and put a dressing on it and tie the slings in two minutes time. They were trained to do that, and our men are trained to do that. Every move counts. Every move must count, and General Thompson, the surgeon general of the First British Army told me their record was one minute forty-five seconds, to get a splint with traction on and starting the patient to the rear. Of course, the importance is obvious to every one of you. These splints have been put on right on the battle field; they have been ever since last January when our men began their raiding parties. And our men rivaled each other to see how far forward they could carry these splints. At first we didn't know how far we should go. But the orthopedic men with the men in the divisions carried these farther and farther forward, until finally when a raiding party went over the top every party carried with it a certain number of stretcher bearers and stretchers and with them went the Thomas splints, leg and arm splint, and they were applied in No Man's Land or the German trenches, wherever the man fell. With such a system of training as was worked out in the British Army, and which has been practically copied by us, it means the difference between a mortality of 80 per cent, such as they had in the beginning, and a mortality of not over 30 per cent. At the Battle of Arras the British Third Army had over 60,000 casualties pass through the casualty clearing station—our evacuation hospital. Of that number 1,009 were fractured femurs, and the mortality in that fight when the stress was the greatest, when they had things working under great disadvantages, the mortality in that fight was cut from 80 per cent down to 30 per cent.

You often see men dying, not because of the original wound; a man may be badly wounded and lie out in the field two days and not be badly shocked when you find him. On the other hand, a man may be picked up a couple of hours after he is wounded and be brought back, however, in great shock. Moving a man around with the bones loose inside the muscles may lacerate the muscles and you tear the blood vessels or the nerves to such an extent that the man either loses his leg from the rupture of the vessels or develops such a state of shock that he doesn't get to the evacuation hospital at all, and that has been so clearly demonstrated as a principle, the need of proper support to control that, that Colonel Crile in his last article on shock, in his short, terse sentences, in his things that you are to do, he says; "Put on the Thomas splint as far forward as possible," and he is talking about shock. Now that is the first principle of the treatment of your wounded man—get him in alive. That's the first thing; to get him in alive and in condition so that the surgeon can operate on him; this is of the utmost importance.

Now in the work of the Third British Army, when they started to use splints they found this condition: Previous to that time the femur cases, not only a large number of them died, but a large number of them when they arrived at the casualty clearing station were in such a state of shock that they could not be operated upon and had to be deshocked before they could undergo operation, which, of course, lessens the chances of recovery and gave the infection a better start. Now in the Battle of Arras not only did they all come in, but every one arrived in such condition that they could perform the operation immediately. This saved shock and the physical damage to the tissue that would otherwise take place. Now that is so important that it has been made a definite part of the training of stretcher bearers and ambulance corps men in all our units, and that has been one of the special tasks of the orthopedic surgeon, and the orthopedic surgeons assigned to the divisions have given a regular course of instruction for the stretcher bearers, and no man goes forward for the wounded who hasn't been taught to use these splints and get away with it, and they have gone just as far forward as the troops have gone. There was a very suggestive and touching side to this feature in front of a machine-gun nest in front of Montfaucon—a lot of our men lying dead, and among them was a stretcher bearer with a Thomas leg splint and arm splint under his arm. As far as our men have gone forward the bearers have gone forward with the things to take care of the men where they fall, and no words of mine can be too strong in praise for these men of ours who have gone up there. A good many of them have been killed, but the work of the corps has saved numbers of men who otherwise would never have gotten out. Our men can put on a Thomas leg splint in two minutes' time without any difficulty.

Now when you get your man into the evacuation hospital: The closing and cleaning of the wound, that is simply surgical, and whether one man or another does it is immaterial. In our organization, the chief of the surgical division has taken charge of the case when he gets to the hospital; getting him there is the duty of the divisional orthopedic surgeons. After he has had his operation performed then the question of putting him up in proper splints begins again and the men try to handle the cases they were responsible for themselves. That didn't work, as they themselves admitted, and the result of that was that splinting teams were organized; and since the St. Mihiel fight as soon as the surgeon has finished his operation he steps aside from the table and the splint team takes charge, headed by one young orthopedic man—most of them have never had much orthopedic training before, but we have taught them how, whipped them into shape, and started a lot of them off with this responsibility. The team is composed of one orthopedic officer and two enlisted corps men, and these have all been men salvaged from the training battalions. They put the splint on, arranged in standard position. Then they see that they are started off right to the rear, or follow them to the wards to see that they are taken care of. From the standpoint of the surgeon he is free when he has finished the operation. He steps to the next table and goes on with his operating. The organization which is now in use has resulted in saving of from 30 to 50 per cent of the output of the hospital. One evacuation hospital stated that they had lost less than 30 per cent since the surgeons have been freed from doing the splinting and are doing operating only, and the commanding officers have reported that the saving in material has been tremendous; they don't lose the time nor material they otherwise did.

Now, in the war game, of course you do not have a patient in one hospital any considerable length of time. At home we expect to keep a patient in a hospital until he is well. You don't do that over here. You have him perhaps a day at this hospital; probably two days at the next one; a day or two at the next, and so on; the man may be in half a dozen before he gets to a base port to go home. It is absolutely necessary, you see, that being the case, to decide upon positions as well as splints in which you will put that man in order to keep him in the best way. If you do as was done in the beginning, put the leg with a broken femur in a Balkan frame, and the order comes to evacuate the case the next day, you can not evacuate him in that position; you have to pull it down. If you have had him up there three or four weeks and ossification has set in, and you pull that leg down, you open it, and many long delays in healing were due to that. Now after having a certain amount of that, we decided upon certain positions that were most favorable for transport; and if you put the man up in that position on the operating table in the evacuation hospital that man can be taken out of the hospital and sent to another place without disturbing the fragments of bone a bit. The positions which have been standardized are positions which will be pictured in the new splint manual, which will be a handbook on the treatment of these things.

Now you can put the man up to 30° inflection with a wound of the thigh, with traction in that position, with your slings over your support, and with traction down the leg. In that position the man can be moved perfectly well, but your Balkan frame is used for convenience and comfort. That man can be moved in any ambulance, he can be taken in a hospital train, or put on shipboard and sent home without once disturbing his fragments. In that way you shorten the period of recovery and you save a lot of cases that would otherwise have been lost. The exception, for the upper leg cases, is when you get a certain number of big, lacerated wounds around the buttock in which you can not use the ring. Then you have to manage it another way. For these we use the Hudson splint. It doesn't help the fracture; it just gives you a chance to sling the leg so that the fragments will not be disturbed as the patient moves about. Usually when you have to transport a man with a big buttock wound you put him in one of the long Liston splints or a temporary plaster of Paris splint.

Now with this small group of splints that I have shown you here you have splints that will meet almost everything that is necessary for army work. I will show you how wonderfully the thing worked when it came to the question of transporting a large number of our seriously wounded men to the States, the reason for sending them being that with the rapid expansion of the Army there was difficulty in establishing hospitals fast enough to take care of the wounded coming on; we tried out a system of handling cases to see if we could get them home without harm to the men. At first it was thought impossible, but the military necessity

said it must be done. When the first group of men were taken down to the ship and put aboard I went myself with the convoy and with the lighter to the ship. We went on board each ship and explained to each ship's surgeons the type of splints which the men in the convoy had, and demonstrated four splints—no more. And I was able to say to them that the only thing they need learn would be four splints and that would cover everything we would send home except the fracture splint. It cut the handling down to surprising simplicity. Now you can not put on a Jones humerus splint wrong end up and you can not put on a Thomas splint and get it very much wrong; they are almost foolproof.

What I have shown you now represents the splints that are standard in the United States Army. They will meet everything required, and it is quite obvious that these same things, that have shown such splendid results, will be used in civil hospitals, and it behooves all of us to learn how to put up these cases. You are never going back to the box extension and T splints if you want to get the best results. This gives you the chance for the best result, and there is no question but what it will be so.

Now there is one simple splint that is used for a large number of cases. That is this so-called Jones-Cabot splint. This is used in a great many cases of gunshot wounds. In these cases it becomes necessary to put them on in such a manner that the function the member will get will not be imperfect. It should be put up in the position most feasible for ultimate function. You put it up in this splint. It leaves the fingers free. It is a very good splint for musculospiral cases and for wrist drop, which is common from all these battle casualties.

Now that we have so many amputations, of course we can make a demand on the instrument makers or start our own shop. That is being planned in the States, and the man who is already back of it is Captain Wilson, who has done such splendid work. This means working out a system that means ultimate function for our men, and the United States means to keep these men in the Army, and under Army control, until everything that can be done in a medical or surgical way is accomplished. When the men go to the States they don't ask how soon they can go home, but they wonder if they will go to a hospital near their town. That's the kind of questions they ask, and the Government has planned an organization so that these men won't have to lie in bed with nothing to do. In the first place they would get out of sorts and would have indigestion and other things. If a man has a hand damaged and has nothing to do but lie there, his hand many times gets stiff because he has nothing to do, but if you can supply him with an occupation, he lies there quietly and has a good time and doesn't get out of sorts, and his hand will heal faster because he is doing something with it; the muscle reflexes will prevent harmful things happening to it. So if you can give him something to do you will get him well in half the time and he will have much more perfect function. I saw a man with a gunshot wound of the hand. He had almost perfect function in his fingers and he was doing something to get the circulation going in the fingers at the time. That proposition has been so much a part of the medical department that it has made it a part of its organization—reconstruction. This is one of the most important things we have; and it doesn't matter so much what you give him, so long as it is something that will help him to use the part that is damaged; and you get him well in half the time and some times less. That's a part of the medical organization, the reconstruction era. You will find it in hospitals where these cases are being segregated in large numbers. For instance, the men are making splints while getting well; and dressings are being made by the men under the direction of aides. That is a very positive therapeutic measure which not only supplies hospitals, but it means that the men are going back to the line quicker, if they are going back to the line, and that they get well with much better function.

That, in general, gentlemen, is the plan and general scheme under which our division has been operating, and I can not speak too strongly in compliment of the men who have done so much of the work and the way the Army has provided things, which are just as important as surgery or nursing. I have a very strong feeling that when we go home and see these wounded men about—as we are bound to—that there will not be very many of them that we will be ashamed of. And I believe that the same principles that we have worked out here must be equally applicable to our civil hospitals, and you and I after this war are going to be judged by the condition of our patient a week after we treat him and not a month or two afterwards and after he has had to go to the Christian Scientist or osteopathist to get treatment. The military need is one thing, but the civil need is exactly the same.

Army Sanitary School No. 177.

THE DUTIES OF DIRECTOR OF AMBULANCE COMPANIES (EXPERIENCES WITH THE 82D DIVISION)

By Maj. R. R. Spahr, M. C., December 3, 1918

Gentlemen, I was ordered to this school last May, but never reached it. I have had to learn through experience, and you men have the advantage of going through the course of instruction here. I don't know how many of you are in the sanitary trains of the different divisions, but it is the only work I have been in in the last 18 months. It is my hobby; I hope to remain in the Army, and hope to do nothing but that. At the present time we are reequipping our men, getting back to the old schedule we had in the States.

I have here maps of the various sectors the Eighty-second has been in since the train arrived in France. I will try to show on these maps where we placed our triages, dressing stations, etc., both in the quiet sector and in what was the most difficult and hardest fight of the war—the Argonne Woods drive. It is understood, of course, in the matter of evacuation of sick and wounded, the ambulance men were responsible for the evacuation of all sick and wounded from the battalion aid station, through the ambulance dressing station, through the triage, and in a great part from triage to the rear.

In a quiet sector such as we had on the Toul front at Montsec, we had practically stationary warfare, and rather quiet; though as Captain Coleman told you, when we were leaving the Toul sector we were relieved by the Eighty-ninth, and the Germans, knowing it, launched a gas attack, which was hard luck for the Eighty-ninth but very fortunate for the Eighty-second and the sanitary train in that we had to do the work and get the experience. In that we evacuated 800 men in 24 hours. In the Argonne we evacuated a thousand a day for several days straight. That was our first big lesson in learning that it was our duty not only to evacuate the sick and wounded from the battalion aid stations, through the dressing station to triage, but to provide evacuation from the triage to the rear by means of additional ambulance companies, generally evacuation ambulance companies and trucks. In a quiet sector with that sort of trench system there was little need for ambulance company dressing stations. On that sector, which was the largest sector we were ever in as regards breadth, we had three ambulance company dressing stations. I can say here that the animal-drawn company has never set up a dressing station as a company. I, personally, do not consider the animal-drawn company a "white elephant," and will reserve a few remarks on that until later. However, in that sector we evacuated the normal sick and wounded through a chief dressing station; we did not have a triage. Two of my dressing stations evacuated to the two field hospitals of the sanitary train which were in the city of Toul and acted in the capacity of base hospitals.

Placing the ambulances, both motor and animal drawn, as we have done in our division, with the regimental surgeons and separate battalions, such as machine gun, field signal battalions, etc., you really did not need an ambulance company dressing station in a quiet sector like that, provided, of course, your triage is fairly well forward, and I think—whether we are to be judged harshly or not—the sanitary units of the Eighty-second were too far forward; and I can say one thing for that: I do not think in the hardest fighting there ever was an officer or man left on the field unevacuated for 48 hours, as did occur in divisions with older names and more experience than ours. On the other hand, it exposed the sanitary train to an unusual amount of shellfire which we suffered from, such as we had at Pont-a-Mousson, where we held the right flank in the St. Mihiel drive. The ambulance company dressing stations were, of course, absolutely essential in the Argonne-Meuse drive. In the positions shown on these two maps here, where we were for five weeks, the fighting strength of our division was burned down to less than 3,500 men. You can imagine what we went through. Out of a division of 28,000 men, exclusive of our Artillery brigade and putting in our Engineers, our four Infantry units and machine-gun units, were reduced to a fighting strength of less than 3,500. In sectors of that sort the ambulance company dressing station is absolutely essential.

Where the sectors became more ordinary, and the fighting less desperate, we could get along with perhaps one or two dressing stations. In the sector back of Pont-a-Mousson we attempted to have only one triage and one dressing station, but the Moselle River split the divisional sector in two and we had to double what we intended putting in. The plan was that there would be one large triage, which would be established by a field hospital company, and one ambulance company on duty from that to the remaining three hospitals which were formed in a group at the hospital base—the gas hospital, the hospital for non-transportable wounded, and a hospital for the normally sick and wounded. That we carried out as far as we could, except, as I have said, the river cut the division in two and we had to double all our resources. That applied to the line as well as to the Medical Department. Unless you have been through it and through the congestion, the jam of artillery, cars broken down, the Frenchmen who don't observe any rules, artillery, ammunition supplies, and ambulances, you haven't any idea how essential it is to get the wounded away from the battalion aid station to the dressing station. There must be some place where patients can be treated, and it is more essential to clear the field of wounded and get them to some station than it is to rapidly evacuate from the battalion aid station to the triage.

When we began the Argonne-Meuse drive, relieving the Twenty-eighth at Varennes, we sent forward with the ambulance companies 160 litter bearers. These were for the purpose of collecting the wounded between the battalion aid station and the ambulance post or ambulance company dressing station, and were not to go over the top with troops. That privilege was sadly abused by a great many of the regimental and battalion surgeons, and consequently the system did not work out as we had hoped. It never really happened that the battalion aid station got to such a point that our Ford ambulances could not reach them or at least come within 500 yards. I might also say that we had very embarrassing transportation facilities in comparison to other divisions, but in spite of all that could be done, we were unable to secure any more ambulances for the Eighty-second other than 8 G. M. C.'s and 4 Fords. The two directors of the sanitary train never had Dodge cars; I have none to-day—I ride a Ford jitney. But we had attached to us one of the American ambulance sections—S. S. U. 647—and if you read the newspapers rightly, you know a great many of their drivers received the distinguished service cross and other decorations. It is the same service I was in two years ago with the French. These men evacuated from the battalion aid station to the dressing station and a G. M. C. carried to the triage, and evacuation ambulance companies furnished by the corps and supply train trucks carried the wounded from the triage to the rear. You can easily put 20 slightly wounded on a truck.

Now comes the question of gas. You have all heard of the rules laid down that every patient supposed to be gassed shall come in on a stretcher, and the men would soon get on to that and we would get a great number of men at a dressing station without a tag perhaps, and we would ask him how he was gassed and how he felt, and he would say: "My sergeant said I was gassed." In the Argonne-Meuse drive we gave up the litters and we handled the slightly gassed on trucks, standing up or sitting down, 20 at a time. That soon became a loophole for the men to leave the line—simply say "I am gassed."

The location of the ambulance dressing station depends not entirely but to a great extent on two things, namely, on the number of patients which you are handling or expect to handle, and, second, on the number of ambulances which you have. But in spite of that, if you had 50 or 60 ambulances, the transportation can throw everything to the winds—you get along just as well with 6 as with 30. That we found to be so. While in the Argonne we had these 20 Fords and 7 or 8 G. M. C.'s. With the corps ambulance companies, sometimes two at a time, generally G. M. C.'s, we were able to handle the evacuation quite satisfactorily. Now as you know, these S. S. U. units, which is the American ambulance service, have very peculiar rules and regulations. In other words, if you ask them at any time to evacuate a sick man from the dressing station to a triage, they kick and say they do front-line work only; and not having any Fords of our own they did the front-line work and we furnished drivers. They didn't have enough to man half of them, so our men were working along with their men. I believe the director of field hospitals will speak to you to-morrow, Major Spear, and I don't wish to encroach upon his work, but I think the divisional triage might be taken up. Previous to the St. Mihiel drive orders were given that there should be one

triage which should be run by one field hospital company augmented by an ambulance company, and in the rear the remaining three hospital companies should form a hospital center.

That we carried out in that drive, and in the Argonne-Meuse drive we did the same thing; even more, we ran a supply depot and base hospital. It so turned out that we were here with the First, Second, Forty-second, and Seventy-seventh, which was then taken out for two weeks, the Seventy-eighth coming in after we had attained the line which runs through Fleville, and the line remained practically stationary for six days. I don't think the whole corps advanced 2 km.; they simply couldn't. As you know, about that time, the middle of October was the stiffest of the German resistance in this Argonne sector, and at the same time our men were literally worn out from influenza, pneumonia, diarrhea, and constant rain, that brought our fighting strength down to less than 3,500 men in our entire division; and this along with the constant shelling and the night bombing. None of us got any rest. But as I say, as a result of that we began to evacuate a large number of sick and wounded toward the end, and our triage developed into a hospital center. By orders of the commanding general we put up tent after tent, and, in spite of the constant shelling, we remained there; and then they put the quartermaster and ordnance dumps there and we were outfitting the men there, in view of the enemy. We also had some of the 77th Division—the Argonne Players were there, from New York City—and we did everything we could to recuperate there. The divisional triage was not intended to become a rest place for soldiers. We were then at this town called Apremont, and there above this town of Fleville—a matter of only 5 km.—we had a dressing station. As I say, this field hospital had a job on its hands—not only running a triage, but a rest camp and the outfitting camp.

The matter of the evacuation to the rear from the triage I think I have already spoken to you about. There was also another thing which we had to contend with in repose, as in the battle line, and that is unreasonable requests for ambulances from both line officers and medical officers. We would get an S O S call from the front for 300 or 400 men; send 15 ambulances. I don't know whether they thought we picked ambulances off the trees or where we got them, but they were not necessary. All the business was done by sending notes by the ambulance drivers, and these men kept in touch with the battalion aid men, and as soon as the battalion aid station advanced we immediately advanced a litter post or an ambulance post to the evacuated aid station and in time advanced our dressing station to that point. We never listened—unless it was an order from headquarters itself, the commanding general—we never listened to any calls for ambulances or things of that sort, and we generally knew how many casualties there were and handled them. And at one time we evacuated the entire work of the 78th Division. Their sanitary train wasn't there. We had 9 of their men to 1 of ours. The same thing happens in repose. You know line officers still adhere to the old idea of an ambulance being used, in spite of what Army Regulations say, for everything—officers' baggage, officers' wives, everything; but up there we didn't see any women so we weren't bothered with them, except in the rear, where we ran across the Red Cross, Salvation Army, and Young Men's Christian Association. We have had the S. S. U. taken away and we got 20 ambulances down here, and we no sooner got them than everybody wanted an ambulance.

A great many questions are still being asked about the use and the function of the animal-drawn ambulance. I remember Lieutenant Colonel McCormick, who visited the division at Camp Gordon last April, and we discussed with him the animal-drawn ambulances of the division. We wanted to transfer the mules and change them for Fords. He said the day would come when we would pray for a shower of mules. I am not convinced, and I think they serve the Artillery, perhaps, but I believe they should be kept in the division and not in the sanitary train. What we have done with them is to place an animal-drawn ambulance with every organization in the division; every separate battalion and regiment has an animal-drawn ambulance with it, and when they move they always have an ambulance. Now, our regimental officers have a habit of writing letters about not getting ambulances. In addition to that, every organization has a Ford ambulance stationed right with it, and in addition our G. M. C.'s make the rounds every day in repose; of course, it can't be done in activity.

The men of the litter bearer section were added to other companies. The company, as a company, has never established a dressing station; they serve the Artillery, perhaps. These animals help out on a great many occasions, but they are a great source of trouble and care, especially when they are short of food, as they are in every organization in France in the American Expeditionary Forces.

Now the camp infirmaries and their personnel, as you know, come under the direction of the director of ambulance companies. Some place them with the regiments, as was originally intended in the Manual for the Medical Department. We have never done that except when the division left for France. Since the division has been in France Captain Coleman has used to very good advantage about 12 to 14 out of the 16 men. There are 8 camp infirmaries to the division. The remaining we scatter here and there. When we left for the line we salvaged the camp infirmaries, and as such they have had no function in our division.

We also read articles—I got them from this school and other schools—about the station for slightly wounded. We never had it in our division anywhere. Generally the areas were too narrow to permit of it. The slightly wounded get the habit of drifting to the battalion aid station, and when the battalion aid advanced we would put in an ambulance post; the men are in the habit of coming through this place. The slightly wounded came there to be treated, and that later represented the point to which ambulances could go, and, eventually, as the front advanced, we worked up a dressing station in there, and the slightly wounded and the seriously wounded and gassed came there, and in my opinion there is no use for a station for slightly wounded as such. From there they are sent back by trucks or heavier ambulances.

There is another thing the battalion surgeons are apt to do and that is to rush Ford ambulances forward of their battalion aid stations. An ambulance should not go forward of the battalion aid station. When the situation is such that they could go forward of that, the battalion aid station should be moved forward; and we made it a rule, a divisional order, that no ambulance should go forward of the battalion aid station. The use of them was abused in that way. Litter bearers were sent forward with the sanitary personnel. Our bearers were for the purpose of keeping clear the territory between the ambulance dressing station and the battalion aid station.

Rules regarding the running of ambulances and things of that sort: Of course, we have had the ambulances outfitted and they keep so many splints, so many blankets so many litters, so many dressings, so many bandages. We have had to adhere strictly to the rules regarding the traffic regulations and things of that sort, and until we got back here two weeks ago we used to travel in the dark absolutely without light. The whistles are a help.

The matter of keeping the oil and gas supplies, the matter of keeping cars and depots, and things of that sort, devolves upon the director as well as the supply officer. In fact, I am everything from a military policeman to street cleaner, but as a doctor the work to me during the past 18 months has been intensely interesting.

Army Sanitary School No. 179.

THE DUTIES OF THE DIRECTOR OF AMBULANCE COMPANIES

By Captain Taylor, M. C., United States Army, Director of Ambulance Companies, 26th Division

I will endeavor to outline the salient features of ambulance company service in a combat division under two distinct headlines, namely: (1) Service in the rear areas, with the division in training or at rest; (2) service at the fighting front with the division in more or less constant combat.

The personnel, both officers and men, as well as the equipment, is, as you already know, definitely laid down in the Manual for the Medical Department, 1916, with such changes as have from time to time been published. There is, therefore, but little of interest to be said as to the prescribed organization of an ambulance company. However, I should feel that perhaps I was shirking a duty did I not speak briefly of those changes which we, who have had rather extensive experience in ambulance company work, feel would greatly improve the service.

There may be, and undoubtedly there are, a great many minor changes which would benefit all concerned and lead to a greater degree of efficiency in this particular branch of the Medical Department, but to me there are two which stand out above all others. They are radical changes and such as could not be accomplished without definite legislation, but could they made I am confident that they would lead to a more efficient organization, a more rapid receiving of the wounded from the field of battle, a more speedy recovery of such wounded in hospital, and the solving of many difficult problems which division surgeons have had to face during the last few months of war.

These changes in organization are, first, the creation of an ambulance company for the evacuation of sick and wounded, with no other function to perform. Such an ambulance company should be equipped with 12 ambulances of the Ford type and with 8 ambulances of the G. M. C. type. There should be four such companies to a division, and they should have sufficient personnel and equipment to enable them to operate independently of all other units. Such a company should be in command of a trained transportation officer, and should be provided with good mechanics and repair men.

The second change of organization which I would propose is the establishment of a divisional battalion of litter bearers; such a battalion to consist of 4 companies of not less than 4 officers and 168 enlisted men each. The function of such an organization would consist in the evacuation of all battalion and regimental dressing stations to one or more main dressing stations operated by this unit. Each company should be complete in itself and capable of operating independently. The divisional battalion of litter bearers should have at all times sufficient truck transportation at its disposal to transport its personnel and material, inasmuch as experience has shown that the work of litter bearers is too strenuous to allow of long marches. These two changes of major importance are but two of the thousands which undoubtedly have been made in the past, and which will continue to be made in the future, so I shall not tire you with the details of them, notwithstanding the fact that there is much, very much, which could be said in their favor.

Let us first consider the ambulance section with a division "in training"—a section of four companies, each having its definite personnel and equipment. How should it function, and how should it train for the more serious work under conditions of combat? First in importance, to my mind, is the establishment of an esprit de corps, a healthy competition between the companies, and a good state of morale which naturally follows as soon as these are in evidence.

It will take intensive training in the school of the soldier, squad, platoon, and company, and a period of weeks and months before a company can be considered in good condition, and I firmly believe that we should go further and maneuver the four companies as a battalion during the period of training for the value of the lessons which it would undoubtedly teach in management, discipline, and maneuver of sanitary soldiers. I am of the opinion that these soldiers should receive more drill, more discipline, and more general instruction than the infantrymen, for are they not training for the specialized form of work? Are they not wholly "on their own" (if you will allow the expression) when they are functioning? Do they not have to exhibit a greater degree of incentive and ingenuity? Their service is so absolutely different from all others that it will require the highest degree of discipline and training as a soldier. They do not have the close supervision the men of the line have; they do not have the excitement of actual combat to buoy them up, still they must work on and often through the worst of the shelled areas with never a chance to strike back, and always and ever with but one thought in mind—that of service. This, gentlemen, takes discipline and courage such as you must put in the mind and heart of every soldier under you would you have him do his full duty to his country and his comrades.

So, let your training of the sanitary soldier be exacting. Teach him self-respect, his proper relation to others, the importance of the duty for which he is training, and as much concerning the other arms of the service as is possible in order that he may be a distinct help in coordinating the work of the different departments and carry out more intelligently such orders as are given to him.

The selection and training of officers is another most important matter, for this particular branch of the medical service requires a different type of man. He must, first of all, be red blooded and have plenty of endurance. He must be interested in the work at the

exclusion of everything else; he must be a lover of out-of-door life; a man with personality and character and one who does his work for the love of service and in order to sustain certain definite high ideals.

Each officer should receive a special form of training and instruction to properly fit him for his duties later for I do not believe the work of these officers to be interchangeable once they are in active service at the front. For this reason we divide our officers as follows: (1) The commanding officer; (2) the second in command, who may be trained to take charge of the advance dressing station; (3) the motor transport officer; (4) the litter-bearer officer; (5) the officer in reserve to be used to reinforce Infantry either in the line if necessary, or for the relief of any of the other officers of the company during times when active combat over a period of days makes such a relief necessary.

Just a few words as to the definite training required by each of these officers. The commanding officer must be a man in whom all others can place their confidence; a man of good judgment, of unquestionable principles, and a man accustomed to the giving of orders and seeing that they are obeyed. He should know Army paper work well, and should so train his office force in this particular that they will turn out their work accurately and always on time. During the training period he must familiarize himself with every little detail of company organization and administration. He must create a definite system of work in each of the company departments such as will lead to greater efficiency. He must personally drill and maneuver his company, and he must not neglect his own education in mechanics if he would prepare himself to command an ambulance company. The commanding officer will personally check all paper work of his office and he should impress upon his officers that first mistakes are pardonable, but that to make the same mistake twice is not. He must give much attention to the subject of map reading in order that he may instruct others in this most important subject, and he must from the very first learn how to control men, provide for their needs, and obtain from them the hearty and freely given cooperation which is absolutely necessary for his own success as well as the success of the company which he is commanding.

The second officer in command must become the understudy of the commanding officer. He must pattern after him, learn his various systems of operation, and in addition prepare himself for the most important duty as dressing station officer. He is the one officer of an ambulance company who can not afford to forget that he is a practitioner of medicine and surgery, and yet this officer must not pay too much attention to the niceties of his work. Rather, he must be a maker of systems, a man capable of organizing teams and a man of excellent judgment. It is his duty to organize the advance dressing station upon a firm basis, a basis which will allow of the passage through such station of the maximum number of cases in the minimum time, giving to each individual care and such emergency treatment as his condition demands. The advance dressing station is not a station for the practice of medicine and surgery, and he who commands it must be able to discriminate between cases which do not require such attention. Time is an all-important factor, and we have no business temporizing with a patient in the advance dressing station unless we can at least see our way clear to bringing about an improvement in the conditions as they exist at the time. In other words we must not move the patient about and make various changes in his dressings unless we can see that such movement and changes in and such rearrangement of dressing will result in a definite benefit to him. Previously undiagnosed fractures must be discovered here and the proper treatment applied. There is no excuse for patients going beyond this point without having received their initial dose of A. T. S. In so far as is possible all cases should receive hot drinks and a cigarette in the advance dressing station, and of these I believe the cigarette to be of the most benefit. In some instances it will be found to be a distinct advantage if primary gas treatment is given at this station, but such treatment can not always be given in the cramped quarters, and it should never be attempted if it is going to produce congestion and consequent delay in evacuating the more seriously wounded.

The training of the motor-transport officer is, to my mind, best accomplished at a motor-transport school. He must be thoroughly familiar with motors, their construction, maintenance, and repair, and he must have had such experience in the handling of evacuation, both by single ambulance and by convoy, as will make him efficient in the supervision of

the entire motor section of his company. During the training period he should conduct a school daily for drivers and orderlies in order that they may receive instruction in the management of difficult situations, in the care and repair of their machines, and in those things of a military nature which they should know in order to function properly.

The instruction and training of the litter-bearer officer is perhaps more difficult than the training of all others. He must be well grounded in map reading, and must be able to lead his men over a difficult terrain during the night as well as the day. He must be a man of courage, a keen observer of everything he sees, a man who can form an accurate judgment hurriedly and who can, from the very first, gain the absolute confidence of those under him. This man should receive instruction in the making and maintenance of contact, in liaison, in rapid deployment and assembly of his men while marching by compass and in every smallest detail of map orientation, map making, and map reading. Lives often depend upon his accuracy of movement, his good judgment, and his willingness to always go wherever he may find it necessary to send his men.

The fifth and last-named officer of the ambulance company should receive such training as will enable him to be used as a substitute for the other officers should they become incapacitated, and, further, to thoroughly equip him for work with the line at any time that he may be ordered in to relieve a battalion surgeon. This officer is, to my mind, the only one that can be spared from the ambulance company, and if we are to train and prepare medical officer for duty with the line organization, then we should have at all times two or three extras, who can be so trained and prepared and sent into the line to fill emergencies as battalion surgeons become unfit for service or require additional assistance at their stations.

Following the training of officers there is no part of your work of more importance than the training of specialists. I refer to those men and groups of men who, when you have actually commenced to function at the front, will make it possible for you to "carry on" under any and all circumstances, and whose work is vitally necessary to the entire ambulance section. These specialists are of three kinds: (a) The pioneer squad, (b) liaison runners, (c) signalmen.

Let us consider the pioneer squad first. This squad is made up from extra mechanics, drivers, or orderlies of the motor section, its personnel being as follows: 1 noncommissioned officer, 1 carpenter, 1 mechanic, and 5 wagoners (privates first class, or privates). This group is trained in the company and later turned over to the divisional engineers for further instruction. Hence they learn to make rapid road repairs, to bolster up bridges, to lay a corduroy roadbed, to remove obstacles, destroy wire entanglements, and the best method of getting ambulances over or around tank traps. This squad operates at the head of all ambulance routes, precedes all other units of the company in going forward into captured territory, and by use of the repair car of the company make their way to whatever point in the area that may require their attention. For this purpose the repair car is fitted out with two planks, 12 feet of 10 by 2 inches, carried on either side resting in the litter hangers. The following tools are always packed in the car: 1 saw, 1 hammer, 2 pickaxes, 3 shovels, 1 crowbar, 2 pairs of wire cutters, and 1 ax. In addition to this, the car carries a few short and long pieces of studding and several pounds of heavy spikes. We have found the work of this pioneer squad most important, and one is often surprised to see how much can be accomplished in a short space of time, and how many, many difficulties this squad will get your motor section out of. They are an actual necessity in an advance of the line where a company finds itself operating over territory which was but a few hours before held by the enemy; and during the more quiet times, even in an inactive sector, you will find this squad, if well trained, a great help to you. The members of this squad must be reliable men; men who are interested in their work and men who are willing to work overtime and under most trying circumstances to increase efficiency of their company.

The next group of specialists are the liaison runners. This group consists of approximately 20 men, drawn in equal numbers from the 4 ambulance companies, and selected because of their intelligence, their aptitude for the work, and their endurance. These men are trained in making and maintaining contact with battalions of Infantry and of machine guns. They are taught to work by coordinated maps, and only through them is proper liaison maintained with the units in combat. They are disposed of as follows: 1 at each

battalion aid station, 1 at each regimental headquarters, 1 with each machine-gun battalion, 1 at the ambulance section message center, and the remaining number at ambulance section headquarters. These men remain in position usually with the battalion or regimental surgeon, and are fed and billeted by him. They are under orders to report to the headquarters ambulance section at least once a day, and more often as the situation may require. Their chief duties are in promptly reporting any change in location of the units to which they are attached in order that the headquarters may never lose contact with the units, but they are also expected to report upon many other things, such as anticipated raids, either by our troops or by the enemy, the conditions and needs of the forward dressing stations, the conditions of the roads and litter-bearer routes, the results of combat, the number of wounded to be evacuated, and, in fact, a general summary of the whole situation in order that the work may be properly coordinated between the ambulance companies and the Medical Department personnel functioning in the line. They frequently bring in messages from the regimental and battalion surgeons, as well as requisitions for medical supplies needed in the forward stations. When the division is out of the line they are used as couriers and road scouts, and in this way obtain information which is always of great value to your transportation officer, and further keeps you in touch with every unit in the division. This last is necessary if you would function as a full-fledged ambulance company and discharge your full duty to the division as a whole.

The third and last group of specialists who will require training to prepare them for work at the front are the signalmen. They are 16 in number, 4 to each company, and they are taught, in addition to the usual methods of signaling, the use of the blinker signal light, its installation, upkeep, and repair. Two of each set of fours are taught how to send messages, while the remaining two men learn to receive accurately. We train two men for each end of the signal work in order to always have a substitute or a relief, should the regular man doing this special work become incapacitated or lost to the company. Signalmen are taken from various sources in the company, the chief aim of the commanding officer being not to deplete his strength in any of the sections. Therefore, we have taken the extra man in the company office, the third cook, which we can do without during times of stress, and sometimes a man from the advance dressing station party or from the motor section who can be spared for the time being. Signals will be found most useful between ambulance heads, ambulance relay posts, and ambulance dressing stations. They must be used intelligently and not more often than is absolutely necessary. When the blinker signal is to be used you should notify all neighboring units, especially the Infantry. In such a communication state specifically where the blinker is located, what code you intend using—the details of why you need a blinker signal in that particular position and when you expect to remove it. All of this is necessary in order that your signals may not be confusing to the Infantry units, who frequently have to resort to this method of communication for the proper control of their own men and officers. You will not find use for these men in every sector, and when not actually operating the signal apparatus they should, of course, revert back to their former work, but when these men are needed they are needed badly, and you will find a distinct advantage in having trained men capable of establishing communication by means of signal apparatus in your units. Signal apparatus is perhaps more often of value to us when we are preparing to care for a planned raid into enemy territory, for the means to rapid establishment of new ambulance heads and ambulance relay posts, and as they are under such conditions but temporary posts, and, further, since it is so vitally important that the work of establishment and withdrawal be made at exact stated time, we must use some form of signal apparatus for rapid communication from post to post.

In addition to all the work of preparation and training which an ambulance company does in a rear area, it must still care for the daily evacuation of the divisional sick, and in some instances various companies may be called upon to form ambulance convoys for the proper clearing of field and camp hospitals to larger base hospitals farther to the rear. Companies are frequently requested to furnish large fatigue details for construction work, road repairs, and service in the hospitals of the division when such hospitals become somewhat congested with sick.

This period is, therefore, one of long, hard hours of work, and the competent commanding officer is one who can, under such circumstances, mold the character of the men under him and coordinate the work of all elements of the company in such a manner as to make it thoroughly efficient and capable of demonstrating such efficiency under any and all conditions. Every soldier must be kept interested and thoroughly cognizant of the great importance of his own particular work, for without this element of personal pride of the service rendered the average soldier becomes an unthinking, and, in many instances, an uncaring individual.

Do all in your power to establish a fine spirit of service, a jealousy of reputation, and a willingness on the part of each and every man to give to the very last of his strength for the company and for the service as a whole. Such a spirit will invariably be reflected in the character of the services which your company performs.

And now, gentlemen, we shall assume that the training and preparation of the company for more serious work has been completed; that your equipment is complete; that your motors have been put into the best possible state of repair; that your office has been cleaned of its work; that repeated inspections of your officers, men, and specialists have demonstrated their fitness for combat work, and that officers and men alike are ready and anxious to prove themselves in that great cause which brought them into their present environment.

Therefore, let us consider for a moment the "service at the fighting front" with the division in more or less constant combat. Although this is the very kind of service for which you have been preparing, still you will find many surprises awaiting you, and many difficulties to overcome which you had not anticipated in your earlier training. Every position which your men go into must be improved; dugouts must be provided, with protection against gas; the overhead covers must, in most instances, be increased; all ambulances must run without lights, no matter how dark the night or how difficult the road; maps of a larger scale than you have previously used must be obtained, or, if they are not to be had, you must prepare a rough map of the territory over which you are to operate. Here you must commence to give your subordinates written orders, rather than trust to their memory the important tasks which you will have to turn over to them. Your men must quickly accustom themselves to the new conditions; they must be contented to work 24 hours a day when occasion demands; eat but two meals during this time, and catch such little rest as they may in a wet, stinking dugout on lousy straw. Your company will, undoubtedly, receive "orders" in which it will be charged with the establishment of its advance dressing station at a stated point, and the entire care and evacuation of a definite portion of the sector front.

You will, perhaps, be given an opportunity to make a reconnaissance of your new position; at least such an opportunity should be afforded you if the military situation will allow. This first reconnaissance should, if properly made, clear up many matters and allow you to proceed with the duty with which you are charged in a businesslike manner. It should be made with a map of large scale in your hand, and from such a map every feature of the terrain should be checked and indelibly fixed in mind. Positions should be selected with the utmost care, always having in mind your chief duty, "the evacuation of the wounded," the protection of your men, and the rapidity of movement which is so important during "rush" times.

It has been customary in our division to charge an ambulance company with the evacuation of either the right or left half of the sector front, another company taking the remaining half, and the holding of the major part of the other two companies in close reserve. These last two companies will, however, often be used to reinforce the two operating on the line, and it is frequently necessary to charge them with the clearing of the two ambulance dressing stations. It will likewise be necessary for the two companies in reserve to furnish litter bearers reliefs, especially during active periods or during raids in force. It is well, I believe, to take all such details in so far as is possible from one company in reserve, leaving the other company in reserve to cover any unusual and unexpected activities which may develop.

Companies of the line should be relieved "as a company" by one of the companies in reserve as often as may be necessary, depending, of course, upon the width of their portion of the sector front, length of litter-bearer carriers, and the general activity of the troops engaged.

But to return to the first reconnaissance by the company commander. He must arrange for the establishment of ambulance heads, ambulance-relay posts, litter-bearer posts, and

litter bearer relay posts. It must be obvious to all then that he should be accompanied by his motor-transport officer and his litter-bearer officer, in order that they may gain a comprehensive idea of the scheme by which he will attempt to carry out his mission. I firmly believe that in addition to this a second and separate reconnaissance should be made by the motor-transport officer and by the litter-bearer officer, the first to obtain more detailed information concerning the roads of the sector, and the latter in order to familiarize himself more definitely with that part of the terrain lying between the highways and well up to the very front. While such reconnaissance is being made all men belonging to the "liaison runner" groups should have been sent out to their respective posts; that is, sent out to find the units assigned to each in order that they may report the exact location of such units at the earliest possible moment. Some of this information will undoubtedly be given you in "location orders" sent out by division headquarters, but in many more instances you will be obliged to look them up for yourself. Once contact is made, there is little or no excuse for not knowing at all times the exact location of such units as you are serving, if your liaison runners have been properly trained and are dependable.

Following the reconnaissance, and after the whole problem has been considered from many angles and the definite scheme of operation within the sector are outlined, the commanding officer disposes of the various elements of his company in accordance with these plans, ambulance heads and relay posts being taken up, the advanced dressing station established, and the litter bearer officer sent forward with his several groups to make contact with and evacuate all battalion dressing stations along his portion of the front. Their location has been learned through information brought in by the liaison runners, and we are now able to place them exactly on the map. These stations are cleared to the ambulance head, which is located as far forward as possible. This is usually a dangerous point, and we therefore rarely keep more than one ambulance here. Below this head, and on the same route of evacuation, is the ambulance-relay post, one or more, depending upon the distance and the needs of the particular posts served. As the ambulance from the head passed down the route, one from the relay post runs forward to take up its position at the ambulance head. If there be two relay posts, a machine runs forward from the second relay post and takes up its position at the first relay post. Ambulances returning from the advance dressing station or from the triage always take up their position at the post farthest from the battle line. The whole system is considered as one "line of evacuation," and it is often quite necessary for a company to establish two such lines in serving one-half a divisional front. The most important point on this line is the establishment of the ambulance head. It must be well selected and with special reference to the litter-bearer routes. Everything possible must be done to shorten the litter carry, for it is most difficult and gruelling work even under the most favorable conditions. It will further be absolutely necessary for the litter-bearer officer to know the exact location of all ambulance heads, and these positions should never be changed or altered in any degree without first notifying him.

All plans which have to do with an advance or a withdrawal of troops, the relief of various units on the line, or the changing of the tactical situations, must be made only after consulting your company officers, for such radical changes are of great importance to them, and you will find it impossible to successfully carry out your plans without their full and intelligent cooperation.

When a raid into enemy territory is anticipated it is the duty of the commanding general to give all details of such raid to the division surgeon, who in turn gives the director of ambulance companies such data as are necessary for the proper covering of the operations. But one must not rely too much on receiving information direct in this manner, and you will often find that the very first intimation of increased activity will be brought in by your liaison runners who have obtained such information through the battalion surgeon and other officers serving with the Infantry in the lines. Here, then, is another bit of most important work which is of vital necessity to your organization, and which is performed by one of the trained groups of men.

As soon as the commanding officer receives such information he should immediately visit the surgeons of the units concerned and here make such plans as are necessary for the proper covering of the movement. He should obtain all the information which there is to be had from the regimental and battalion surgeons, from the regimental intelligence officer,

and, if possible, from the very officers who are to command the units involved. From such information he lays out his own plan of operation, communicates his intentions to all surgeons concerned, and, after making such new dispositions as are required, checks up personally on these in order to make sure that all are in position and in a state of readiness. Such operations will frequently require the establishment of temporary ambulance heads, relay posts, petite postes, and dressing stations, and always, without exception, such additional work on the part of your litter-bearer section as will call for the greatest resourcefulness, courage, and endurance. Every detail must be given proper attention, nothing can safely be left to chance, watches must be coordinated, large-scale maps must be placed in the hands of your litter-bearer officer in order that he may gain therefrom a clear mental picture of the terrain over which he is to take his men, the location of new battalion aid stations established to cover the emergency, the exact points of attack, the purpose of such attack, and the line of withdrawal from the new to the old position should this be anticipated in orders.

Main dressing stations must be reinforced and cleared for greater activity; ambulance drivers and orderlies should be as thoroughly rested as possible to prepare them for the work at hand; mechanics should look carefully to the conditions of their machines; in fact, one and all must do everything in his power to provide against mishaps and subsequent failure of any part of the anticipated operations on the line.

In short, all must prepare for the hardest work they have yet known, work crammed full of excitement and danger to life and limb, and work which is at all times of vital importance to the successful carrying out of the military operations planned. Wounded must be removed quickly from the fighting line if we are to preserve the fighting spirit and morale of those who are left to engage the enemy; and no matter how long the carry, no matter how difficult the terrain, no matter how thick and murderous is the enemy's fire, this must and will be accomplished.

Such, gentlemen, are the duties of the sanitary soldier at the front—a service of self-sacrifice and denial; a service which requires men strong in body, clear of mind; men of determination and courage; men who fully realize how little it matters where one dies, but of how great importance is the way in which one dies. I have seen these men, gentlemen, under the most trying circumstances, and I have yet to see them fail. In proof of such statements I would recall to your mind the wonderful work accomplished by these soldiers of the Medical Department of our Army, at Bois Brule, Seicheprey, Chateau Thierry, in the St. Mihiel salient, and lastly in that hell hole of all fronts, the sector north of Verdun. In these positions the soldiers of the sanitary formation has proven himself a soldier in every sense of the word, his sacrifices have been great, but he has invariably discharged his full duty toward his fellow men and humanity in a way that makes us all proud of him.

The director of ambulance companies should, as soon as practicable after taking up a new position, prepare a comprehensive plan of anticipated operations under the following headings, for the information of the commanding officer of the train, the division surgeon, and all officers of the ambulance section.

- (a) Plan of action in defense of the sector, combatant troops holding present positions.
- (b) Plan of action in forward movement of our combatant troops to the next objective.
- (c) Plan of action in a withdrawal of our combatant troops to a position of defense in the rear.

To prepare such a plan of anticipated operations will require much general information and a most thorough reconnaissance over a wide stretch of territory. Every effort should be made to use narrow-gauge railways and canals, and to determine, in so far as is possible, the exact positions of dressing stations and ambulance heads in the new positions which must be taken up on an advance or a withdrawal. All will not proceed in accordance with your plan. This can hardly be expected, for many conditions will supervene to make changes in the disposal of units in combat, thus making it necessary for you to make different plans for their support. But if you have gone thoroughly into the matter, have made a careful and painstaking reconnaissance, and have used good judgment in the preparation of such plans, you will find them of the greatest benefit to you at the critical moment, and the information which

they should always contain relative to roads, railways, canals, bridges and routes of evacuation from designated places will prove of great assistance to the division surgeon and commander of the sanitary train.

There are many other details with which one must familiarize himself at the front, but these are too varied and too numerous to bring up for discussion here. The matter of "taking over" and the relief of other units who have partially or fully organized the work of the sector are information the details of which every commanding officer should have clearly in mind.

We must never forget our principles of gas defense, and we must at all times and under all conditions endeavor to improve the living conditions of our men, and afford them all the protection from enemy operations as is possible in the full and proper performance of their full duty. Your work of training along these lines never ceases. Even after relief has come and after you have taken up a "position in rest" far from the front, you will find it always necessary to continue your instruction. Let such instruction be made interesting and such as will be of obvious benefit to the enlisted man personally. Teach him the reasons for certain things, and give him such a diversity of mental employment as will stimulate his imaginative powers, and keep him ever alert and ready to absorb all information pertaining to his position as a soldier, thereby making him of greater value to himself and to his country.

Question. How many men do you use on a litter?

Answer. Four, always.

Army Sanitary School No. 180.

THE DUTIES OF THE PSYCHIATRIST OF A DIVISION

By Capt. H. A. Steckel, M. C., division psychiatrist, 26th Division, November 27, 1918

I hope to be able to give you some points which I picked up during service at the front and which may be of value to you in the future. The problems of the war have been many, but none more striking than those due to the extraordinary incidence of mental and nervous diseases, the divisional features of which I shall endeavor to take up with you, based on my experience in the 26th Division. I was first assigned to the division in January, while we were yet in the training area. For the purpose of culling out the undesirables, we opened a psychopathic ward in Base Hospital No. 66, at Neufchateau. This was a prophylactic measure against the development of war neuroses and was attempted in all the cantonments at home in the draft divisions; but as the 26th Division left the United States rather hurriedly and unexpectedly, it was not thoroughly done and many mental defectives and undesirable individuals were found in the division. I saw many—I mean comparatively many. I worked for 10 days in this observation ward at base 66, examining during that period approximately 40 cases. Of these about 25 were evacuated to the rear as being unsuitable for front-line work, and about 15 were sent back to their organizations. We were first sent to the sector in and about Soissons, in the Chemin des Dames region, remaining there about six weeks. During this time only 18 cases of neurosis came through the French psychopathic hospital located behind the lines. The reason for this low incidence of the neurosis was, first, the men were fresh; second, they were brigaded with the French and a certain amount of the responsibility which they later took over rested with the French and the men felt this lack of responsibility; and, third, the sector, as Captain Blood said, was a quiet one—that is, there were no extensive engagements, no heavy shelling at any particular time. After six weeks at this front we came back to a rest area for a supposed month's rest. We were back probably four or five days when we were suddenly ordered to the front and the men, naturally, were disappointed, not only that they did not get their rest, but neither did they get the leaves which were promised them. On entering the Toul sector the first great shelling to which the men were subjected, and which resulted in a considerable number of war neuroses, occurred at Apremont on April 10, and during that time we had the first great number of cases coming through. I have prepared a chart here, which is rather small, but perhaps you can see it sufficiently clearly to serve our purpose. It shows in a diagrammatic way the admission curve of these cases. Now during the 1st, 2d, 3d, 4th, up to the 10th of April you see there were only one or at most two cases admitted daily to our field hospital, which was operating then really as an evacuation hospital in Toul; but on the 10th, at the time that

this rise in the curve occurred, there was heavy shelling and the positions were rather unprotected. We had 13 cases admitted on the 10th, on the 11th, 6, and on the 12th, 11. These were rather severe cases. They were the first real "shell shock" cases (if you will allow me to use that term once this afternoon) we had had in the 26th Division up to this time. The diagnosis "shell shock" has been forbidden, and we now use the term "psychoneurosis," which is better for many reasons. It was there I saw the first real early cases of war psychoneurosis. We were then located in a comparatively quiet sector and our field hospital system was so situated that it was comparatively easy to hold cases at least 10 or 14 days in a field hospital, which is not the usual scheme. We had two hospitals up forward, probably 4 or 5 km. from the line, acting as sorting stations, and two farther in the rear, 14 or 15 km. behind the line, being situated in Toul. The 101st Field Hospital, to which all psychopathic cases were sent, had 600 beds and accommodations that could be expanded up to 800. We usually had between 500 and 600 patients there. Major Thornton and I had charge of the psychopathic cases, and we had three wards which accommodated 75 patients, which was a very excellent scheme. As I say, we could, with such a large capacity and a quiet sector, keep our cases as long as two weeks, and on one occasion where two of the wards were quarantined, one for measles and one for scarlet fever, we were able to keep them as long as four weeks, which gave us an opportunity to study the cases rather thoroughly and also see how long it would require some of the worst cases to recover sufficiently to go back to the line.

The second great number that came through while we were in this sector was during the Seicheprey affair on April 20. The line on the chart shoots up rather high. We had 27 cases on that day, and three or four days later it went up as high as 70. Now the reason for these two curves. The Seicheprey attack, when the boche came over into our lines, threw over a heavy bombardment causing the first curve, and the second slight rise was due to the counterattack by our own troops a few days later. Now I want to call your attention to the fact that of all these cases occurring between the 16th and 30th of April, a total of 133, 31 per cent—that is to say, 53 in numbers—were returned to their organizations directly from the field hospital. Now we could do that because we were allowed to keep the cases 10 days or more—the average treatment for these cases being approximately 10 to 12 days. Following along with this chart as an illustration, we see along here two and three admissions of psychopathic cases each day. That doesn't mean that we have constantly developed the real war neurosis. It means simply, the constitutional defects are beginning to show up and the psychopathies are beginning to be discovered, although perhaps a few are neurosis due entirely to war conditions.

Then on June 16, the Xivray affair, at which time all the areas around that front were heavily shelled, back as far as division headquarters—the town in which the division headquarters were located was so heavily shelled that they had to move—there were 27 cases admitted, and these cases, strangely enough, came not only from the front line but also from the second and third lines, and even from the 101st Engineer echelon, which was located as far back as division headquarters. On the 18th, 10 cases were admitted. These were old cases which occurred on the first day of the bombardment but which were held over at the various dressing and battalion stations before they were sent back, thinking probably they might recover there. We were, I think, fairly successful in the treatment of these cases, in that we got as many as 31 per cent back to their organizations from the divisional area itself, preventing them from going back to the Services of Supply, which is so bad for this class of cases.

After leaving the Toul sector, the latter part of June, we went to the Chateau-Thierry sector, and we saw more cases there; at least more went through our station than at any other time either before or since. We were laboring under difficulties which have since been rectified. The difficulty I want to bring out particularly is the inability to hold the cases in the divisional field hospitals for any length of time. Of course, in open warfare, such as we had at Chateau-Thierry, where the line is moving constantly, it is necessary to keep the field hospitals free of patients so far as possible so that they may follow the troops. We had at that time one field hospital operating fairly well forward as a triage or sorting station; one field hospital acting as a surgical hospital for severely wounded, and we had two field hospitals combined, which were functioning not only as a secondary sorting station or an ambulance

transfer station, you might say, but also as a sick hospital; but because of the activities of the time and the expected movement of the line we were not allowed to hold cases more than three or four days. That absolutely ruled out the holding of any psychoneurosis, because I don't believe there are any of them that will be able to go back to the line in that short period of time. As a consequence these cases were evacuated immediately to the rear, passing through the evacuation hospitals, and on through to the bases. In the period from the 9th of July to the 24th—I made a chart covering that period. We first went into the area early in July, but it was fairly quiet just at that time. The first great number of cases came in on the 14th, at which time there were 21 cases. That followed a heavy bombardment of Belleau Woods, and 6 cases were evacuated by one Infantry regiment and 8 by the 101st Engineers, who were located in these woods and were subjected to this shelling. Almost immediately the curve drops. On the 16th there were only 5 cases admitted, but on the 18th the beginning of the offensive, there were 68 cases admitted, and on the 19th, 74 cases came through our station. Now I think that probably if we had had a place to keep them, practically all of these could have been held in the divisional area, at least saved from going back to the Services of Supply, and returned to duty in an average period of 10 days. But we had no room to keep them; we had to keep our field hospitals clear; so they went back to the bases and were scattered all over France. I might say that approximately 4,000 cases of psychoneurosis, at least evacuated as psychoneurosis, went back through the Services of Supply and were lost in various base hospitals in that period from the 9th to the 24th of July. Our division was not the only one which suffered from this condition of affairs. We had to get our cases back because sick and wounded were coming through and we had to keep moving to follow the troops. About 400 from the 26th Division alone were evacuated during this period.

We then went into rest for approximately two weeks, after which we went back to the St. Mihiel sector. On September 12, the beginning of the offensive, 38 cases were admitted. You will notice the curve shoots up suddenly on that day, and then on the second day only five cases. The troops were moving forward; they were successful; the boche were retreating; and there was no reason for psychoneuroses to develop. The troops were victorious and this adds to the morale, and with high morale psychoneuroses are not so apt to develop. Furthermore, there was no heavy shelling after the first day.

In the St. Mihiel sector we had no field hospital to hold these cases; they were all evacuated to the neurological centers, three of which were located back of the American sector. During the Verdun work, which extended from approximately the 14th of October up to the finish of the war, there were a number of cases that came through, but we were able in this instance to hold many of them in the field hospitals. We had one field hospital operating very close to the lines as a sorting station, and two at the rear acting as sick hospitals, so that we had accommodations for approximately 400 patients, and every opportunity was afforded the division psychiatrist to keep cases for as much as five and six days, in consequence of which 32 per cent were returned to duty during that period. Now it was in this sector that very heavy shelling in all the areas occurred. The Verdun sector is probably the worst that our division has ever been in, and we were in at a time when the troops were not only tired—they had been working hard ever since February, practically continuously—but the weather was bad; they were in exposed places, lying in shell holes three or four days at a time with no other protection, and the shelling was very heavy in all the areas, so that the neuroses came through almost constantly. But there were two days in particular when the curve was rather high. One was on the 16th of October, when 21 cases were admitted, and the other on the 27th, when 49 cases were admitted. On both of these days attacks were made by our division. Of these cases, 32 per cent were returned to full duty, these being rather slight cases and were due largely to fatigue and exhaustion. There has been considerable discussion as to how great a part exhaustion plays as an etiological factor in the production of these war neuroses, but we must admit that a man who lies in a shell hole three or four days with only his iron rations for sustenance, under constant bombardment, has considerable time for introspection, and he is not in the best physical health to bear up under the combined physical and mental strain to which he is subjected.

Now I might say that after the Chateau-Thierry affair, through the efforts of the neuro-psychiatric consultants, three neurological hospitals were located behind the field hospitals, but not considered in the Services of Supply as far as evacuation of patients is concerned—that is to say, the patients could be returned from these neurological hospitals, back to their own divisions without traveling through the base, up through the replacement camps, and all the difficulties through which a man passes when he goes to a base and which are so prone to produce neuroses of a chronic type. In each of these hospitals they had accommodations—Nos. 1 and 3 were directly back of Verdun and St. Mihiel—I think for three or four hundred patients. During the St. Mihiel and Verdun offensives, from the figures I have been able to obtain, which perhaps are not exactly correct but fairly so, there were 2,000 cases admitted to these hospitals, only 600 of which were evacuated into the Services of Supply. In other words, we held up about 32 per cent in the field hospitals, and approximately the same per cent in the neurological hospitals, and only a third of the total number of cases got into the Services of Supply, whereas during the Chateau-Thierry affair they were all lost in the Services of Supply.

Now, why is it so important that these cases should be prevented from getting back into the Services of Supply? The reason is this: These conditions occur, as a rule, in individuals of perhaps a constitutionally mental defective make-up, or at least in practically all of them there is a psychopathic tendency. It is true that neuroses do occur in what we ordinarily call a normal individual, but that question can never be settled because it is very difficult to say what is a normal individual. As I say, these cases as a rule are potentially psychopathic and the further back they go the more pronounced their symptoms and the more chronic are they apt to become. The regimental surgeon seldom sees a well-pronounced episode in a psychoneurotic individual in the front line. It is when he is sent farther back that these chronic symptoms develop, and they are difficult ones to treat, and that is why it is necessary, as far as possible, to prevent these men getting back through the bases.

Now what would be the ideal conditions to handle the situation in a division? In the first place, I believe there should be two men experienced in psychiatry in each tactical division. One to work in the "triage" in order to see the cases early so that they are properly collected and are sent to the proper centers. A certain percentage of the cases, as we have demonstrated before, can be held in field hospitals for a period of 5 or 10 days, and it would be the duty of the division psychiatrist operating at the triage to pick out the most favorable cases, holding them in the field hospital. Then there should be a psychiatrist in the field hospital itself to treat these cases. The man who is working in the triage often finds it difficult to get back to the field hospital—the sick hospital—which usually operated 8 or 10 km. behind the triage, and spend sufficient time there to take proper care of the cases. I tried as far as possible to do that, but I did feel that we would have had better success by having a psychiatrist there constantly. There should be at least 50 beds available in the field hospital to treat these cases. During the Verdun offensive the best conditions prevailed, but even then, with the number of other sick cases held in the field hospitals, we were forced to send back to the neurological center cases that should have remained, because now and then the capacity of the field hospital would be too small to hold all the cases that were coming through. The sick rate was high because of bad weather conditions, and on a number of occasions I was forced against my judgment to send these cases on through to the neurological center.

One difficulty experienced again in the Verdun offensive was that these neurological centers were too far in the rear of our triage—the distance was approximately 40 km. and from our sick hospital at least 30. With transportation facilities poor, we were required to transport patients by trucks in a great many instances. It was difficult to get them back promptly. We usually, in the triages, attempted as much as possible to equalize the loads, to send patients for certain hospitals on certain ambulances in order to conserve gas. The slightly wounded went to one hospital, the severely wounded to another, the psychopathic to still another, and frequently cases would be held in the triage a number of hours before a sufficient number had accumulated to warrant sending an ambulance there. If the distance had been less it would have been a great deal easier to get the patients down more promptly.

Now, in the division itself the psychiatrist can do considerable work, even when the division is not in an active sector; that is to say, during the rest periods he can make super-

ficial surveys of the various organizations, picking out any defectives he may see, and in that way attempt to hold down as much as possible the incidence of the neuroses. And I might say that the regimental surgeon would be of great assistance to the psychiatrist if he would when referring cases to the psychiatrist make short notes on the behavior of the patient, thus giving the psychiatrist a basis upon which to make his examination. When I was making the survey of the supposed defective cases at Neufchateau in the observation ward at base 66 the cases were sent in simply marked: "For observation"; and I had nothing whatever to work on. The men refused to admit that they had had any trouble in their organizations, and it frequently required a number of days before I could get in touch with the regimental surgeon or the line officer to get some information as to why the man had been sent in for observation, because some of them, the first few days in the ward, appeared perfectly normal. So those of you who are regimental surgeons can be of great assistance to the psychiatrist by making a few notes, just a few words—for instance, "Patient has been irritable; disciplinary action has been taken a certain number of times," etc., just a few words, a few lines, to give the division psychiatrist something upon which to base his observations. Furthermore, the battalion and regimental surgeons can assist the psychiatrist during action by tagging the patient properly. There are, of course, a number of forms of neuroses developing under different conditions; some develop without any concussion, others are due not directly but indirectly to exposure to high-explosive concussion, and it is necessary to know the early symptoms in order to diagnose your case properly. Therefore, the battalion man can at least make a note as to whether or not the patient was unconscious when he came to the battalion dressing station, also if the patient revived in the dressing station; he can make a brief note as to whether the patient came to suddenly or slowly, because on that fact at least partially depends diagnosis of the case. If actual concussion occurred it should be noted on the tag.

I will not take up the symptomatology of the psychoneuroses to any great extent, but I will simply go over briefly what we find usually in the cases admitted to the field hospital, particularly because all my work has been confined to that location. The hysterical case may be unconscious. He gives a history as a rule of having been unconscious before he reaches you; he may occasionally be unconscious when he reaches the field hospital. Now, the character of this unconsciousness varies in the various classes of cases. As a rule, the hysterical will have recovered consciousness before he reaches the field hospital. He can give you a history that he remembers the shell breaking and perhaps remembers seeking shelter after the shell broke; sometimes he reaches shelter, but becomes unconscious immediately thereafter, and doesn't remember the trip to the dressing station. He will tell you that he came to, suddenly, in the dressing station or the ambulance station, or, perhaps, not till he reaches the field hospital, but he comes to suddenly and remains conscious. In a true concussion case the unconsciousness is prolonged and he comes to gradually; like a man coming out of ether. He will open his eyes, look about, and lapse into an unconscious state again, frequently repeatedly. Also the unconsciousness comes in immediately the shell breaks; he never has time to seek shelter because he is stunned almost immediately. I will say there are very few of these true concussion cases. Most of them are of the hysterical type.

Regarding the minor forms of hysterical neuroses, I may say that the main symptoms which we noticed in field hospitals were tics, tremors, choreiform movements, anesthetics, and disorders of hearing and speech. I might say I have seen very few disorders of speech in the field hospital, but they may develop as the patient goes back to the base hospital. I have seen a few hysterical anesthetics. The officers we usually find suffer from an anxiety neuroses, the history of a typical case being as follows: He complains of feeling exhausted, that he needs sleep, not having slept well recently and having had disturbing dreams. His dreams are usually of the occupation variety, he having trouble with his men, being bothered by the enemy, etc. If an Artillery officer, having trouble getting the cartridge into the gun, etc. He usually wakes with a start two or three times during the night and then has difficulty returning to sleep. He may go on in this way for three or four or more weeks, but the slightest unusual occurrence will upset him and he will become disabled for three or four weeks or perhaps months, depending upon his make-up. These are the cases that

should be given a rest, either in the back areas or, perhaps, sent on leave before an actual breakdown occurs. The exhaustion neuroses are due purely to exhaustion, and are always slight, show usually only tremors, and recover in a very few days—usually after three or four days' rest in a field hospital. It is rather important, I think, to have field hospitals set up in such location that baths can be provided for these cases, because, usually, after a warm bath, a change of clothing, and a night's rest in bed, these men appear entirely different from when we first see them at the time of admission to the field hospital. There are always a few cases in a division, disciplinary cases, which may be referred to the divisional psychiatrist. A man who has come up for disciplinary action a number of times certainly must be abnormal mentally. His adaption must be poor and we find it is in many cases, especially in our own Army, because we are not a military Nation. We have been picked out of civil life and placed in an environment which is entirely new to us, and it is very difficult to adapt oneself to this new environment. A psychopathic personality has more trouble than the average individual; therefore, these cases come to the attention of the psychiatrist and should be examined with care, as some of them are actually insane, or at least not cases actually deserving punishment for their shortcomings.

Now, I have tried to cover as much as possible the development of the work in our own division and I have tried to explain what might be done perhaps in the future. In addition to these neurological hospitals, which are army hospitals operating behind the field hospitals, I have suggested that a field hospital of 50 beds, known as a psychopathic field unit, be attached perhaps to the division or the corps—a hospital that would operate farther up than the army neurological bases. A unit of this kind with 50 beds could take care of quite a number of the milder cases and in that way not overcrowd the field hospitals, which need to be kept open for other sick and also kept open for movement in case the line goes forward. Any questions?

A STUDENT. Did you find any morons in the service?

Answer. There haven't been very many in the 26th Division. The early replacements which came to the division in April were rather a poor type, but I wouldn't call them a moron type. They were more the constitutionally psychopathic individual—perhaps the farm boy who finds it difficult because of his lack of education, lack of travel, etc., to adjust himself properly. He has never been in contact with many people; he has been brought into a new condition, a new environment, which he finds difficult; but of true morons, there haven't been many over here. I believe they have been culled out before they reached the American Expeditionary Forces.

Question. Did you ever find any acute insanity developing that had to be put under restraint?

Answer. We had one case that came into a field hospital under restraint. He was a case of hysteria and came in on a litter, all tied down with blankets and straps of all kinds, which we immediately removed, and by a little quiet talk and persuasion we were able to overcome his acute excitement. Let me emphasize the fact that the war neuroses is nothing new. We find the same conditions in civil life as well. The symptomatology is the same as we find in civil practice, except that the coloring is different because of the etiological factor, namely, the stress and strain of modern warfare.

Army Sanitary School 182.

SANITARY TACTICS

By Col. M. A. W. Shockley, M. C., United States Army, October 20, 1918

I want to say at the start that there is absolutely nothing new in sanitary tactics; neither is there anything new in combatant tactics. The only things new or in the nature of variations in the combatant principles have been caused by motor transportation, the use of high-power artillery, and the use of poisonous gases in warfare, and, of course, aviation. But tactical principles, either combatant or sanitary, remain exactly the same. If you go into the history of the military service and the history of the sanitary service you will find practically the same old organizations, particularly in combatant service, from the time of written history. The sanitary service was, of course, not organized as a service practically until

the beginning of the present century. The first record that we have of sanitary service is perhaps some hieroglyphics, picture writing, near the pyramids of Sahara, about one thousand one hundred and odd years before Christ, in which there is a picture of an Egyptian soldier receiving first-aid treatment. When we get into legendary history this is undoubtedly correct because the Egyptians did depict historical events in this manner. In written history the first mention is in the Homeric hymns of Machaon and Podalirius, who accompanied the Homeric soldiers to the city of Troy, and in the *Iliad* we find the wounded being treated by Achilles, who seems himself to have been a surgeon, more or less. You will remember in this war Machaon and Podalirius were the sons of Æsculapius, who was the son of his god-like father. He brought doctors who were taught by Æsculapius, so much so that Pluto complained to Jupiter that Hades was becoming depopulated on account of decreased population due to the skill of Æsculapius. There has been no such complaint since that time, however.

The next we hear of sanitary service was some Greek physician who accompanied the Greeks in their war with the Persians about 450 B. C. Then in Julius Caesar's armies we find the battalion surgeon. He is called the medicus, attached to each battalion, and also they had a staff surgeon attached to the legion. That corresponded practically to our large regiment of to-day; our Infantry regiment is the old Roman legion, and our battalion is the Roman cohort, which had a battalion surgeon attached to it. We find artillery organizations and the tactical formations were practically as they are to-day except as affected by increased projectory weapons and high-power explosives, and also motor transportation.

The next thing we have in the sanitary service was the Monkish sanitary surgeon; because after the fall of Rome and the decrease in the wanderings of the Greek physicians, the practice of medicine, and in fact all the sciences, fell into the hands of the clergy, and continued in the hands of the clergy until about 1100 A. D., when at the Second Lateran Council the clergy were prohibited from engaging in secular pursuits, and medicine and the other sciences at large were relegated to the laymen. The laymen were not educated and surgery degenerated to barber surgery, where it remained until about the sixteenth century. At the time of our Revolutionary War there existed the difference between the surgeon and physician. We had a Surgeon General and Physician General, and that continued until some time around 1803, when the Medical Department was reorganized. The medical officers at that time, except the Surgeon General and Physician General, were not military officers. They were civilians, and the medical officers were not commissioned officers at all. They were practically barber surgeons. They had noncommissioned rank. When the Medical Department was reorganized the medical officers were given rank. The Surgeon General issued a bulletin to the newly created officers that they were now officers and gentlemen and expected to conduct themselves as such, and as officers and gentlemen they should resent affronts. The result was that up to 1846, when duelling was suppressed, the officers of the Medical Department fought more duels and killed more men than the Army did. The Medical Department consisted of very little except some transports, but during the Mexican War they had some ambulances. The first we know about was the ambulance wagon. That was organized in connection with the Queen's Hospital, by Isabella of Spain, which she organized for the siege of Alora in 1484, which consisted of about 400 wagons, and the chronicle further states that the nurses that presided were good matrons and not the usual camp followers. So at that time ambulances came into use. There was little before that time.

The British in their expedition against Ireland in 1200 appointed some physicians to accompany the expedition. Nothing was done, however, after the time of Isabella, and the Queen's Hospital fell into disuse, and the old tortoise that the British produced about 40 years ago with roll sides which filled out and formed a tent was substituted for Isabella's traveling wagons of 1485. In 1796, I think it was, Baron Larrey, of the French, who organized the first ambulance company, which was very much like the French field ambulance of to-day. It consisted of a tent section and ambulance wagons. It was considered a great advance. In the campaign in Egypt the baron speaks rather feelingly and says that he prepared to put the litters on camels, but the combatant troops took them to carry ammunition. I think a good many medical officers can say something about that to-day. The next thing was in 1801,

when there was some organization in the French service. Baron Percy conceived a long, sausage-like looking wagon on which were placed saddles. The medical officers rode in the saddles and they placed a thousand dressings and other things in the sausage-shaped body. The Germans about this time woke up and changed their barber surgeons into officers of a commissioned rank. They had regimental surgeons about this time and increased their service. However, there was not a great deal done up to the time of our Civil War, although in the Crimean campaign the French and British sent ambulances to Crimea which did fairly well, but they had no very good organization. The Crimean War was in 1856 or 1859, if I remember rightly. Even at the Battle of Solferino the wounded were not particularly well cared for; and as a result of that the Swiss instituted the idea of the International Red Cross, which was started but got little distance at the time. After our Civil War it was further instituted and worked out quite well in the Franco-Prussian War of 1870-71.

Our Civil War practically gave the impetus to the organization of the sanitary service. We had ambulance wagons before that time; we had them in the Mexican War and in the frontier service in the West, but there was no necessity for any organization other than the sanitary service of a regiment. We had a couple of sergeants and some men detailed from the line for the sanitary troops. At the Battle of Bull Run that situation existed. The Army at the beginning of the Civil War was about 16,000 men. Surgeon General King, at the Battle of Bull Run, was not interested in the management of the sanitary service at all because there existed none. They had some ambulances and a few troops which were the east-offs of organizations. There was a field hospital fixed up, and Surgeon General King spent his time dressing wounded instead of managing the sanitary service, and when the retreat began he states that he followed General McDowell back some distance and then lost him. He was greatly afraid that supplies which he had ordered up might fall into the hands of the Confederates, so he went to Washington to stop the supplies, and when he got there he found they had not been sent. The second year produced some organization, and finally Letterman organized the ambulance company. It was handled by combatant troops that were practically under the control of the quartermaster, and this formed the ambulance detachment pure and simple, and they ran it on this basis for a while, without ambulance equipment, without any sanitary troops or any technically trained personnel with the organization. In 1862, however, Letterman instituted, in addition to the sanitary corps, the formation of divisional hospital units, and they were worked out so that at the Battle of Antietam he had fairly satisfactory divisional hospital organizations. After that battle and the retirement of the Confederates south, in the following winter, the organization was increased and improved very much. In the meantime the armies of the West produced a similar organization, including an evacuation service by hospital train, but no Services of Supply as we know it. So that when Grant went south, across the Rapidan, in 1864, we find that the Army of the Potomac had corps and division hospitals and a reserve medical supply unit very efficiently organized. You remember that the divisions weren't large at that time; they consisted of only between four and eight thousand men, and a division hospital would correspond more or less to our field hospital at the present time, and it worked out fairly well. They had in addition a brigade medical wagon, which corresponded to our camp infirmary wagon. At the Battle of the Wilderness we find the first indication of the use of the station for slightly wounded. At the Battle of Fredericksburg, they found great necessity for the station for slightly wounded, because in December, 1862, we know that the patients who were slightly wounded crossed from Fredericksburg around to the Portsmouth side, where a hospital train was arranged to carry the casualties that had to be evacuated to base hospitals; and they also used boats to carry the casualties, and in fact casualties coming by boat brought the first news of the battle to Washington.

The slightly wounded grabbed all the accommodations on the boats and trains and graver cases did not get out.

On May 5, 1864, at the Battle of the Wilderness, a division hospital was established at Wilderness Junction as a station for slightly wounded and held them for evacuation. Remember the route of evacuation was up north to Washington, and they started their casualties out on the 6th of May, but the Confederate cavalry had crossed the Rapidan and cut the route, and 356 ambulances countermarched and moved down over to Fredericksburg, where a new base was established. They evacuated their casualties there. They kept their patients in the

ambulance wagons 36 hours. On the following days, the 7th and 8th, the army moved down and encountered the enemy at Spottsylvania. A number of the division hospitals, with their patients, were abandoned on the field and the Confederates took the extra rations for the patients for their personal use, and the patients went rather hungry until relief parties were sent to get them.

There was no sanitary service because there was no Services of Supply. The ambulance corps companies having been sent with all their patients over to Fredericksburg, had something like 15,000 slightly wounded, or skulkers, or stragglers. There was no military police service to search out the well from the sick, and any man who could put a bandage on went through. That should not occur, but it has occurred. However, in the present days, with military police, no person should be allowed to go beyond the regimental lines without a diagnosis card or a pass.

Now we have the development of additional sanitary units tactically and on the basis that we had at the beginning of this war. As the Army of the Potomac went south in the Virginia campaign, they found the necessity for these organizations very markedly pronounced, and they describe the necessity for evacuation hospitals. They could not arrange for them in the campaign, but later they organized the evacuation hospital and put it on the railway, so that when Lee retired from Richmond this evacuation hospital, a very large organization, was sent south and stopped at the proper place on the railway and the chain was complete, because base hospitals had been organized at the beginning of the war at Alexandria, at Washington, and other places. Through the West, and all through the East, they had base hospitals but no evacuation hospitals to couple them up, up to this time. They had hospital trains, very simple but very good, at the beginning of the year 1862 and completed their organization well up in 1864, but the first evacuation hospital was in the very early spring of 1865. Now when Sherman made his movement from Chattanooga to Atlanta they had developed the hospital trains very thoroughly; and while they had started out with a corps hospital or reserve hospitals, they finally wound up with division hospitals, which correspond to our field hospitals because our regiment was their brigade, our battalion their regiment, and so on; and when Sherman went south from Atlanta up the sea the transportation factor was very important and their equipment had to be reduced. They supplied the ambulance corps with very light field equipment and moved it. He had only 256 casualties between Atlanta and Savannah. All of these were carried through in the ambulances except the Cavalry, who were dropped off, and the natives were given \$1 gold per day for taking care of them, also a threat that the troops might be along again soon if they didn't take good care of them, and if they expected to have roofs over their heads when the Yankee troops returned the men would be cared for, and they were cared for. After a while the civilians discovered that the soldiers were ordinary individuals the same as they, and they were willing to play the game from a humanitarian standpoint. That was the basis in the Civil War and that is the basis on which the sanitary services of all the armies of the world were organized. We forgot the lessons of the Civil War promptly because we forgot that there was an organization larger than a regiment. We had no necessity for it and lapsed into smaller posts and small operations after the Civil War, usually against the Indians. In the Spanish-American War we went back to the old basis, and then forgot about it after the Spanish-American War. In that war we had regimental hospitals and evacuation hospitals. They were forgotten after awhile. Then some individuals in our sanitary service—two, who have since been retired—commenced to look into our history of war in sanitary service and decided that it must be reorganized. It was, and reorganized on the basis of field service operations, and that is the sanitary service that we have to-day, and that is the sanitary service all armies had prior to the World War which began in 1914. Some semblance to an ambulance company, field hospital, evacuation hospital or casualty clearing station, and base hospital, with means of transportation or transportation by railway or ambulance company or by boat, was brought about. That was the organization, and if you will look into the organization of the sanitary service of the various European nations you will find that the organization is almost identical. You will find deviations in the method of handling it, but you will find that there are similar organizations for all armies in general, and the methods in general of handling the wounded of battle and the sick are practically the same, and the means of evacuation are the same.

Now with regard to the question of war. I think we can safely say that it may be divided into two types of operations—offensive and defensive. With defense always comes the use of natural or artificial features which protect the individual from the effects of weapons, usually trajectory weapons launched by the enemy. In war since the beginning of history artificial features and natural features have been used. The ancient walls and fortifications and the earth and breastworks of the nineteenth and twentieth centuries, and the present trenches, which, of course, have been used largely since the beginning of this century; but they were used long before that. In Julius Caesar's books you see the entrenched camp very clearly, with earthworks and means for the prevention of the rapid advance of the enemy thrown up; so there is nothing new about the use of artificial or natural means for protection, but only in the European war has it been extended quite as far as we now see it. Now the reason why we have the so-called trench operations, which are simply operations in defense, is because we have had on the Western Front armies committed to attack or defense on a field which is protected on one side by the British Channel and on the other by the neutral country of Switzerland. Consequently this position could not be flanked, and if it was well defended by trenches the war is reduced more or less to a state of stabilization. Neither army could maneuver all the force they could gather to attack properly, neither army wished to commit itself absolutely to an overwhelming defeat by throwing all of this force in and taking the consequences. They have made limited attacks at various points and have broken through many times and used up some of their reserves, but neither of them has made a general attack clear through.

Now don't think of warfare as trench operations, as a great many people tried to teach us two or three years ago, saying warfare existed only as trench operations. That is not true. Some few American officers, in fact a great many, who had been in the service for some years, were on duty at the service schools either at Washington or Leavenworth, and they adopted for themselves a doctrine that open operations must begin and must usually end a war. Trench operations are only one incidence of warfare, and the American Army was equipped and trained on that basis, as were all armies prior to 1914, and the American Army still believes, and believes that within the year it has been proven, that their doctrine is correct; that trench operations are simply incidences of warfare, that warfare may be conducted either in the open or in trench; and I think you will agree with us on that now. There are a great many gentlemen who did not agree to that a year ago. Now, if that is the case the organization of the sanitary service must be on the basis of open warfare, and that is what our sanitary service is based on. If we use that as a basis, and it must be, we must have mobility and military economy as the basis of the establishment of our sanitary service and our system of evacuation. We must not think in terms of one casualty and we must not arrange our service for the benefit of a single casualty—that is, we must not attempt to give the single casualty the best treatment, but we must arrange our service to give all casualties the best treatment in the most economical manner. That doesn't mean, consequently, that every single case will get the best treatment indicated by its condition, but that all will get the best treatment possible under the circumstances—the elements of time and distance, the number of cases, and the condition of the many patients. So when you see a single case treated a certain way don't say that is poor treatment from a military standpoint. You may say from the standpoint of the single case it is poor treatment, but we must arrange our sanitary service for the economical treatment and evacuation of all casualties and not always for the best treatment of each individual casualty. Now in absolute cold blood you have to consider the value of the various types of casualties. What is the actual military value of your extensive abdominal wound? Very low, isn't it? That patient is entitled to all that you can give him in the way of treatment, and should receive, but he should not receive it to the exclusion of proper treatment for the lighter case which has the greater military value. Consequently, we have arranged our sanitary service on the basis of rapid evacuation and first-aid treatment for all cases. The question whether the abdominal case should be operated immediately under field conditions or given rest is one for the surgeon to discuss, and probably the military surgeon or the civil surgeon or abdominal surgeon will be discussing that long after we have gone to our fathers. It is a question whether surgical teams should be used to look after these cases early or whether

more lightly wounded cases should not get their look in, because we can dress so many more of them and can handle so many more of them than we can abdominal cases who need immediate operation.

The basis of the sanitary service is mobility and rapid evacuation, because we believe that the chief feature of warfare, whether we are defending or attacking, will be mobility and not stabilization. That being the fact, I think we have no apology to offer for our light equipment in the ambulance company and the field hospital, and that light equipment we should have also in the evacuation hospital. We will get to that later.

Now, for trench operations. When you have gone over the subject of sanitary tactics carefully you will discover that you can use all of the establishments that we have in the division and in the Services of Supply, sanitary formations for trench operations where you are definitely stabilized, and all that is required is an overhead to give the patients the best that can be offered in stabilization, but you must not consider that overhead is any part of the equipment of your mobile organization; that overhead equipment and also, possibly, the personnel must be considered as area equipment and personnel, because in trench operations you do many things from a sanitary standpoint. You organize the sector for the care of casualties and also you organize it on a sanitary basis as a cantonment, and consequently you can use cantonment equipment—camp hospitals, stationary establishments in general. You keep your mobile equipment still mobile and you bring in overhead equipment to arrange for the cantonment feature, either if you are in the line or in the back area.

Now, I think that we have cleared up the points about so-called stationary warfare and mobile warfare. As I said before, there is no such thing as stationary warfare and no such thing as mobile warfare; there are trench operations and open operations incident to warfare. We must have our equipment to cover both. Our mobile equipment will cover trenches when supplemented by overhead personnel and equipment.

The sanitary service over here, and also now in the United States, is as it was before the war, and is organized in general as it is in the Manual for the Medical Department. The control is coordinated, as are all other services and arms of the Army, by the General Staff. With the Quartermaster Corps, the Ordnance Corps, the Signal Corps, Judge Advocate's Department, Inspector General's Department, and what not, all under different chiefs, Artillery, Cavalry, etc., we have had a running fight of it in the United States for a great many years—and the Dental Corps also—and the General Staff had to coordinate. Well, in some cases the bureaus were as big as the General Staff and they had as much influence as the General Staff, and consequently they weren't coordinated. The American Army came over here and each chief—the Medical Department included—wanted to run his own game, as he was looking out always to the interest of his department. We put in a general staff organization which perforce had to coordinate, and that's what they are doing. Consequently the rightful activities of the supply department are controlled by the fourth section of the general staff, and also the evacuation of casualties. Now, the general staff found that this was a wise thing to do, and one day, and most vigorously, the various bureaus were put in the corner out of the way and didn't function. The general staff officer was usually a good man, but it was hard to find a good man who knew it all. They tried to handle it and tried hard; but they had bitten off more than they could chew. So we cut out the bureaus, and the corps chiefs are now coordinating and the general staff is now working out most remarkably well. So if you have a run in with G-1 or G-4 or G-5, remember they are not trying to run your business, they are trying to run the whole army and you are playing on the team, and when you are playing on the team you have to take orders. You can't do it in football, you have to take signals from somebody; and you have to do it in the army. The fullback or the quarterback happens to be in a position where he can cover the whole team pretty well and see what is doing, so we usually make him captain of the team—at least that's the way they did it years ago. We did it that way and that's what the general staff is organized for, to give them a view of the whole situation and coordinate the various units, and G-4 performs this function for the Medical Department.

Within the Medical Department itself, of course, the chief surgeon and the surgeon general control their personnel, unless they have been separated from them in some way for special duty. That don't mean that they can take any medical officer they want and put him in something else. The people he is with are entitled to something to say, I think. A great

many persons think not and that it is advantageous for each corps to look after its personnel and to recommend changes, and if they can secure them well and good, but if the conditions are such that some organization to which they are attached finds that they are absolutely essential they must be given a hearing in the matter to be considered. That is only fair and it is being worked out over here and in the United States. Take, for instance, these schools here. It is essential that the personnel of the service schools, and particularly the sanitary school, should be selected personnel for the work. Now, if the Signal Corps and the various other organizations want to take these officers at any time it will produce a condition that is not satisfactory. Consequently, separate organizations and institutions are protected. Now we will get into sanitary tactics.

To have a knowledge of sanitary tactics one must have a knowledge of the organization of the Army at large, and the organization and capabilities of the Army at large, the relative mobility, the uses for which the organizations are intended, their strength, and their function, and also we must have the same knowledge, and intimately, of the organization of the sanitary service. In addition to that we must have a knowledge, more or less, of military history and tactics; that is, we must have a knowledge of conditions so that in arranging for his sanitary service an officer will be able to foresee an attack or a retirement, or an active or passive defense, according to the conditions. If he does not have more or less of that knowledge and arrange his services on that basis, he will be up against it in a military situation, because few commanders notify their subordinates until immediately before the operation begins of a retirement or a retreat, on account of the moral effect, so that the average medical officer serving with troops must learn something of the tactical use of troops, their methods of attack or retirement, their formation in these functions, and apply this knowledge in the management of the sanitary service or the tactical use of the sanitary service. In order to have this knowledge he must have also a thorough knowledge of map reading and locations by coordinates. His orders will come that way and his information will come in such a manner that he must be able to read a map thoroughly, and also for the purpose of map reading—and in juniors for the purpose of reports—he should have some knowledge of sketching and contour, at least the placing of form lines indicating the locations; that includes orientation and things of that kind. Also, of course, he should have a knowledge of the regulations of his services to begin.

The medical officer preparing for tactical management, say, of the sanitary troops of a division must know his organization, must know the conditions, must exact reports with regard to the condition, and follow up by inspection to verify the veracity of the reports, because reports are not always correct; the other chap may have different ideas on the subject. He must estimate the various medical officers according to their special capabilities and qualities, and everyone is different, and having that he is ready to go to work. He should have as his commanding officer of the sanitary train and his directors of ambulances and field hospital companies the best trained men in the division, besides himself and probably his assistant, and select them also for their control of men and their knowledge of handling their units particularly. Having that, he is ready to go to work. The first thing that he must require in the management of the sanitary service is to know the situation, the general situation, what actually has happened, where the enemy is in general, where our own troops are, whether the division he is attached to belongs to a corps or army; what corps troops there are and what army sanitary troops there are; what divisions comprise the corps and what corps the army; because all that information is going to have an effect on the solution of his divisional problems. He should have an idea of the duties of the corps surgeon with regard to evacuation without the division, because there may be different ideas on the subject. In general, the management of the sanitary service is the same behind the lines, but special army or corps surgeons have special ideas they want carried out. He can get his information at least from the corps surgeon or G-3 or G-1 of the division, because G-1 of the division takes over the duties of G-4, there being no G-4 or G-5 with the division. He then is ready to go to work. He finds out the special situation of the division and insists on having a map of the locality where he is, whether in a rest billet, whether in ordinary marching campaign, marching in contact with the enemy, or in entrenched position or preparing for the assault. He must have a map to form an idea of the country. You can not form an idea of the country

in one minute by looking at the map. The first thing he will probably do is to examine the map for the extent and direction of roads, and he will then study his roads, because the question of the vertical features and roads is very close. He then looks up the position of the troops. Having that information on the map, he looks up the question of camp sites or positions to be occupied.

If on an ordinary march, the division surgeon continues to look about to see what he is going to do to-night. He looks over the water, he looks over the roads, he finds out from G-2 or G-1 where the march halt is going to be; whether there is going to be a noon halt and a night halt; the distance where the camping or bivouac or billeting area is going to be. Having found out those things, he can determine about how many daily sick he is going to have. If the column is marching on a single road or on two or three roads, he must know it, and know how to distribute his sanitary units accordingly, or at least recommend it to G-3 that the march order of the day make such and such disposition of them. It makes little difference what disposition is made of the motor units unless there are impassable obstacles. Remember a division closed up as close as it can be will be 25 miles long, with an advance guard. On a march in contact with the enemy, in order to recommend his disposition of his sanitary units he must know these things. He must have knowledge of the length of any column; he must have knowledge of the road distance of any brigade. He must have all that, and that's what you gentlemen are here to learn. Now what's he going to do on the march? We have introduced the subject with a full field of fire. What's he going to do? If not in contact with the enemy, he will follow the regulations and distribute the ambulances accordingly. You can not expect a man to drop out and stay on the side of the road and wait for an ambulance 20 miles back. What does he do? He follows the regulations and divides his animal-drawn ambulances with the troops. One regiment of Engineers, three Artillery, four Infantry; so he turns out probably two ambulances to each regiment of Infantry and one ambulance to each of the other regiments, and he has practically disposed of his ambulances on that basis. What does he do with his personnel section? He has his bearer detachments and his wagon detachments, and his dressing station parties. If it is an ordinary march, he keeps them with the sanitary train. How does he get this disposition? Probably by written order after he has made his recommendation to G-1 on the subject. He will say, you will have to follow that routine. He reports it to G-3, who issues operation and march orders. So thereafter the division surgeon is notified that the ambulances will be distributed to the regiments on that basis, one marching at the tail of the small regiments and two at the tail of the large regiments. If they are to march on two roads and contact with the enemy is likely to occur, what is expected of each column will depend on how it is arranged. If a brigade is separated in the march the ambulance company probably will march with the motor section of the train attached to that section of the brigade, also a motor field hospital, and probably a couple of camp infirmaries marching with the sanitary train will be told off to move with them, because the regiments may be separated and it may be necessary to send out a camp infirmary with the separated regiments. The equipment is little; one small mule and one large cart, and if you get bad roads, which is possible, you are going to separate yourself from your sanitary cart. I haven't seen a regiment that had one in the operations at St. Mihiel and in the Argonne. They can not run. You will either reinforce them or carry the stuff up by hand.

Now to get back to sanitary tactics. In an ordinary marching campaign, at the completion of the march the ambulances usually stay within the regiments a reasonable time. Usually the order reads, that within 20 minutes after arrival at the camp site the casualties will be evacuated. The surgeon has a line on them, because it is the business of the battalion surgeon to look over the cases and classify them. As to the routine of evacuation: The ambulances will be assembled at a certain point and a motor company will continue the evacuation to the rear. The animals have been on the march all day in the column and by the time they have evacuated their casualties they have done all they can. You can't wear out motors like you can mules; and where you have mules keep them fat. Now how does the surgeon know how many casualties he is going to have? He knows that ordinarily, with seasoned troops, he gets nine-tenths of 1 per cent, and that he will evacuate from one-third. One-half of these will be recumbent and others will be sitting. So he knows how many ambu-

lances he needs. If he has a division of 28,000 men, he will have 1 per cent, roughly, or 280 casualties, and one-third of them will have to be evacuated, and for a factor of safety he can divide them in two and say between one-half and one-third of these cases will go recumbent and the others sitting, and you can figure out that one ambulance company can probably handle them on the basis of each ambulance holding 1 sitting and 4 recumbent, or 9 sitting. One of the sitting can always ride with the driver, and the orderly can ride the tail gate or radiator if necessary. That is the basis of the old division of 20,000 men.

Now the capacity of our sanitary service was arranged on this basis, with a 6-hour period of evacuation and care. Usually it runs about 8 hours, and we figure on giving the sanitary troops at least 4 hours rest every night. If that continued for a year they would get tired, but that's all they get in active campaign. When we boosted our division up to 28,000 men we simply reduced the number of casualties we could shelter and evacuate in that period of 6 to 8 hours about $6\frac{2}{3}$ per cent. Now you take a field hospital on that basis of battle casualties and it works out the same thing. You work it on a basis of 10 per cent casualties. Take the old figures which are given in Straub and they run very low every day. If you are engaged in trench operations your casualties go up to 25 per cent dead and your disposition of recumbents and sitting is proportionate. If you are engaged in open operations, with rear guards with machine-gun fire, as it is occurring now, your casualties are between 14 and 20 per cent; usually about 14 to 18 per cent in the Argonne and in the St. Mihiel offensive, which was there largely machine-gun fire and not much artillery because they pulled their artillery out to save it. In ordinary operations, in open warfare, the percentage given by Straub, taken from Cohen's figures, of 20 per cent dead usually holds. You can work on that and you will be safe. So much for that.

Now the division surgeon having arranged automatically for evacuation by the ambulance companies, he must arrange for the care of patients. If on a railway or waterway he can arrange for the service of evacuation to the rear to come up and take over his cases by train or motor, or boat. He will arrange for evacuation points and will usually choose water or railways or motor service for evacuation service. Remember a division will go into camp or into the trenches with its advance guard well up, and the brigades will be camped in such a manner that it will have a space between it and the outposts so as to favor advance to the line of resistance, favor deployment and occupation of that line of resistance, and the trains will be in position so as to cover all that formation. The sanitary trains will be in their proper position. Now if it is an ordinary march in campaign without contact or a march where contact may be expected, these trains being in the column in their proper position will camp in such position so they can get into the column the next day without countermarching. We will recommend, consequently, according to the military situation, the method of camping the trains, the camp site of sanitary train; the brigades will determine the assembling points of casualties for evacuation, the motor ambulances coming from the division trains, and if the distance is not too great they will probably be continued in that as a matter of economy and are taken over at the evacuation point by the Services of Supply or army service, and he will recommend to G-1 what should be done and he will telephone that to G-1 or G-4 of the Services of Supply or the army to have the Services of Supply or the army service pick up these cases at that point, and he chooses that point according to the military situation, generally choosing a central point to save the transportation. What if there is no evacuation point near? He can do two things. He can bring up his camp infirmaries to cover the few cases in the area, or if they are going to halt a few days he will attach camp infirmaries to them, and also a regimental dispensary, and move his ambulances between the camp infirmaries. If the brigade is separated he will have a field hospital cover that. He moves his field hospitals up to cover them, and they set up as little as possible, according to the indications, to take care of cases until evacuated.

Never set up more of a field hospital than is necessary to shelter and cover the cases until they can be evacuated, when on the march. That's the old doctrine and it applies as much now as it ever did. In open warfare the doctrine is the same as it was before 1914, except that by reason of the road conditions in France, where you have good roads frequently, but always radiating from an axis without parallel lines. Wherever you have a division

attacking on a normal front of 2 or 3 km. you will have only one road. The division is 28,000 men, the artillery is enormously increased over the old, the transportation greatly increased. Attacks are made usually through more or less entrenched areas. The attacks are preceded by large heavy barrage and artillery. You will find roads badly shelled so that they require reconstruction; bridges and culverts destroyed or badly damaged. Consequently in an advance you can not expect, ordinarily, that you will move wheel transportation to any extent; through a zone that has been hotly defended you will not be able to move wheel transportation to any extent before 12 hours. The first to move will be the artillery, and the ammunition trains are a kind of "military necessity," which will be given right of way. You are not to evacuate your patients within 12 hours. Now in order that the surgeon may do débridement or primary suture, he has got to have the patients within 12 hours. How are you going to do it, gentlemen? You are not going to do it, that's all. I haven't seen it done and I don't believe it will be done. What's the answer? It is exactly as you were taught in 1914 and before. Send your bearer section forward as soon as possible after the advance is made. Keep them within a thousand or so yards of the line—not in billets, nor at crossroads, because they might be shelled; send your dressing station party up with equipment on litters, your animal-drawn section and your wheeled transportation up there as best you can.

Now the only wheeled transportation that you can move before this is your animal-drawn transportation because the animals can move the wheeled transportation through some of the holes—not all of them—but you can not move motors through there at all. Now I have gone up with Cadillac cars and tried to go through there, and I think a Cadillac will go anywhere a G. M. C. or a Ford will go; I have ridden Ford cars and I know their hill-climbing ability, but they can not climb out of shell holes. In fact, I saw a Ford tank that couldn't get out of some of them. But you can sometimes get them up by mules where you can not try motors. So if you have animal-drawn ambulances, keep your animals fat and in good condition, and if you have open warfare that's the first you will get up. If you don't you won't get anything up. Now when they get up there what are their orders? The division surgeon will get the usual copy of field order and the administrative order annexed. The field order simply states, as you find in field regulations, what is to happen and not necessarily what will happen, and on that the surgeon bases his plan of operation. If you are attached to an army or corps you will have an army or corps order, which will show where the evacuations will be made. The evacuation hospitals are under the control of the army or corps of Services of Supply. The order will show where they will be, and for the sake of economy they will have various functions. Some hospitals will be devoted to gas, some to special types of surgical cases, some to the moderately wounded; some will be devoted to ordinary sick, and some of them to infectious and contagious sick. They will be distributed according to the plan of attack. The division surgeon, ordinarily, will not have this incorporated in the field order. Nobody needs to know it except four or five persons; the division surgeon, the commanding officers of the sanitary train, and they will transmit that information to the ambulance-company commanders. The field hospitals don't need to know it; they are only interested in the functions they are required to perform.

So far as the management of the regimental personnel is concerned, the sanitary personnel attached to the regiments should be divided into four parts, and enlisted personnel exactly on that basis. A dental surgeon will be attached to each battalion and he will be the assistant to the battalion surgeon and do his work exactly the same as the other medical officer. The battalion surgeon will divide his enlisted personnel into five parties as quickly as possible and attach one party to each company, because, remember, companies are going to attack on a front of about 200 m., if the regiment attacks in column of battalions, so your front will be between 500 and 600 m., and the front of each company in the first line will cover from 200 to 300 m. Consequently you will attach some sanitary troops to take care of the fall outs. That company will attack in depth of 2 platoons in the line and 2 in support, or it may attack with 3 platoons on the line in two or three waves, and 1 platoon back in support. You should cover that company with sanitary troops. On the basis of 48 men you will have mighty few; on the basis of 105 you will have more to allot. All the sanitary troops should do is to dress and group the cases. The battalion surgeon will keep in touch with them and with his

liaison group, replace casualties, and will also look over the nests or groups, and will have a man walk the line of nests that are left as the companies go forward. The regimental surgeon will be with the regimental commander, probably in the second organization, if the regiment is attacking in column of battalions. He will have his own liaison group, his sanitary troops, attached to companies of the second and third battalions. The regimental surgeon will cover the line with his liaison group and reinforce battalion groups as necessary and relieve the sanitary troops that have been tolled off to cover the battalion groups of wounded within the area, which is now 500 yards wide and probably about 1,200 to 1,400 yards deep by reason of the battalions being in depth. You will have men that will have to be dressed and sanitary troops to do it. What are you going to do about establishing regimental or battalion aid stations? The regimental surgeons that I have seen haven't established any. You won't have any equipment except what you carry on your backs or litters and that won't last long. Now there is one thing to do about it. If you can put a pannier on the back of a mule you can take it up before you can get a pack mule forward. The Medical Department packsaddle is too heavy for this kind of work and the size of these mules. What they have done when they went forward was usually to take a sandbag, filled it half full with dressings, and every man carried one. It was quite satisfactory, but the question of establishing aid stations is impossible in these advances. Some of our men, under the influence of trench operations, which will be discussed at another time, have tried it. You shouldn't do it. Depend on your ambulance companies and your bearer outfits to collect your casualties and do the evacuation. Do first aid and group your casualties; leave a man in charge to make liaison with your bearer sections of ambulance companies. That's all you can do. Now with closed roads and the fact that you are not going to move ambulances within 24 hours, as I saw in many cases, means that your bearer group and dressing party must be up early. They must not camp in villages or crossroads, because they get fire. Put them on roads protected by natural features, and you usually find that there is a dugout or something around. But don't be too keen on dugouts unless they are deep, because your friends who have just left them know where they are, and if they don't get you they will get the litter parties leaving there. I figured it out two or three years ago, when I had a discussion with a class at a service school, what possibility there was of a dressing station that was in a trench getting a direct hit, as I found that would take 333,000 shots accurately placed to hit a dressing station located in an area a mile long and half mile deep. When you establish a collecting point get your patients there, warm them up, feed them, give them antitetanic serum, and hope to God some time you will get some transportation there.

The reason why I have taken up the subject of open operations so fully was because a great many in our sanitary service have forgotten about it apparently, although it is well outlined in the publications of the service schools, those excellent publications of General Munson. The sanitary tactics of General Munson and the service schools hold to-day as of old. As I told you before, the concentration of long-range high-power artillery and motor transportation have affected distances somewhat.

Now, so far as sanitary tactics of a division are concerned, with the introduction we have had discussing the sanitary tactics of regiments in advance, which is all I wish to emphasize particularly, I think we can work it out. We have the question of concentration of our men and transportation in the rear, the increase in Artillery from 1 regiment to 3 in a division, the 3 machine-gun battalions, and the increase of the machine-gun company from the old machine-gun platoon, which has increased the transportation enormously, and also the increase in ammunition trains as the result of the increase of the Artillery and machine-gun battalions and companies. So you can lay it down almost as an axiom that in an advance or in pursuit you are going to have material destruction of means of communication, particularly of roads, bridges, and culverts, and you are not going to move your wheeled transportation. Consequently you must think of hand transportation for your sanitary troops and your ambulance company or pack-mule transportation—of course, the latter is much more desirable. With regard to the position of your ambulance company dressing station and bearer detachments in combat, the distances need not be greater than they were in open operations, by reason of the fact that any distance that would give them efficiency would expose them to the same fire from Artillery on account of the long range, so the thing to do under the circumstances

is to put them up in that middle zone between the intermediate batteries' fire and the long-range batteries' fire, which are operated for counterbattery work or interdiction fire against the crossroads and villages. If you will keep your bearers and your dressing station in that intermediate zone you will probably be in the safest place for this detachment. You will have interdiction fire in the rear and there will be a zone where you will be relatively safe, although, of course, some fire will be directed there, but there is no distance within the zone of advance where your organizations can work properly that will not be subject to more or less fire, so in choosing places for the establishment of dressing stations use places away from crossroads and away from villages which the enemy has marked and will fire upon, because troops pass through, and he expects a certain number of them to pass through, so the roads will have interdiction fire placed upon them. Your dressing station under these circumstances will be little more than hand equipment and supplies of drinks and food, hot preferably, for the collection of patients. Now the plan of collecting patients is, you get them off the field and put them in some sheltered position where you can give them antishock treatment; you have some place to sort them, some place to send your ambulances.

Now the question of establishing regimental and battalion aid stations. In open operations I consider them simply as collecting points for casualties. If the regiment is stopped or bivouacked for the night and you can get your wheeled transportation up, the division surgeon may assign camp infirmaries for a regiment which is rather isolated for some reason or other. You may get up your battalion carts and you can use the captured equipment of the enemy, which was done at Soissons. The divisions went into that operation without knowledge that they were going into combat and took hardly any litters. One or two regiments took extra supplies in gunny sacks or sandbags and carried that up. The regiments that did not, fortunately, found supplies, first aid and litters, abandoned by the enemy in their flight. Now there is nothing in the management of the sanitary service except a full appreciation of the functions of the units, and a full appreciation of the terrain and the enemy's fire. Given that and common sense, you can arrive at the proper solution.

Now, with regard to the ambulance company proper, the tactical handling of that. We have discussed the tactical handling of the bearer and dressing station largely. Of course, the bearers have only one function and that is they are the liaison between the regimental sanitary group and the division sanitary units. They must as soon as they are sent up get contact with the regimental sanitary headquarters' unit by agents sent forward. That is not the duty of the regimental personnel. The duty of the regimental sanitary personnel finishes with the rear of the last echelon of that regiment, practically the rear of the combat echelon of that regiment for the time. In an advance they should have nothing more to do than group their wounded, probably in windrows, and leave a man in the sanitary service in charge to walk that windrow and give such aid to the group of wounded as may be necessary and make contact with the agents of the bearer detachment of the ambulance company when they come forward. Having done this, the man in charge should rejoin his regimental headquarters sanitary unit to be used as a replacement or reinforcement later. In stabilization you have exactly the same distribution, except by reason of stabilization you can bring up the camp infirmary equipment to cover the regiment. The regiment will probably be in column of battalions again, with one battalion in the first line of support and outpost first line, one in support position, one in reserve, and one in rest. That is a very frequent formation. Usually the regimental post of command covers the support battalion, and there, usually, there is equipment brought up for a regimental infirmary. It will cover the regiment and serve as a main collecting point for casualties for the regiment. In trench operations the evacuating service need not be tied to evacuation through the regimental aid station.

If it is more convenient to make direct evacuation from the battalion aid station or collecting points, either in trench or open operations, do it. It is a question of common sense, fire conditions, communications, and convenience, and it has to be worked out on that basis. That the regimental aid station is abandoned is not true; that all evacuations must go through it is not true. The regimental aid station would be facultative. If it is necessary to establish it, set up the equipment of a camp infirmary. If it is not necessary, why establish it? It is absolutely necessary many times, for a patient may not be able to get proper first-aid treatment until he reaches the regimental aid station. On the other hand, oftentimes it may be

possible to evacuate a patient direct from the battalion aid station, and in that case it is not necessary to send him to the regimental aid station at all. I think that is the answer to all this discussion about regimental aid stations. Now, the idea of the nonnecessity of the regimental aid station probably arose from the method of handling troops in the British and French Armies. Organizations are largely handled by battalions both in the French and British service, and the regiment is not always a fixed unit, consequently the sanitary service grew up around the battalion, and very properly, instead of around the regiment, and it depends entirely on how we will handle the battalions in our service, whether we will handle the evacuations through the regimental aid station, if it exists, or directly from the battalion. There is no definite, fixed rule about it, so why bother about it? In open operations the regimental sanitary personnel is necessary because it must make the liaison between the battalions and the regiment and the bearers of the ambulance company detachment. It also serves as a reservoir for replacements. If one battalion has a hard time, it is up to the regimental surgeon to send reinforcements up from the regimental aid party, and if necessary from the reserve battalions.

Now with regard to the method of disposition of the ambulance company. There should be no fixed rule for that except this: In an advance it is most desirable to have issued, when it becomes necessary, an order to the commanding officer of the sanitary train, or, if the train has been relieved, an order issued directly to the director of ambulance companies, stating, say "You will cover the first brigade with one or two ambulance companies, according to the terrain, the communications, the probable number of casualties." If one brigade is up and attacking with one brigade in reserve and the zones of advance are definitely fixed, one of them covers a zone which is going to have a considerable number of casualties. The ambulance company covering that one will be supported by another when necessary. If there is no possibility of many casualties, have one company cover it, with the others in readiness to assist if necessary. If the road conditions are such that you believe you are going to have your roads jammed, send them up early. Now the question of road conditions comes up with ambulance companies. In a great many of our operations it would have been impossible to get ambulance company wheel transportation forward for very considerable times, as we have said before. In some operations, where there is an advance over greatly devastated areas, as in a pursuit where the enemy is hurried, it may be advisable to send up with the pursuing brigade your animal-drawn ambulance company, because it can march in the column and motors can't; they must march back with the motor-driven sections of the trains; all animal-drawn transportation must be ahead of it, so that in some cases it is advisable to send the animal-drawn ambulance company well forward and put it in the column where necessary. Then the ambulance dressing station can get in early and your ambulances will be in ahead of the Artillery, or on the road to go in position behind the Infantry, so the animal-drawn ambulances will not interfere with them and they can go forward and pass over obstacles that will prevent the movement of motor cars. Now, there is a general objection to that over here, probably caused by the fact that they were in trench positions for many years and had good macadamized roads so that animal transportation was unnecessary. Under these conditions no one should use animal-drawn transportation; it isn't intended for that purpose if we have motor transportation. Motor transportation is advantageous for many reasons. It moves so quickly that it interferes with directed fire against it, and where zone fire is given your motors can dash through from one place to another before the fire is advanced or moved. In that way it has a great advantage over animal-drawn transportation and also the relative efficiency as to time of evacuation. But we can not dispense with the animal-drawn transportation.

In the St. Mihiel offensive, a medical officer whose services have been recognized and who has since been promoted was very much opposed to the continuance of the animal-drawn transportation in our service, and he stated to me that after on day's advance he had changed his mind and saw the absolute necessity of having animal-drawn transportation. I think we have the amount we should have. We need more in bad weather, but we can not get them on account of the small supply of animals, so we will have to get along with those we have. Animals don't do well over here—they can not get enough forage—but on the whole I think we manage pretty well with them. I notice organizations already calling for pack

animals that were very much wedded to motor transportation before. So I think you will find it will be necessary frequently to send your animals up, and in looking over the axial road, in looking over the probable zone of casualties, you will choose which side of the axial road you are going to send your animal train in according to the communications on that side. If you have roads deep in mud you may get out six ambulances and send them up with four animal teams and your animals can pick their way through. You have only six ambulances going it is true, but you will get something done. Don't try to do long evacuations with them, but simply send them back to your motor head and transfer your patients on the original litter to your motor ambulances. Look over the axial road very carefully and look at the number of bridges and number of culverts, and figure how much damage your artillery fire preparation is going to do, then determine what kind of transportation you are going to use and where to place it. If the roads are going to be jammed and there are some small roads that will not be used on each side of it, beforehand, before your organizations are committed, go to work and fix two assembly points for your ambulance companies at least. If you have to use one on one side and two on the other, do that and put them in position to advance when necessary, so that your evacuations will not be on the axial road but relatively parallel to it and will not have to cross it at congested points at least. So in arranging your field order for the attack, so far as your ambulance company is concerned, if you choose to put that in the field order, and it is sometimes advisable to do so, say simply two ambulance companies at coordinate 2684, one ambulance company at coordinate 68-94. Now, you will have ambulance companies on each side of the axial road, which has been designated in the corps order probably, and you won't have to cross that road probably. You have to work it out on a practical basis, that's all. There is no use to mention distances. Wherever you put your ambulance company, ambulance head, field hospital, you will be exposed to some fire if the enemy chooses to go after that point. What should you do? Avoid points of probable fire, even take points of lesser convenience, but don't in open operations increase your distance as you do in trench operations. When you have your open operations you are doing one of two things; you are preparing to retire and the enemy is concentrating his artillery. In that case you have to be well up to get the wounded back. If the enemy is going to retire he is going to pull out his long-range artillery and he will fight rear-guard actions, and so far as your ambulance company is concerned the distance won't affect it because the range will be short.

Now, what is the function of the ambulance company? First-aid dressing, the collection of patients, evacuation, of care pending evacuation, antishock measures if possible, feeding, and primary sorting. That is, you will sort your cases into about four classes—five, perhaps—you will probably have no dead, or at least few dead, because they will have died at the dressing station; they will not bring dead in there ordinarily. Some other branch of the service will look after that for you. Those able to walk will be classified as able to walk to the post and able to walk reasonable distances. You will promptly start them back as soon as their condition and the firing condition justifies. The sitting and recumbents you will classify; that is, the moderately wounded you will classify under sitting and recumbent, but under the gross classification of moderately wounded and desperately wounded and the relatively nontransportable a case will have an additional classification. Now a nontransportable, of course, will be sent back as soon as his condition permits; all moderately wounded will be sent back as soon as possible; gas cases, ordinarily, will be sent to a special gas hospital, unless army orders, as they exist in the First Army, prevent them. They will be sent to the special gas hospital direct.

Now, with regard to your field hospitals. You have four of them. One of them is used for a gas hospital, depending upon the situation. If the corps order has arranged a definite gas hospital and it is very close up, which it may be in some cases, the division surgeon will not have to concern himself with gas cases. If the gas hospital is not close up, he probably will designate a field hospital in a fairly central position covering the lines of evacuation through the axial road and on each side of it, so it will be near a point of intersection, more or less, which he will designate for gas and special cases, and attach a degassing outfit so they will get prompt removal of clothing and bathing and ultimate evacuation of the gas hospital. That depends on distance entirely, and with regard to the corps order, and if there be any

mobile surgical hospitals near at hand it may be necessary to establish one field hospital as a hospital for nontransportable and attach to it the mobile laboratory and a mobile surgical unit which may have been assigned for that purpose from the corps or army troops. With this distribution made, you have two field hospitals remaining, which will be normally used for the moderately sick and wounded, as a temporary resting place if direct evacuation is not possible to army, corps or Services of Supply establishments, such as evacuation hospitals, which are designated to receive these cases. You will have to cover these two conditions, depending upon your connection with corps and army units. Now, these two field hospitals will also serve as a secondary triage for the distribution of the transportable wounded, according to the special conditions. It may be that army orders, as in the First Army, require the establishment of such a triage. In each case you must presuppose a mobile surgical hospital for care of the nontransportable beyond that, and in that case nontransportables will, of course, go through it.

Your kind of management of the field hospitals depends entirely on the conditions, but, gentlemen, they must be mobile and the ambulance companies must be mobile, because if you start out from the jumping-off place with fixed establishments, such as evacuation hospitals and mobile surgical hospitals, definite gas hospitals, neurological hospitals, hospitals for contagious and infectious cases, venereal hospitals, etc., and you make an extended advance, and these are fixed places, you are up against it. Of course, when you are under stabilized conditions you can have all the refinements and luxuries you want, and you can use them on the first day of an attack ordinarily and you can use them in trench operations. So much the better if you have them, as you are then in pretty much the same position as a municipal sanitary organization. Take any city and that's what you have. Your battalion aid post corresponds to a little police infirmary where cases are sorted and distributed to various places. Then you have little use for field hospitals except to care for the moderately or slightly sick, who will be returned in a few days and who should not get back of the service of the zone of the armies, because if they get back there they will be evacuated to the Services of Supply and you will lose them for months, while if you keep them they will recover in a few days, so that your field hospitals will be used in that case only as a secondary triage, because you must do triage where you have a casualty rate which is congested. Now, if you have local gas hospitals, the question of gas malingering comes up, and I think the ordinary officer ought to be able to tell something about gas. There is an order in the First Army that all suspicious gas cases shall be evacuated recumbent. That's all right; obey the order; but if you have any doubt, put the man on his back at the collecting point and keep him at rest, and if he doesn't require any immediate treatment evacuate the more important cases and he may recover in time.

Now, the question of sorting can not be too much emphasized. It can be emphasized so much it will affect evacuation, but it is very essential nevertheless and should be followed out. We haven't discussed the question of operation of a field hospital company. I have noticed in a good many orders of late that in attack they have been rather hasty in establishing their field hospitals. There is no necessity of establishing a field hospital when an attack begins; you don't know how far it is going, and you are not going to get your cases back to field hospitals within six hours anyway because fire and road conditions and confusion won't permit it. So you have six good hours to get your field hospital put in if the advance is carried forward well. If the enemy has been forced to retire with their artillery, you can tell where to put your field hospitals to get the most number of casualties and to avoid the fire of the enemy. If you put your field hospitals down before the attack begins, you must put them far back. If the attack succeeds, the line goes forward, as it usually does on the first day when you have the element of surprise in it, the field hospital is too far back, and you have to pull stakes and go forward. Don't be in too much of a hurry to establish your field hospitals. Don't establish your dressing stations until you know where and why you are establishing them. Get them up early to avoid interference with the roads. You may have to work off roads, so figure on taking them up by hand or pack mule. Be slow on establishing your field hospitals. If they are mobile there is no reason why you can not have them running in half an hour with trained men. In 45 minutes you will have the water heated and everything going beautifully—no hurry about it. And when the estab-

lishment is moved it doesn't require a general order, it only requires an administrative order covering that one feature, and as I said before there are only four or five persons who have to know where they are—the G-1 of the division, the division surgeon, the commanding officer of the train, and the two directors—and they will notify the ambulances and get connection very quickly. That's all you have to do. Otherwise you are distributing information that is making the patients run all over the country. It is better that the wounded should know nothing about it. They should know the location of their battalion aid post when the organization is at halt or stopped. And there should always be in the field order the location of the station for slightly wounded, and that, of course, should be at the point which drains the line of approach. Now, if your division has gone in on a front of 2 or 3 km.—the distance isn't great—you can usually choose some place near at hand. Don't get it too far back. It should be in front of the field hospitals. The road should be marked and should be patrolled by military police, and there should be a detachment of military police at the point who should have malingerers turned over to them to be escorted back to their commands. No person should be permitted to move beyond this place who claims to be wounded unless conducted by persons that are properly authorized or unless they have a diagnosis tag on them, or a pass. I think in the future patients on foot will be conducted by military police and each will be required to have a diagnosis tag. That will stop straggling beyond that point, and regiments will hereafter have their line of straggler posts behind the reserve battalion. Our troops have gone into these fights not the best trained in the world; they haven't had enough training; they have shown extraordinary initiative and lack of personal fear; but we have had a considerable number of gas malingerers and persons who succumb to feelings of fatigue when they are not; quite a number of loafers and skulkers who are on hand in every organization. It is to be expected of course.

Now regarding the equipment for the station for slightly wounded; it depends entirely on what you have. Ordinarily you have quite a number of camp infirmaries that will not be doing anything. You can soon put it up, and establish that early, because they must be established at the time the attack begins. The British don't call these "walkers"; they call them "runners"; they get in early; they get their diagnosis tag and beat it to the rear as promptly as possible. They go alone and make very good speed, so it must be established early. You can get your equipment from the camp infirmaries. The personnel: If the Services of Supply have handy any sanitary squads, as they usually will, use them; because, remember, a division in entrenched position is living in a cantonment, part of which is entrenched; hence they get sanitary squads, or part of them should be detailed for duty at the slightly wounded station and the rest used as reserve litter bearers. If you haven't this, the most satisfactory organization to make a detachment from is a field hospital because frequently the station for the slightly wounded will have been finished before the strain on the field hospitals begins. This is not as with the ambulance company. The field hospital should ordinarily be used for this purpose, and ordinarily the station for slightly wounded should be on the line of evacuation through which transportable cases pass, and you should have some provision to pass them along. In arranging for evacuation the question is whether it is more economical to send them by foot or bring them down. That has to be determined on the conditions, so it is well to put in the first administrative order, paragraph 4, with regard to evacuation, the method of evacuation, and the route. If they are to be evacuated on foot, let the route coincide with the route of wheeled evacuation of transport cases, so that those that fall out can be picked up by sanitary transportation passing. If it be by rail, or by water, or by motor convoy, it is a different matter. They can usually be pulled through to the next étapes, because their travel will be rapid and they will be cared for; if necessary some sanitary personnel should go with them, but military police should go to prevent the loafing and the looting of slightly wounded that occurs so much en route. No man should move behind the line of the station for slightly wounded without some control, either military police or sanitary control.

Now, with regard to the methods for securing information of the operation and the issuance of these orders. The method of doing this is to make a written memorandum to G-1 and G-3 of the division. After you have secured the information of the operation from G-3 and G-1, getting the details from G-1 of his ordinary evacuation scheme, you will see usually the corps or army orders, or quotations from them. When you get the informa-

tion, prepare a written memorandum, and keep a copy of it yourself. It may be that G-1 or G-3 can not agree with your recommendations, because they have not only to look after the thousand and odd sanitary troops, but they have some 26,000 other troops to look after, so that while you believe you must have the best for your organization, don't always expect to get it, because other outfits have to be considered, and the particular business of these people is to coordinate the demands of all for places, transportation, and roads for the good of the many, and don't be sore if you don't get what you want. Of course, if you get the wrong end of the stick all the time you may have a growl, but at the same time give the other chap a chance to think it over. He will probably recommend that such and such be incorporated in the field order, the station for slightly wounded will be established at such and such a place, say, at "the bend of the road in the vicinity of the big hill." Always use "in the vicinity of" instead of saying "at." That gives the director some leeway in choosing, having regard to terrain, conditions of road, fire, etc. The question of supplies and water figured very much in our sanitary tactics in the past and should be considered now and in the future. But remember it is easy to carry water and fuel, so don't worry about it. A good many times it is a bone-dry proposition, and you will have to bring up your water supply, and you will probably get bad water, because almost all the water over here is bad. Don't always expect to get water and don't figure that all the water you find in the area of operations will be fit to use; because it isn't. It will be damaged in shell holes by mustard gas and by fecal matter and dead bodies. You will have to do lots of chlorination and probably a good deal of settling before the water is much good. So look for protection against fire, etc., rather than convenience and water, food and shelter, and remember that the ordinary cover of houses in villages, as I said before, serves rather to expose your patients to fire; and it is better to expose your patients to the weather than to expose them and yourself, incidentally, to a hot fire of lead and steel.

I think if you make your recommendations in that form you will have no trouble in getting them carried out. G-1 and 3 are not experts in sanitary service, and they are usually looking for your recommendations. You are not asking them for any transportation, because you are using your own, and they will probably adopt your recommendations.

Now the field order. This is usually covered by paragraph 4, which in the field order relates to trains and supplies for sanitary troops. I think ordinarily, if you don't know what to do, the best thing to do is to fix an assembly point for the ambulance companies so they can get it ready and can get to the various points in the zone of operations if necessary; so if you don't know what else to do with the outfits, and you frequently don't, fix an assembly point for them—say, ambulance companies to point 6284; the field hospitals, which are farther in the rear, to another point, so that you can get them out, and then watch developments. Don't go to work and give them fixed positions in attack or pursuit, as so many orders do. Ordinarily you always have time to get them up when it is necessary. When the roads are congested it is well to attach the animal-drawn outfit to the Artillery. Or attach it to troops and then take it away from them when you get up there. The Artillery usually moves with its animal-drawn transportation; so when you know the Artillery is going in, attach the animal-drawn outfit to it and you will have it when you get there, and if you need some camp infirmaries load them on wagons and send them up with the Artillery. In these advances most of the Infantry outfits don't see their medical carts for three or four days. The only way to obviate that is to take the material up by hand or pack mule. You can get him up all right and you can get him over bad places or lead him around them. I think the mule is very necessary. We wanted him before, but the beautiful French roads rather seduced us from the idea of animals, but I think most of us now are quite willing to go back to it. At least I am. I have gone over this matter at rather great length, but some details were necessary to give you an outline.

With regard to trench operations, I want to say that it is a good deal like a municipal sanitary establishment but equipped with mobile sanitary equipment for moving troops. The mobile equipment must be kept mobile for the future advance or retirement. If the troops become stabilized in trench operations, then bring up overhead equipment, which you must not at any time consider part of your mobile equipment, but supplement it with that or, preferably, supersede it with your overhead and keep your mobile equipment packed in

readiness for future use. That means, in the case of a battalion aid party, collecting up all extra dressing, a considerable portion of which will be the larger shell dressings. It means bringing up warming apparatus; it means making dugouts splinter proof; it means extra litters; it means degassing outfits and masks and inhalers; it means entrenching tools for digging trenches and dugouts; and tables, and benches, and bunks. All of these things will be required, but let these overhead things belong to the area and be turned over to the next organization relieving you in that battalion aid station or that regimental aid station, but no part of your rightful equipment if you can avoid it. Keep it mobile, and, where possible keep it packed.

With regard to the evacuation hospital and the evacuation ambulance company, which have been formally classified as belonging to the Services of Supply and really do, owing to the organization and depth of the army and corps they will be normally turned over to the corps for administration, although they are Services of Supply units. In extended open operations it will be necessary to move the evacuation hospitals forward on motor or by rail. As at present constituted they are relatively immobile, without much means of transportation which will be needed for that purpose. Consequently, we will have to organize our evacuation hospitals on the old 482-bed basis, as formerly, in two sections, which will represent the equipment, largely, of the present field hospital, and have a third section for a headquarters and for overhead equipment, which may be drawn up if possible, but, ordinarily, it won't come up until later. Your evacuation hospitals can be brought up and established and their overhead equipment brought up later, such as X-ray outfits and heavier equipment.

Now with regard to open operations and trench operation necessities and equipment, I think we will find our equipment as laid down is satisfactory, except the number of litters. The ambulance company should have at least 150 litters and possibly more, in order to move the casualties from a regiment back to the evacuation hospital on the original litter, and it really is necessary to keep the patient on the original litter at all times. Now if you increase your bearer detachment, as is likely, to 40 litters instead of 20, you will go well beyond the 150 limit even when you consider the 48 on the ambulances. Now at present there is no sort of bed arranged for the field hospital, it being expected that the patient will be brought in on the original litter. Now the number of litters needed by a field hospital is indefinite because it is based on the capacity of the station, but the minimum number of litters in a field hospital, which is being used as a triage and shelter for cases, must be 250. You will oftentimes have above 300, but you can easily expand the field hospital to 300.

I hope that I have impressed you with the fact that our organizations must be mobile for open warfare, and when stabilized we should bring up all the overhead that will make it more efficient and we must keep our mobile equipment mobile and ready for use. If we do not do that we will be in the position of the French during the drive of March 21 and the British at a later date. The British never did become as immobile as the French, because the idea of tactics was not as firmly fixed in the minds of the French as the British. There is nothing extraordinary or wonderful in the work that you are to do over here. It is the same old principle, same old equipment that you have seen in the United States.

Army Sanitary School No. 183.

EVACUATION OFFICER AND HIS DUTIES IN THE ARMY ZONE OF EVACUATION

By First Lieut. John D. Smyser, M. C.

The evacuation of the wounded in our Army to-day plays one of the most important parts in our Medical Department, if not the most important one. It is only natural that every medical officer thinks his service or department is the most important, and so it is, and that is the proper spirit. But the evacuation of the sick and wounded soldier is of the utmost importance, not only to himself, but to every department of medicine—and not only to our Medical Department, but to the line, the fighting and combatant troops, for the sooner these cases, especially the seriously wounded, are collected from the battle fields and transported to the surgeons at field, evacuation, and base hospitals, the better condition are these men found to be in. Much less is the chance of infection, and much

more the chance for the patient. And right here is where the surgeon profits, through the early reception of his cases and his having to deal with a contaminated and not an already infected wound, which is the case if patients are not gotten back within the 12-hour limit. Same also holding good with the gassed and medical cases.

So it is my intention in treating this subject to point out only the most important considerations and information necessary for one to know in order to master, handle, and evacuate the sick and wounded in the army, or that zone between the field hospital and your evacuation points, railheads or boats, which in turn carry these men to Services of Supply and base centers, by first passing them through your evacuation and mobile hospitals, which are located in this army zone.

I have divided this information into eight headings, each of which are subdivided, after which I will take up separately each of the headings and its subdivisions and show the reason for knowing and obtaining this knowledge.

1. The army sector:
 - (1) Extent and boundaries.
 - (2) Railroad facilities.
 - (3) Water facilities.
 - (4) Hard and dirt roads.
2. Hospitals:
 - (1) Number of evacuation hospitals.
 - (2) Number of mobile hospitals.
 - (3) Their location.
 - (4) Personnel—
 - Enlisted.
 - Teams, surgical, shock, gas.
 - Nurses, female.
 - (5) Equipment—
 - Capacity beds.
 - Operating tables.
3. Means of evacuation:
 - (1) Ambulance companies.
 - (2) Trucks.
 - (3) Railroads.
 - (4) Hospital trains.
 - (5) Boats.
 - (6) Ambulance convoys.
4. Your plans for evacuation and other evacuation routes:
 - (1) All railroad tracks.
 - (2) Rivers and small streams.
 - (3) Hard and dirt roads.
 - (4) Tram railways.
5. Supply units:
 - (1) Medical supply depot.
 - (2) Commissary.
 - (3) Quartermaster.
 - (4) Post offices.
 - (5) Salvage dumps.
 - (6) Field signal battalion.
 - (7) Red cross.
 - (8) Young Men's Christian Association.
6. Army reserve:
 - (1) Hospitals—
 - Field.
 - Evacuation.
 - Mobile.

6. Army reserve—Continued.

- (2) Surgical and shock teams.
- (3) Nurses.
- (4) Enlisted personnel.
- (5) Ambulance companies.
- (6) Ambulances.

7. Relation with army corps, army corps surgeons, and the disposition of their sick and wounded.

8. Miscellaneous:

- (1) Office and location of the evacuation officer.
- (2) Orders to be issued to commanding officer of your hospitals and ambulance companies.
- (3) Daily reports.
- (4) Data of all casual organizations.

So then let us assume we are entering a new sector for the first time as evacuation officers. The above questions we have asked ourselves, and why must we work out and know the answers and what are the two general considerations to have always in mind while working out your plans and getting this information? First, your wounded; second, their rapid and safe return to the area.

Extent and boundaries.—You must know and study on your map the boundaries and extent of your sector, so as to be able to know approximately how many hospitals will be needed and at what distance they must be apart, as well as to know that they are equally distributed so as to each render the most efficient service and not throw the work on one or two and leave several with little or no work to do, and to learn how many divisions are to your front, what armies are on either side of you, where the high and lowlands are, what railroads rivers, etc., you have access to, and what avenues of retreat are available should such an occasion arise.

Railroad facilities.—The location and what railroads are in your zone and what are these railroad facilities, spurs, sidings, etc. These points should always be picked as close to your hospital centers as possible, and your hospital sites should be picked as close to your railroad as safety, hard and dirt roads allow, and it is practicable. This point also saves traveling and ambulance services. Also you want to learn if there are any sheds or buildings close to your tracks to receive and house your patients from the elements, if there is a loading platform—how much of it is covered, how many litter cases it will hold, and how many railroad cars it will take, for in loading your hospital trains your first patients will oftentimes have to arrive three or four hours before the scheduled arrival of your train, as the average time given by the French railroad authorities to load a train is three hours.

You have also to consider that in a severe push you must have a reservoir or overflow hospital for evacuable patients, and located at railhead, so that the evacuation hospitals can be immediately emptied of those cases that can be moved, while awaiting the arrival of your train, and room made for those not yet treated.

Again, your patients, some of them, will come quite a distance to entrain and have a long, perhaps cold and wet ride; if it rains, these men must have protection and shelter; if there are not buildings enough to accommodate at least 250 patients close enough to railroad tracks, then tents must be erected and personnel obtained, consisting of 6 to 8 enlisted men and 2 noncommissioned officers, in charge of a medical officer, to take care of these stations (the medical officer also acting as entraining officer). The duties of these enlisted men being the same as ward attendants in hospitals, to prepare the soup and liquids and assist in serving them. At the station should be a canteen where your hot coffee, cocoa, broth, and both hot and cold water are always ready; also a light meal can be served the walking or slightly wounded surgical cases.

The equipment necessary at this station should consist of litter racks which hold four litters and enables you to put three times the number of cases in a tent or shelter than if they were laid on the ground, thus saving both tentage and floor space. Benches for your sitting cases, dressings, emergency drugs, a reserve supply of litters (so that any walking cases might lie down and rest if necessary), blankets, hot-water bags and bottles, pillows, bedpans, urinals, lister bags, galvanized-iron cans, medical officers' field web belt, crutches, and maga-

zines. The men all loving to read and oftentimes not having seen a magazine for months, enjoy this pastime, which breaks the monotony while waiting for the train. These magazines are collected when the train arrives and thus used many times. I advise when possible to get the Young Mens' Christian Association or Red Cross to establish a canteen at this station, which means the assistance of several American ladies and the supply of cigarettes, chocolate, fruit, etc. At this station it is advisable to keep your sitting and walking cases separated from the litter ones; for if you don't the former will crowd around those that can not walk and prevent fresh air from reaching them, besides being constantly in the way of attendants and orderlies.

The ideal unit to properly operate an entraining station and overflow hospital is either a motor-drawn ambulance company or field hospital with their entire personnel, the ambulance company being more preferable, having a larger personnel, which can be used to care for the patients, for the unloading of ambulances, and the loading of trains. Then also you have the reserved ambulances to back up a push at the front, and when called on for help by the corps surgeon you can, by ordering the nearest evacuation ambulance company to the place asking for help and covering its station by the one behind it, and so on, move each of the companies in the rear up; keep all your hospital supplied with this important service to the one nearest your railhead, which is covered by the reserve company, and you have done so in one-fifth the time it would require to send your reserve ambulances from the rear clear to the front.

Then you also have several medical officers who can be used and loaned for temporary duty when and where needed, as well as for your boats. If, however, you can not get either the ambulance company or field hospital for this duty, you will then have to get your enlisted personnel and medical officers from one of the hospitals and require each of the hospitals to send a loading detail of so many men on the first ambulances to each train, or both loading the trains and unloading the ambulances. This detail must remain until after train pulls out and they have collected all the litters and blankets and piled them in a place handy to where ambulances unload, so that on their next trip they can take back to the hospital litter for litter and blanket for blanket.

Water facilities.—What rivers, streams, and bodies of water lie near your railheads or in your zone? How far to the front are they navigable? What is the approach to these bodies of water, by hard or dirt roads, railroads and tram railways? What facilities are there for loading boats, such as wharves, bulkheads, docks, etc.? Into what bodies of water do they flow? How long a sail is it to a base center? And what are the nearest base centers to these rivers or waterways? If they can be unloaded from boats to ambulances and taken direct to base hospitals, or must they be entrained? How long a sail is it, and is there room for a reservoir and overflow hospital to be erected as at railhead? For here also will you need somewhat the same requirements and equipment as at railheads, only not perhaps as elaborate, unless boat evacuation is more to be used than rail.

The evacuation by boat is of two great importances: First, in case your railheads and roads are damaged or destroyed you will still have an outlet for the wounded and avoid long overland hauls by ambulance convoys, to avoid congestion and necessitate the using of all your ambulances and taking them away from the front. Second, because of there being no motion, vibration, rough jarring, and swing as on a train, which affords the more seriously wounded, especially brain, abdominal and severe fractures, an ideal way of transportation and much easier than the train. These boats are equipped with bunks or litter racks, three deep; some of them hold 84 lying cases only, others 40 lying and 60 sitting cases, and some 250 sitters only, and propelled by steam. They should have on board coal and alcohol stoves for cooking and sterilizing; blankets, sheets, pillows, towels, field medical and surgical chests, dressings, field mess chest, drugs, Carrel-Dakin irrigators, stands and tubing, bedpans, urinals, hot-water bags, galvanized-iron cans, lister bags, magazines, rubber sheeting, gauze screening, pails, brooms, mops, lamps, and extra litters. There should always be a three days supply of rations on board.

The personnel consists of 4 or 5 enlisted men, 1 or 2 noncommissioned officers, 2 nurses, or 1 nurse and 1 nurse's aid, and 1 medical officer, which personnel I took from each of my evacuation hospitals by roster. It did the personnel good by being both a change and diversion, and gave them a rest on the return trip (but none on the down trip).

The writer has received several congratulating letters from officers and men taking this trip as patients and all were unanimous in saying that it was the most comfortable and by far the best trip yet made by them on this side of the water, and as all of these cases were later carried from Paris by hospital train to southern France, they had an opportunity of comparing both rides.

Hard and dirt roads.—The roads must be studied in your zone and ridden over for you to become familiar with and to learn their general condition and state of repair, to pick out the best and shortest routes from one evacuation hospital to the other, then to your train and boat station, and to learn if there are two or more roads approaching your hospital that can be used as one-way roads for your ambulance companies, thus avoiding a tie-up and the possibility of a serious accident, especially at night, to pick out sites and locations for the possible moving of your hospitals, both forward and to the rear, in case of a sudden advance or retreat, and pick these places with as pleasing surroundings and as much protection, but as close to two or more roads as possible and safety permits, and not down in the lowest hollow you can find; remember it rains, and rains hard at times.

HOSPITALS

What are they—evacuation, mobile, or field—and their number, how many of each kind, who is their commanding officer, where are they located, what is the personnel of each, officers, nurses, and enlisted men? How many added surgical and shock teams has each; what are the numbers of these teams and their personnel, equipment, capacity, beds, and number of operating tables?

You want to know the number of hospitals and their bed capacity to be able when interviewing your corps surgeons, and learning from them the number of troops each has, if you will have sufficient bed capacity to handle a big drive, the class of hospital, whether mobile or evacuation, for the designation of your cases and which can be decided only after knowing their kind, and respective locations; for your mobile hospitals as a rule are entirely for surgery, should be kept as empty at all times as possible, ready for a quick move, they being smaller and used as a mobile unit and moved before the evacuation hospitals are.

Again their locations are important to know; pick out your roads which you have already been all over and are entirely familiar with, and have marked them on your map.

The personnel of each hospital you should know, so as to be able to judge if there is a sufficient number of enlisted men, nurses, and officers to satisfactorily handle and care for the number of beds that hospital has or can crowd, and if there are a sufficient number of surgical teams to handle the operating tables for four hours continuous work; and if not, to be ready in a big push to supply them. The members and personnel of these teams should be known, so should you be called on by one hospital for more surgical teams and immediate assistance you would know which hospital to obtain these from and what teams to call, as the personnel of teams differs, some have 3 medical officers, 2 nurses, and 2 to 3 enlisted men, while others have 2 medical officers and 2 nurses, and some teams have just 2 and 3 medical officers; sometimes you may just want the operators, so would not want to call a team having enlisted personnel and nurses, when perhaps they are being used and much needed at their present location on account of that hospital being short of enlisted men and nurses and not surgeons.

Equipment: You should know if there is anything needed by your hospitals, especially washers, driers, and portable laundries, X-ray laboratory equipment, excess tentage, blankets, cots, bedding, litters, Thomas splints, sheets (which should be used for burying the dead instead of blankets), medical supplies and dressings, and keep behind these requisitions and see that they are obtained, and thus relieve the buck from being passed to you when a big push comes and that hospital is caught napping and without its necessary equipment.

MEANS OF EVACUATION

Has each evacuation hospital attached to it an ambulance company? How many ambulance companies have you, are they motor or animal-drawn, and how many of each? What condition is there equipment in? How many trucks have your hospitals, as you will oftentimes have to call these into ambulance service and you want to know how many are available when you need them. How many United States and other hospital teams you have to call

on. What is their running time from garage to your railheads, and how long does it require to get team to your evacuation point after ordering them?

Boats.—How many of these you will have and their capacity; if necessary, can you obtain more? When, where, and how?

Ambulance and ambulance convoys.—How many can be gotten from the Services of Supply if you should have any accidents or need them as a convoy? Through whom and how are they obtained? What is the shortest time you can get them? And what evacuation base camp or field hospital could you send an overflow to by ambulance convoy; by what routes? The condition of the roads and time for the run must all be known.

Your plans for evacuation.—Your plans for evacuation can now be worked out with the above information at hand. You know your Army zone and zone of evacuation. You have picked your railheads and boat landings and established your receiving and forwarding stations there. You know all your roads and their condition and have marked them on your maps. You know the number and location of your hospitals—these are also on your map—so have your plans for evacuation issued as follows: What ambulance companies are to serve and evacuate each of your hospitals. What roads are to be used for evacuation, not forgetting to use two roads, if you have them, as one-way roads. When these roads have been decided upon, they should be worked by a signboard with the arrow showing direction and the class and number of your hospital, and especially should these markers be at intersections and turns of the road. Another point to note and avoid if possible is having to use roads that are used by truck convoys; these operate mostly at night, as do your ambulances, and that increases the danger of accidents with no lights. And do not route your ambulances over roads subjected to shell fire if possible, even if it will save a little time.

The average time it takes for your ambulance to run from your different hospitals to your railheads must be learned, so that when you order an evacuation from that particular hospital you can figure out the number of ambulances it has and number of cases, lying and sitting, they are to send, how many round trips will be required, and at what time that hospital must start evacuation.

With these plans ready you are now prepared to start evacuation, but should your transportation fail you at any time, or the roads, both dirt and rail, be destroyed, if your line advances very rapidly or something happens to break up your plans, what is necessary?

That you are familiar with every piece of railroad line in your zone, if they are damaged, by having them repaired, would be of benefit to you. What other dirt roads could be used to carry your wounded, or if you could have the labor and material to build you a new road? If there are any small streams running to or very near your hospital and connect with the rivers, you could run your boats on, that patients could be floated down on barges.

Are there any tram railways down, or are there any available that could be used for transporting your wounded, and are there any places advisable that such a road should be laid; if so, see that this is done.

Supply units, medical supply depot; where is it located? If in Services of Supply, how long does it take to get supplies to your hospital on emergency requisitions and otherwise? If there is not an advance depot in your territory, see to getting one at once; this depot should be used only for emergency and supplying those things that the advance stations and the hospitals can not wait for on requisitions. Here should always be kept a large supply and assortment of splints, 2,500 to 3,000 liters, and as many blankets, first-aid dressings, and front-line cases, emergency drugs, Greely tubes, etc.

Commissary, quartermaster, and salvage dumps should be located for your personal convenience, and to inform your hospital commanders where to get these supplies and materials and to forward the equipment often brought by the wounded men and left at the hospitals.

The Red Cross and Young Men's Christian Association, for assistance in your canteen work, burials, supplies, and the many assistances they can give to your men in the field.

ARMY RESERVES

Hospitals.—How many field, evacuation, and mobile hospitals are there that you can call on and how far back are they, length of time required to get them in case of emergency, and your needing additional hospitals, or should one or more of yours be moved away. When

you will obtain your surgical and gas teams for your own services and to lend or assist your corps surgeons, nurses in case of illness or a severe rush; the same for your enlisted personnel.

Ambulances and ambulance companies you never have enough of, and always want more and can always use more. This service is easier and sooner crippled than any in your sector, it having in busy times a serious and perilous duty.

RELATION WITH ARMY CORPS AND ARMY CORPS SURGEONS, AND THE DISPOSITION OF THEIR SICK AND WOUNDED

Relation with army corps and army corps surgeons, and the disposition of their sick and wounded, must be taken up now that we have all data and information necessary to give the corps surgeons, and ready to answer any question relative to evacuation.

Call on and consult your corps surgeons; learn from him or them the location of their battalion aid stations, field hospitals, and ambulance companies.

The names and locations of their division surgeons, commander of sanitary trains, and commanding officers of field hospitals. How to reach them by phone, and where their triages are located; arrange with the corps surgeons to get in touch with at least twice daily—early in the morning and late in the evening, and what ambulance facilities each has; then when a pinch comes you are prepared to lend ambulances and know to where and whom they are reporting, as well as how many to send.

Remember that the strictest cooperation must exist between the corps surgeons and the evacuation officer, and one should keep the other informed at all times of any changes made by the other, especially the moving of hospitals, ambulance companies, divisions, etc.

In your first interview with a corps surgeon you will give him the location of your hospital and evacuation ambulance companies, the roads and different approaches to them, the names and telephone numbers of the commanding officers, so that he can have orders issued in his corps what classes of cases will go to this and that hospital, and see he has designated the two most advanced hospitals for the so-called nontransportable and seriously wounded cases, what roads the various ambulance companies must take in evacuating their patients from his field hospital for the return trip, thus avoiding a tie-up on one certain road and leaving perhaps two or three other roads unused. You should always travel over these roads and become familiar with them in the daytime, for you will have to go over them many times and at all hours of the night, rain or shine, and all ambulance company commanders should be instructed and then see to it that their ambulance drivers are made familiar with them in quiet times.

After having discussed the triage of patients with the corps surgeons, you want to see that each commanding officer of your hospitals named receives a copy of this order, so that each will know what class of work he is to receive and expect, and what to be prepared and equipped for.

You want to arrange with the corps surgeon that he keep you informed of a contemplated attack, the number of battalions, regiments, companies, etc., to be engaged, the time and location of the attack, so that you can estimate the probable number of wounded and the time the first wounded will start coming in.

After you have received all the above information and given instructions to commanding officers and evacuation hospitals to be on the lookout, you should then remain up between your advanced hospitals and the corps surgeons' headquarters, and see that your front hospitals are kept as empty as possible; that there are sufficient surgical teams, personnel, etc.; that the minor preoperatives are directed on back, and that these hospitals have not more than four hours' advance surgical work ahead of them, and when they do, divert your cases that can go to the next hospital and if necessary transfer a less seriously wounded operative case for the more serious one.

You shall notify the commanding officers when advising them to be on the lookout, where you can be reached by phone, and every few hours you should get in touch with your hospitals and be advised as to how many they have coming in, and so as to know when and how many trains to order, as the evacuation officer must take, and be prepared at all times to take, and receive everything the corps surgeons have to send back. These cases must be equally distributed to your evacuation hospitals as far as their wounds will permit of transit, always making it a practice to keep the most advanced hospitals as empty as

possible for an attack and the inpouring of badly wounded, and for the so-called nontransportable cases, and the farther back you get your cases, when just wounded, the nearer they are to your railheads and the shorter the haul for entraining, which saves motor transportation.

The evacuation officer should have a central location and a telephone, with a competent man beside it day and night, to receive messages and be kept in touch with by you from time to time; also, to be informed where he is most likely to catch you at a certain time of the day. The writer usually made his headquarters at his central railhead or a hospital situated near it.

Orders to be given to the commanding officers of your hospitals and ambulance companies are as follows:

First, see that they have a cheerful reception ward, whether it be barracks or tent, well ventilated and heated, located in as pleasing a site, just as close to the road as practicable and safety permits. This site, as well as all locations selected for any kind or class of a hospital, should be picked with the most pleasing surroundings that the terrain will allow.

I always ordered and saw to it myself that there is hot coffee, broth, or cocoa, cold drinking and plenty of hot water for the boys, and for bathing at each receiving ward, along with cigarettes, chocolate, etc. If the hospital has not a lady personnel enough to handle this work, I got the assistance of either the Red Cross, Young Women's Christian Association, or Smith College relief unit ladies to do it for me, for you must bear in mind that some of our boys, in a big engagement, have gone many hours, sometimes days, without food and water, and sometimes both, and they will be some time longer without these things if not supplied them at the receiving wards.

These ladies should be cautioned and instructed by the receiving officers not to give gas patients anything to eat, drink, or smoke, and are told who may and may not have certain things. Here also is where the cheerful voice, kind word, and good figure of a real true, live, interested American woman plays an almost indescribably psychic action on the boys, and a word dropped here and there to let them know how proud they are of them and how proud the folks back home will be to know and see what a wonderful division they are in and how splendidly they fought that the division has now reached such and such a place, all means a very great deal to these boys and gives them new determination and grit (and these ladies know how to do it).

Another very important point to receive attention is not to tie up your transportation at any time, and in order not to do so you must take up with your commanding officers, and see that they always have sufficient enlisted personnel at receiving wards to unload ambulances as fast as they drive up, and to carry these patients into the receiving wards, that they are not grounded outside and kept there for some time.

Instruct commanding officers and see that they always have a sufficient supply and within easy access to ambulances of blankets, litters, splints, and hot-water bags, so that the ambulance orderlies can take back one of each kind of article he leaves with patient, thus keeping each outfit always supplied, whether at the front or in the rear of you.

And the following I get out in writing:

1. Have an enlisted man in road to meet all patients coming into your area from the front. This man is to notify receiving officer that patients are awaiting distribution.
2. The receiving officer will admit all, or such patients as he can receive, and direct driver to take all or part of load to such and such evacuation hospital, giving number.
3. The receiving officer will not admit more operative cases than can be cared for in four hours without notifying the evacuation officer and receiving permission to do so, through his commanding officer.

In case of patients being forwarded, the receiving officer will see that driver understands that patients are not being refused admission and, further, that he knows the road to the hospital he has been instructed to deliver these cases, for oftentimes drivers will be hours in returning to their stations and give as excuses that these hospitals refused the cases, and that one did likewise, and he could not find the hospital he was told to go to, etc.

To your ambulance company commanders that their drivers study the map and roads of both their zone and that of the corps. That they are familiar with all the roads and locations of each hospital, railhead, and boat landing and that you are notified daily of the number of ambulances serviceable and unserviceable.

DAILY REPORTS OF HOSPITALS

The commanding officers must be ordered to see to it that at least three times a day (you naming the hours) you are phoned the number of evacuable cases in his hospital designated below:

Total evacuable -----	Number lying -----	Number sitting -----
Number unoperated -----	Number of beds -----	Total beds -----
Number remaining -----	Contagious cases -----	; lying -----; sitting -----
-----; kind -----	Number of prisoners -----	

The contagious cases report is very important, for each case will take up a section on our American hospital train, and that means three extra beds, so if you happen to have 1 case of mumps, 1 of measles, and 1 of scarlet fever reported from 3 different hospitals, that means you have lost the use of 9 beds, and especially in push times it would be better to hold these cases and transport the wounded first.

Impress upon the commanding officer the importance of starting his evacuation at the time you order it, and never send but just the total lying and sitting you order, and to only send just that, and not to change a sitting into a lying case or vice versa. Our hospital trains will hold just a certain number of lying cases and so with the sitters. When you order a train, you will know its destination and its number; if it is a full train or minus one or more coaches. The hospital commanding officer does not know these things. You figure up this trainload perhaps from four, five, six or more hospitals by their reports, and unless you are sent just that number of each class of cases by them, you are either going to have too many or too few of one class or the other, which is unfair to the wounded man (and no excuse for it), for if too many lying are sent they must be carried back again, and if too few, you are taking a bed from a man perhaps needing an early evacuation to a base, and that train space is wasted.

In making up a hospital train you must consider its destination, for the amount it is to carry depends upon whether it is a short 3 to 4 hour run or one lasting 18 to 24 hours; and if a long one, you do not want to overcrowd it, but see that you have sufficient room for your sitting cases to lie down (generally two in a bunk is figured); if a short one, you can carry many more sitters, they not being obliged to lie down.

Our regular United States hospital train personnel and capacity consists of commanding officer, 3 medical officers, 3 nurses (female), and 36 enlisted men. There are 10 cars for loading patients, each car will hold 36 litter cases, or a total of 360, and in each litter car can be placed 6 sitters. In your cars for sitters you can place 2 sitters for each litter, or 48 sitters and 12 litters, the latter occupying top bunks, with a total of 60 in all, comfortable.

When your train arrives you should have ready the following information for the train commander; and if it is not possible for you to be there, phone the entraining officer what the trainload is to compose, total number, number lying and sitting, number of contagious cases (and what), and number of prisoners. The total number of officers, lying and sitting, should be gotten by the entraining officer after cases arrive at station. All this information should be had before loading begins, in order that train commander will know how many cars to make up for sitting cases.

The data on any and all casual organizations you should know and learn as soon as possible and constantly keep in touch with, most particularly so with engineer and stevedore companies, should you want labor or repairing work done, graves registration bureau for the handling of your dead, and boche prison camps for police duty, and I used many of them as litter carriers and for unloading ambulances and loading trains.

You want to learn the location of post offices and their numbers. If there are any truck companies handy which you can call on for hauling supplies and carrying wounded. Again, these questions, together with the location of your signal, telegraph, and telephone offices, will be asked you many times in traveling your district, and these are things you should know for yourself as well as for others.

Next, the locations of the railheads of the divisions on your front, for emergency rations and other supplies, and as points to use as railheads, should you advance.

Learn what allied armies are occupying the same district; and if any, call on the commanding officer and evacuation officer, offering them your cooperation and any assistance you can, which means you will receive the same offer in return and find it very useful oftentimes.

In closing my paper let me say that it has been my intention to try and bring forth the most necessary essential and important points for an evacuation officer to know and do. However, there are no hard and set rules, except to keep your hospitals empty. Each evacuation presents its problems—the game is not unlike that of chess—you have got to move, and in order to play the game successfully keep things moving. You must be able to expand or contract as the occasion requires.

You have got to visit your hospitals and commanding officers at least once a day. Know and meet the adjutants and officers appointed to look after the hospital evacuation. A good point to keep in mind is always to do your business with the commanding officer or his adjutant, if the commanding officer so desires. But the commanding officer is the most preferable, for when you give an order to him you will know where to place the blame—so does he when things go wrong—and there is no “passing the buck.”

Orders for evacuation, time, numbers lying and sitting to be sent, and keeping of transportation moving, are all very important factors to be carried to the letter.

Each sector presents new points to be worked out, and at no stage of this evacuation game is there much rest, but many rough and dark roads to travel (literally and in reality).

And probably the one point that gave me the most concern was that many men were being sent to the rear with minor, very minor, injuries; some with nothing but scratches, who had at the time thought their wounds more serious; they were picked up and sent to evacuation hospital through channels, which means that they must go to the rear, lose their companies and divisions, and take up the place more needed by some one else, and who would beg to be returned to their commands, but no authority was given these evacuation hospitals to do so, and they had to be sent back.

Likewise a similar condition with medical cases; those that are sick with diarrhea or some condition which means that they are out of the running for perhaps 10 days or 2 weeks. There should be a hospital designated as a medical and surgical hospital to handle just these classes of cases, that would allow the evacuation hospital, when they have this class of case, to transfer it to this hospital and then to be given authority to return the man to duty and to his command when advisable.
